3 **$\sqrt{s_{NN}} = 200$ GeV using π^0 production at PHENIX**

4 PHENIX Collaboration Author List (Brant will insert later)

PHENIX presents a systematic study of π^0 production from $p+p$, $p+\text{Al}$, $p+\text{Au}$, $d+\text{Au}$, and ${}^3\text{He}+\text{Au}$ collisions at $\sqrt{s} = 200$ GeV. For inelastic collisions, the nuclear modification factors, R_{xA} , are consistent with unity for p_T above 8 GeV/ c , but exhibit an enhancement in peripheral collisions and a suppression in central collisions. The enhancement and suppression characteristics are the same for all systems for the same centrality class. It is shown that for high p_T π^0 production the nucleons in the d and ${}^3\text{He}$ interact mostly independently with the Au nucleus and that the counter intuitive centrality dependence is likely due to a bias in the event selection. These observations disfavor models where parton energy loss has a significant contribution to nuclear modifications in small systems. Nuclear modifications at lower p_T resemble the Cronin effect – an increase of R_{xA} followed by a peak in central or inelastic collisions and a plateau in peripheral collisions. The peak has a characteristic ordering by system size as $p+\text{Au} > d+\text{Au} > {}^3\text{He}+\text{Au} > p+\text{Al}$. This is the exact reverse order compared to what is predicted by current calculations based on initial state cold nuclear matter effects, suggesting the presence of other contributions to nuclear modifications, in particular at lower p_T .

6 **I. INTRODUCTION**

7 Measurements of transverse momentum (p_T) distri-
8 butions of particles produced in hadronic collisions are
9 commonly used to obtain information from these colli-
10 sions. At the Relativistic Heavy Ion Collider (RHIC)
11 at Brookhaven National Laboratory (BNL), studies of
12 neutral pions have led to significant insights. The dis-
13 covery of the suppression of high p_T neutral pions and
14 charged hadrons [1] in Au+Au collisions was one of the
15 first hints of parton energy loss in the strongly coupled
16 Quark Gluon Plasma (QGP). The absence of any sup-
17 pression in reference spectra from $d+\text{Au}$ collisions [2],
18 where the formation of a QGP was not expected, was
19 critical to establish parton energy loss as the origin of
20 the observed suppression in Au+Au collisions. The sub-
21 sequent systematic studies of the suppression pattern of
22 π^0 in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV relative to
23 scaled $p+p$ collisions at the same energy allowed for quan-
24 titative constraints to the medium transport coefficients
25 [3].

26 In the study of heavy-ion collisions, data from $p+p$
27 collisions are often thought to be a baseline for par-
28 ticle production in the absence of the QGP and data
29 from collisions like $p+A$ and $d+\text{Au}$ have been used to
30 benchmark so-called “cold nuclear matter” (CNM) ef-
31 fects. CNM effects capture a number of fundamentally
32 different phenomena in the initial state prior to the colli-
33 sion, during the collision, and immediately following the
34 collision. Generally speaking, initial state CNM effects
35 are discussed as modifications to the parton distribution
36 functions. These modifications include shadowing, anti-
37 shadowing, the EMC effect, momentum smearing due to
38 Fermi motion, and gluon saturation. In contrast, nuclear
39 absorption would be considered a final state effect. Mul-

40 tiple scattering in the nucleus prior to or immediately
41 following a hard scattering process falls in between.

42 Experimentally, evidence for CNM effects was first ob-
43 served in the late 1970s when the ratio of the production
44 cross sections of hadrons from $p+A$ to $p+p$ was found
45 to vary with p_T [4, 5]. This variation has since been re-
46 ferred to as the “Cronin effect”: a suppression at low
47 p_T followed by an enhancement around 2–5 GeV/ c that
48 vanishes towards larger p_T . Historically the Cronin ef-
49 fect was attributed to initial state hard scattering [6, 7],
50 but this explanation remained unsatisfactory because it
51 could not explain the much larger effect for protons com-
52 pared to pions. Measurements of momentum spectra at
53 RHIC in the early 2000s renewed interest in the Cronin
54 effect. Various theoretical models were developed to ex-
55 plain the Cronin effect. Most models were based on hard
56 and soft multiple scattering [8–12], but there were also
57 some more unconventional approaches involving gluon
58 saturation [13] or recombination effects [14]. To date,
59 there is no full quantitative explanation of the Cronin
60 effect.

61 It came as a surprise to find striking similarities of long
62 range particle correlations observed in high multiplicity
63 $p+p$ and $p+\text{Pb}$ collisions at the LHC [15–18] with those
64 found in A+A collisions, since their presence in A+A col-
65 lisions was typically associated with the collective expan-
66 sion of a QGP. Similar correlations were found in $d+\text{Au}$
67 collisions at RHIC [19]. These findings have profound
68 consequences for the interpretation of $p+A$ collisions as
69 a benchmark for CNM effects and suggest that a QGP
70 could be produced in these systems.

71 The PHENIX experiment has used the versatility of
72 RHIC, which allows for collisions of light nuclei like p ,
73 d , and ${}^3\text{He}$ with larger nuclei, for systematic studies of
74 particle correlations in small systems. In all systems

studied, high multiplicity events show large azimuthal anisotropies, measured as v_2 and v_3 , that can be related to the initial geometry of the collision system and the build-up of collective behavior of the produced particles [20–24], which would be indicative of QGP formation.

Results from long range correlations have prompted great interest in finding other evidence of the possible formation of a QGP in small systems, such as parton energy loss or thermal photon emission. In such studies, data sets are typically divided into “centrality classes” according to the particle multiplicity measured at forward rapidity on the side of the outgoing larger nucleus [25]. Indeed, in p +Pb collisions at the LHC [26] and d +Au collisions at RHIC [27], a suppression of the jet yield at high p_T was found for central collisions. However, the same analyses show a significant enhancement of the jet yield in peripheral collisions, putting in question if the observed suppression is due to energy loss [28] or whether there are other mechanisms at play, for example, x -dependent color fluctuation effects in protons [29, 30] or biases in the centrality selection due to energy conservation [31].

In this paper new data on the system size and centrality dependence of π^0 production is presented over a wide p_T range from 1 to 20 GeV/ c from p +Al, p +Au, d +Au, and ^3He +Au collisions at $\sqrt{s_{NN}} = 200$ GeV compared to p + p collisions at the same energy. The data samples were recorded by the PHENIX experiment during the 2008 (p + p 5.2 pb^{-1} , d +Au 80 nb^{-1}), 2014 (^3He +Au 24 nb^{-1}), and 2015 (p + p 60 pb^{-1} , p +Al 0.5 pb^{-1} , p +Au 0.2 pb^{-1}) RHIC runs. The new p + p data are combined with the published results from p + p data taking in 2005 [32].

II. EXPERIMENTAL SETUP

To reconstruct π^0 , the Electromagnetic Calorimeter (EMCal) in the central arms of the PHENIX detector is used. The EMCal is segmented into eight sectors, four in the west and four in the east arm of the PHENIX experiment. The sectors in each arm cover 90 degrees in azimuth and ± 0.35 in pseudo-rapidity. All sectors in the west and the two top sectors in the east arm are made of 2,592 lead-scintillator (PbSc) towers each. The other two sectors are composed of lead-glass (PbGl) crystals. For the analyses presented here only the PbSc sectors were used. At a distance of 5 meters from the interaction point the angular segmentation of the PbSc sectors is $\Delta\phi \times \Delta\eta \approx 0.01 \times 0.01$. The energy resolution achieved is $\delta E/E \approx 2.1\% \oplus 8.3/\sqrt{E}\%$ and arrival times of clusters are recorded with a resolution of about 0.5 ns. Further details can be found in Ref. [33].

For event selection and for centrality characterization the beam-beam counters (BBCs) are used, one on the north and one on the south side of the central arms. For asymmetric collision systems, the smaller (projectile) nucleus travels towards the north side and the larger (tar-

get) nucleus travels towards the south side. Each BBC is comprised of 64 Čerenkov counter modules. The BBCs are located at ± 1.44 m from the interaction point and cover a pseudo-rapidity range of $3.0 < |\eta| < 3.9$. The BBC modules have a timing resolution of about 0.1 ns.

While the EMCal and the BBC were identical for the 2008, 2014, and 2015 RHIC runs, there were new or modified detector components in the PHENIX setup each year. The most notable change was a silicon vertex tracker (VTX) installed in the central arm acceptance in 2011. Though the VTX and other new components are not used in this analysis, the effect on the material budget of the detector needs to be taken into account in the Monte Carlo simulation setup used to calculate efficiency and acceptance corrections for each data set.

III. DATA SAMPLES

Several data samples were taken with different trigger conditions for each of the collision systems. The Minimum-bias (MB) data samples require coincidental hits in each of the two BBCs. For the data recorded in 2014 and 2015 the event vertex was required to be within ± 10 cm of the nominal $z=0$ position. For the data recorded in 2008 the requirement was ± 30 cm.

The collected MB data samples correspond to about 88% of the inelastic cross section for d +Au and ^3He +Au, 84% for p +Au, 72% for p +Al, and 54% for p + p . The events that are not recorded by the MB trigger involve mostly single diffractive (SD) nucleon-nucleon collisions, which predominantly produce particles at forward or backward rapidity and thus do not lead to coincident hits in both BBCs. As the number of binary nucleon-nucleon collisions (N_{coll}) increases from p + p to ^3He +Au collisions, the effect of an individual SD nucleon-nucleon collision is averaged out and a larger fraction of the inelastic cross section is captured by the MB trigger.

All MB data samples in the analysis, except for the p + p samples, are subdivided into four centrality classes using the charge measured in the south BBC, which is the direction the heavier (target) nucleus travels. The selections are 0-20%, 20-40%, 40-60%, and the remainder of the MB sample ($>60\%$). Here the percentage refers to the fraction of events relative to all inelastic collisions.

The high luminosity provided by RHIC enables the increase of the statistics at high p_T , beyond what the data acquisition bandwidth would allow using an MB trigger only, by taking data samples with a high energy threshold photon trigger (ERT). This trigger requires a minimum energy recorded in the EMCal trigger segments (4x4 towers grouped to trigger tiles). Three different energy thresholds were used for each collision system. The ERT trigger thresholds are summarized in Table I. No coincidence in the BBC was required. These samples are again divided into the same centrality classes as the MB sample.

During the ^3He +Au, p +Au, and p +Al data collection

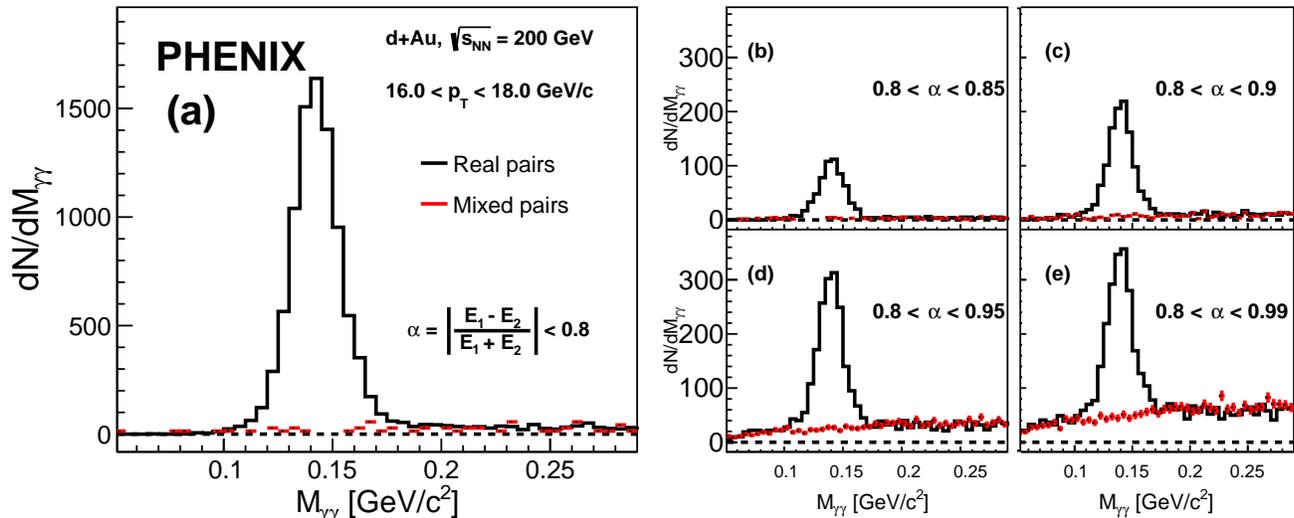

FIG. 1: Invariant mass example from $d+Au$ collisions at $12 < p_T < 14 \text{ GeV}/c$ (left). The mass peak is shown as the function of the asymmetry cut (α) on the two photons (right).

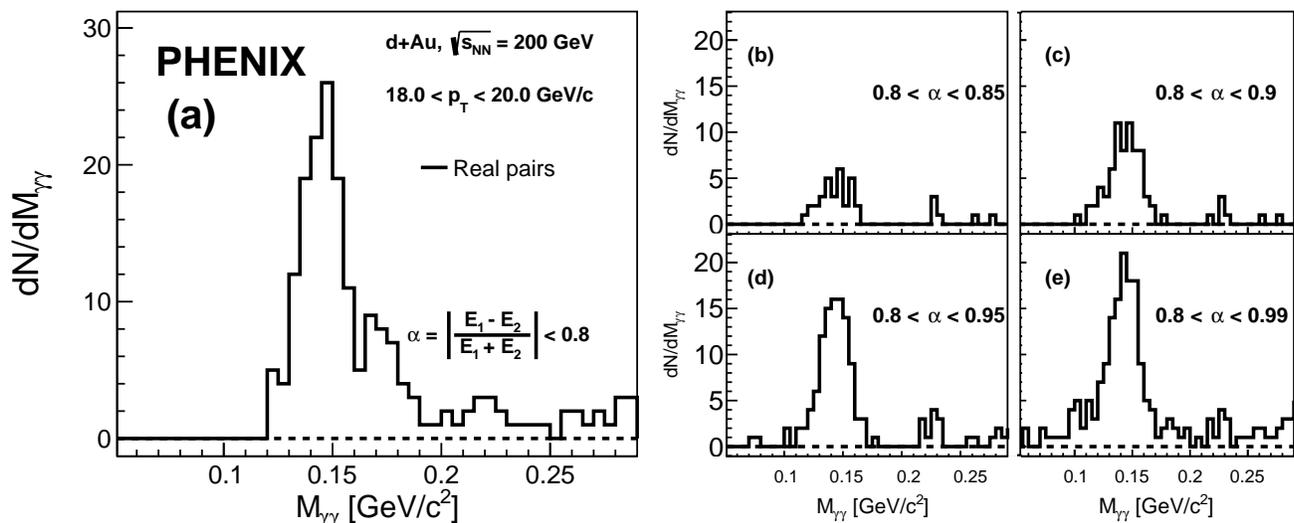

FIG. 2: Invariant mass example from $d+Au$ collisions at $18 < p_T < 20 \text{ GeV}/c$ (left). The mass peak is shown as the function of the asymmetry cut (α) on the two photons (right).

TABLE I: ERT trigger thresholds for each collision system.

	$p+p$	$p+Al$	$p+Au$	$d+Au$	${}^3\text{He}+Au$
[GeV]					
ERTA	2.1	2.8	2.8	2.8	3.5
ERTB	2.8	3.5	3.5	3.5	4.0
ERTC	1.4	2.1	2.1	2.1	2.8

185 samples were also taken with a high multiplicity trig-
 186 ger. This trigger required, in addition to the BBC co-
 187 incidence, a larger minimum charge in the south BBC. 186
 188 In practice, the requirement was that a large number of 187

189 modules should fire. The threshold was set to 25, 35,
 190 and 48 Čerenkov counter modules, for $p+Al$, $p+Au$, and
 191 ${}^3\text{He}+Au$ respectively. The thresholds were chosen such
 192 that the data samples approximately correspond to the
 193 top 5% most central collisions for each system.

IV. DATA ANALYSIS

194
 195 Due to the high beam luminosity RHIC achieved since
 196 2010, PHENIX has recorded an increased number of dou-
 197 ble interactions. The number of double interactions is

largest for the $p+p$ data taken in 2015 and is noticeable for $p+Au$ and $p+Al$ data taken the same year. The effect is negligible for the $p+p$, $d+Au$, and ^3He+Au data taken in 2008 and 2014, respectively. For the 2015 data, double interactions were reduced by making cuts on the time of flight measured for towers in the EMCal and the BBC Čerenkov modules. The cut on the EMCal requires the tower time to be within ± 5 ns of the expected arrival time. This eliminates towers that are from different beam crossings. The BBC timing cut is used to reduce pile-up collisions that happen during the same bunch crossing. Such events are identified by large deviations of the time measured for individual BBC Čerenkov modules from the event average. For data from 2014 and 2008 no cuts were applied. Any residual pileup events are accounted for in the systematic uncertainties.

The reconstruction of neutral pions is performed via the $\pi^0 \rightarrow \gamma\gamma$ decay channel. The methods used by PHENIX have been described extensively in Ref. [34] and will only be summarized in this paper. As a first step, neighbouring PbSc towers with energy deposits above 0.015 GeV are grouped into clusters. All clusters within one sector that have an energy of at least 0.3 GeV are combined into pairs. A minimum distance of 8 cm between the two cluster centers is required, corresponding to about 1.5 tower separation between clusters. For each remaining pair, the invariant mass ($M_{\gamma\gamma}$) and transverse momentum (p_T) is calculated. Invariant mass distributions are generated in bins of p_T and collision centrality. All mass distributions show a clear peak at the π^0 mass and a combinatorial background that is largest at events with low p_T and in central collisions.

To extract the π^0 yield, the background in the π^0 peak region needs to be subtracted. For p_T below 12 GeV/ c an asymmetry cut of $\alpha < 0.8$ is applied to reduce the combinatorial background. Here the asymmetry is defined as $\alpha = \left| \frac{E_1 - E_2}{E_1 + E_2} \right|$, where E_1 and E_2 are the energy of the two photon clusters. For p_T above 12 GeV/ c the cut is relaxed to $\alpha < 0.95$ as discussed below.

The bulk of the background is estimated and subtracted by an event mixing technique that combines clusters from different events with similar vertex position (z_{vtx}) and centrality. The shape of the mass distributions obtained from mixed events does not perfectly describe the combinatorial background in data. The mismatch results from correlated clusters in the event that are not accounted for in the mixed event technique.

For the MB samples, the mismatch is small and a two-step procedure is used for the subtraction. First, the mass distribution from mixed events is normalized in the mass region below and above the π^0 peak, $0.05 < M_{\gamma\gamma} < 0.1$ GeV/ c and $0.2 < M_{\gamma\gamma} < 0.4$ GeV/ c , respectively. After subtracting the normalized distributions from all bins, a residual background remains. This is approximated by a first-order polynomial that is fitted to the same mass regions around the π^0 peak and then also subtracted.

For the ERT data samples, the shape difference is more significant and thus a different approach is used. In-

stead of normalizing the mixed event distribution with a constant, the ratio of data/mixed events is fit with a second-order polynomial in the window around the π^0 peak. This function is then used to normalize the mixed event distributions bin-by-bin. No residual background subtraction is needed in this case.

At very high- p_T , typically > 15 GeV/ c , the combinatorial background is so small that neither normalization strategy for the mixed events gives stable results. Instead, the average count per mass bin, determined in the region below and above the π^0 peak, is subtracted. Yields of π^0 are calculated from the mass spectra after completed background subtraction by counting the entries within 2σ of the peak, where the σ is set by fitting the counts in the π^0 region to a Gaussian.

Above 12 GeV/ c , the two photon clusters from the π^0 begin to overlap more and more and frequently merge into a single cluster. The asymmetry cut at $\alpha < 0.8$, which was used to reduce the combinatorial background, starts to limit the π^0 reconstruction efficiency and with it the effective p_T reach of the measurement. Because the combinatorial background is rather small at high p_T , the asymmetry cut can be relaxed in order to increase the reconstruction efficiency. Figure 1 and Figure 2 shows mass distributions from $d+Au$ collisions in the 12 to 14 GeV/ c and 18 to 20 GeV/ c p_T bins with different asymmetry cuts. The additional statistics recovered by extending the asymmetry cut is clearly visible. In particular, in the higher p_T bin, increasing the cut from $\alpha < 0.8$ to < 0.95 effectively doubles the statistics. Since it is also evident that the background increases, the looser cut is only used above $p_T > 12$ GeV/ c . The background subtraction and π^0 yield calculation follow the same steps as outlined above for lower p_T . The background estimate from event mixing is also shown on Figure 1. For the case of Figure 2, the background is estimated from the average bin content around the π^0 peak.

At this stage of the analysis, raw π^0 yields are available for all data samples in different bins of p_T and centrality. In the next step the raw yields from the MB and ERT trigger samples are combined for a given collision system and centrality. First, the ERT trigger samples are corrected for the trigger efficiency, which has a smooth turn around the trigger energy threshold and plateaus near 100% at higher p_T . A data driven method is used that compares the ERTC to the MB sample and the ERTA/ERTB to the ERTC sample to establish the turn on curve of the different trigger thresholds. The corrected spectra agree very well in the range where the trigger efficiency is larger than 30%.

In order to assure the largest statistical accuracy in each p_T bin, the MB triggered events are used in the low- p_T region, the ERTC trigger in the mid- p_T region, and the ERTB trigger at high- p_T . These transitions happen at different p_T thresholds for different collision systems. The p_T thresholds are set near the point where the trigger efficiency reaches its plateau value, typically close to twice the trigger threshold shown in Table I. The ERTA

TABLE II: Summary of the N_{coll} , N_{part} , N_{proj} , f_{bias} calculated using a Glauber Monte Carlo simulation. The ratio $N_{\text{coll}}/N_{\text{proj}}$ is also quoted for d and ${}^3\text{He}$ projectiles, since some systematic uncertainties cancel in this ratio. The last column is the measured charged particle multiplicity ($dN_{\text{ch}}/d\eta$) in the mid-rapidity region.

314 triggered samples are used to crosscheck the results.

315 Next, the raw p_{T} spectra need to be corrected for dis-
316 tortions due to the finite detector acceptance, inefficien-
317 cies in the π^0 reconstruction, limited energy resolution,
318 etc.. These are determined simultaneously as one sin-
319 gle correction as a function of p_{T} using a full Monte
320 Carlo simulation of the PHENIX detector setup. They
321 are commonly referred to as acceptance-efficiency cor-
322 rections. For each running period, a separate simula-
323 tion setup is used that describes the PHENIX detector
324 configuration specific to that period. Samples of single
325 π^0 are simulated with a flat p_{T} distribution from 0 to
326 30 GeV/ c , full azimuthal coverage, and in one unit of
327 rapidity at mid-rapidity. These π^0 are tracked through
328 the full simulation of the PHENIX detector setup for the
329 different running periods. The resulting simulated de-
330 tector responses are embedded into real data from the
331 same running period and reconstructed using the same
332 analysis methods applied to the data. Great care was
333 taken to tune the simulation so that π^0 peak positions
334 and widths reconstructed from the simulation match the
335 experimental data. Each reconstructed π^0 is weighted
336 with a realistic "trial" production probability for the p_{T}

337 of the input π^0 . Since the true production probability is
338 unknown, the weighting needs to be iterated. For this
339 the "trial" probability is multiplied by the ratio of the
340 measured raw π^0 distribution over the reconstructed π^0
341 distribution from the simulation. The modified "trial"
342 probability is then used as the new weight. The process is
343 iterated until convergence, which typically requires only
344 a few steps. The final acceptance-efficiency corrections
345 are calculated as the ratio of the probability to recon-
346 struct a π^0 at a given p_{T} over the production probability
347 at that p_{T} in one unit of pseudo-rapidity at midrapidity
348 and 2π in azimuth. The acceptance-efficiency corrections
349 are determined separately for each centrality selection in
350 order to account for any multiplicity dependent effects.

351 Additionally, each collision system and each centrality
352 selection for a given collision system must be corrected
353 for the bias towards higher event multiplicity and hence
354 higher centrality for non-diffractive nucleon-nucleon col-
355 lisions compared to diffractive collision events with the
356 same impact parameter (see [25] for full details). The
357 bias factor f_{bias} , which is used to scale the p_{T} spec-
358 tra, is calculated using a Glauber Model Monte Carlo
359 calculation [35] in conjunction with the assumption of

360 a negative-binomial multiplicity distribution of particles
 361 produced in individual nucleon-nucleon collisions. The
 362 same Glauber calculation is used to characterize each
 363 centrality class by the number of binary nucleon-nucleon
 364 collisions N_{coll} , number of nucleon participants N_{part} ,
 365 and other relevant properties related to the collision ge-
 366 ometry like N_{proj} , the number of participants in the pro-
 367 jectile nucleus. For MB collisions, the f_{bias} also includes
 368 the extrapolation from the recorded cross section to the
 369 full inelastic cross section (0-100% centrality). The N_{coll} ,
 370 N_{part} , N_{proj} , and f_{bias} values are given in Table II.

371 V. SYSTEMATIC UNCERTAINTY

372 There are many sources of systematic uncertainty that
 373 need to be evaluated. They are separated into two
 374 groups: (i) uncertainty on the event characterization, and
 375 (ii) on the π^0 yield extraction.

376 The event characterization is done using Glauber
 377 model simulations and the uncertainties were determined
 378 by varying the input to the Glauber model and various
 379 assumptions used in [25]. The results are included in Ta-
 380 ble II. All quantities extracted from the Glauber model
 381 simulation are correlated, which leads to a partial cancel-
 382 lation of the uncertainties. This was taken into account.

383 The uncertainties on the π^0 invariant yield are summa-
 384 rized in Table III for the different running periods. The
 385 total uncertainty on the π^0 invariant yield varies between
 386 8-10% for p_T below 8 GeV/c and increases to nearly 15%
 387 at 20 GeV/c. They have little dependence on collision
 388 systems or centrality selection. The uncertainties on the
 389 π^0 invariant yield were obtained with similar methods
 390 for all data sets. They are highly correlated within a
 391 running period and somewhat correlated between run-
 392 ning periods. These correlations have been taken into
 393 account when combining data sets or calculating ratios
 394 of data sets. The remainder of this section provides more
 395 details on the evaluation of the systematic uncertainties
 396 on the π^0 yield determination, which is split into the ex-
 397 traction of the raw π^0 yield and the corrections that need
 398 to be applied to it.

399 A. Raw π^0 Yield Extraction

400 The raw π^0 yield is extracted from an invariant mass
 401 $M_{\gamma\gamma}$ distribution, which involves the subtraction of a
 402 background distribution below a π^0 peak. Except for
 403 very high p_T this is done using the mixed event technique.
 404 This subtraction is typically accurate to better than 4%.
 405 In general, the uncertainties on the background subtrac-
 406 tion are determined by changing the assumption on the
 407 shape of the background and how it is normalized. Many
 408 different strategies can be used, as they all give similar
 409 results. Here, one example is given, the strategy that was
 410 used for the 2015 MB data sets, which were used to ex-
 411 tract the π^0 yield at lower p_T values for $p+\text{Au}$, $p+\text{Al}$, and

412 $p+p$. The normalization of the mixed event background
 413 is determined in different ranges below and above the
 414 π^0 peak. For any normalization, after the mixed event
 415 subtraction there is a residual background, which is then
 416 fitted. For each normalization the fit range is varied to
 417 extract the residual background via a first-order poly-
 418 nomial. Then in each case the window for the π^0 yield
 419 extraction is varied from 1 to 3 sigma around the π^0
 420 peak. The variation of the resulting π^0 yields, after cor-
 421 recting for the different σ ranges, is used to estimate the
 422 systematic uncertainty.

423 The accuracy with which the π^0 yield can be extracted
 424 depends on the amount of background. In general, the
 425 smaller the particle multiplicity in the event and/or the
 426 larger the π^0 p_T , the smaller the background. However,
 427 the accuracy with which the background can be deter-
 428 mined for a particular p_T and centrality bin is driven by
 429 the available statistics. Since the π^0 p_T spectra is a result
 430 of combining MB and various ERT triggered data sets,
 431 the p_T dependence of the π^0 extraction uncertainty may
 432 sometimes show counter-intuitive decreasing uncertainty
 433 with increasing p_T .

B. Corrections of the Raw Yield

434 The acceptance-efficiency correction accounts for all
 435 distortions to the π^0 spectra that can be evaluated
 436 with the detailed simulation of π^0 measurements in the
 437 PHENIX experiment. The accuracy of the simulation de-
 438 termines the size of systematic uncertainties. Thus, great
 439 care is taken to assure that the output of the simulation
 440 agrees with the data.

441 These distortions include, besides the actual correc-
 442 tions for detector acceptance and π^0 reconstruction, the
 443 one for the energy scale and resolution, merging of clus-
 444 ters, and losses due to photon conversions. While the
 445 corrections were determined simultaneously, possible un-
 446 certainties are studied separately. In Table III these are
 447 identified as "Acceptance/Efficiency", "Energy Scale",
 448 "Cluster Merging", and "Conversion Loss", respectively.

449 The energy scale and resolution was tuned by match-
 450 ing the π^0 peak position and width in simulation and
 451 data, as function of p_T , to a better than 0.5-1% agree-
 452 ment, depending on the data set. The uncertainty is
 453 then determined by varying the energy scale and reso-
 454 lution within the achieved accuracy. The π^0 yields are
 455 consistent within 4-5% at 2 GeV/c and up to 7-9% at 20
 456 GeV/c.

457 To study the accuracy of the reconstruction efficiency
 458 correction, cuts applied in the π^0 reconstruction were var-
 459 ied and the analysis was repeated. The changes in the π^0
 460 yield were used to set the systematic uncertainties. They
 461 are typically smaller than 4%, but may be limited by sta-
 462 tistical uncertainties. The uncertainty on the acceptance
 463 was determined from the precision of the survey of the
 464 EMCal. It is negligible compared to the uncertainties on
 465 the reconstruction efficiency.

TABLE III: Summary of systematic uncertainties on the π^0 invariant yields from different running periods.

Systematic uncer. p_T [GeV/c]	2015 $p+Au$, $p+Al$, $p+p$			2014 ^3He+Au			2008 $d+Au$, $p+p$		
	2	8	20	2	8	20	2	8	20
Peak Extraction	4.4%	3.4%	1%	2.7%	4.1%	2%	4.8%	2.9%	1.5%
Energy Scale	3.8%	6.5%	7.1%	3.0%	5.2%	5.7%	4.6%	7.9%	8.7%
Acceptance-Efficiency	3%	2.5%	1%	4	4%	4%	3%	2.5%	1%
Cluster Merging	0%	0%	9.0%	0%	0%	12%	0%	0%	10%
Conversion Loss	5%	5%	5%	5%	5%	5%	2.5%	2.5%	2.5%
Double Interactions	4%	3%	4%	<1%	<1%	<1%	1%	2.5%	4%
Off Vertex Decays	3%	3%	3%	3%	3%	3%	3%	3%	3%
Total	9.6%	10.1%	13.0%	8.3%	9.8%	14.1%	8.3%	10.0%	14.5%

467 The two decay photons from the decay of a high p_T π^0 468 are strongly boosted along the π^0 direction, the average 469 opening angle becomes small, resulting in only a small 470 separation between the impact points on the surface of 471 the EMCal. At about 10 GeV/c, the two clusters start 472 to merge. Initially, this happens only for very symmetric 473 decays characterized by a small energy asymmetry 474 (α). With increasing p_T , more and more clusters merge, 475 leading to an increasing drop in reconstruction efficiency 476 towards higher p_T . The accuracy with which the Monte 477 Carlo simulation reproduces the cluster merging is verified 478 by reconstructing π^0 from three exclusive asymmetry 479 bins: 0–0.4, 0.4–0.8, and 0.8–0.95. After fully correcting 480 the π^0 yields, the results are compared and the differences 481 are used to estimate the systematic uncertainty. 482 It reaches about 10% towards the end of the kinematic 483 reach of the measurement.

484 Some photons convert into e^+e^- pairs before they 485 reach the EMCal. If the radial location of the conversion 486 point is close to the EMCal, outside the magnetic 487 field, the e^+ and e^- will hit the EMCal in close proximity, 488 resulting in one cluster with the full energy of the 489 converted photon. In that case, it is likely that the π^0 is 490 reconstructed. However, if the conversion point is closer 491 to the vertex, and in the magnetic field, the π^0 will not 492 be reconstructed, since the electron tracks bend in opposite 493 direction, depositing their energy in two separate 494 clusters. Prior to 2010, before the VTX was installed, 495 about 81% of the π^0 were reconstructed. Due to the additional 496 material of the VTX detector close to the vertex, 497 this number drops to 61% after 2010. The accuracy with 498 which the loss can be determined depends solely on the 499 accuracy with which the material budget is known and 500 implemented in the Monte Carlo simulation. The resulting 501 uncertainties on the π^0 yield are 2.5% and 5%, before 502 and after installation of the VTX. There is no significant 503 momentum dependence.

504 All data sets from 2015 ($p+p$, $p+Al$, and $p+Au$) were 505 taken at high beam luminosity, resulting in a significant 506 number of recorded double interactions. These were actively 507 identified and removed by timing cuts on the EMCal 508 and BBC. The effect of any remnant double inter-

509 action was estimated by splitting the data samples into 510 subsets taken at higher, medium, and lower luminosity. 511 The analysis was repeated for each sample, and the π^0 512 yields were found to be consistent within 3-4%. This difference 513 was assigned as systematic uncertainty. For the 2008 data sets 514 ($p+p$ and $d+Au$), only the EMCal timing cuts were applied 515 to remove pileup events. Here, the possible contamination 516 was estimated by the number of π^0 for which at least one 517 cluster had a time off by >5 ns. The contribution was 1% 518 at high p_T and about 4% at lower p_T . For the 2014 ^3He+Au 519 data no sizable effect was found. 520

521 Some reconstructed π^0 originate from weak decays that 522 occur at a significant distance from the interaction point, 523 so called "off vertex π^0 ". The main source of such π^0 524 are decays of $K_s \rightarrow \pi^0\pi^0$. This source was extensively 525 studied and found to drop from approximately 5% at 526 1 GeV/c to 3% at 2 GeV/c from where on it remains 527 approximately constant. The small p_T dependence of 528 this contribution is due to the two arm acceptance of the 529 PHENIX detector, where the high- p_T decay products are 530 more likely to be inside the acceptance. This contribution 531 was not subtracted from the π^0 spectra and a 3% 532 systematic uncertainty is assigned to it.

533 Finally, the uncertainty of the the normalization of the 534 data taken with the ERT trigger to the MB data is examined. 535 This uncertainty is smaller than 1% and not listed 536 in Table III.

VI. RESULTS AND DISCUSSION

A. The $p+p$ reference

537 PHENIX has previously published the π^0 p_T spectrum 538 from $p+p$ collisions at $\sqrt{s} = 200$ GeV [32] based on data 539 taken in 2005 corresponding to $3.4 pb^{-1}$. In 2008 and 540 2015 RHIC provided further $p+p$ collisions, increasing 541 the integrated luminosity by $5.2 pb^{-1}$ and $60 pb^{-1}$ respectively. 542

543 With the increased statistics, the precision of the measurement 544 was improved and extended to higher p_T . Since 545 546

547 the detector configurations and the ERT trigger settings
 548 were different for the 2008 and 2015 data sets, the π^0
 549 spectra were measured separately. The results were combined
 550 with those from 2005.

551 The new and published measurements were made with
 552 the PHENIX EMCAL using the same analysis strategy,
 553 thus the π^0 yield determinations have largely, but not
 554 completely, correlated systematic uncertainties. To combine
 555 the three data sets, the correlations between individual
 556 systematic uncertainties were carefully studied and
 557 accounted for using the BLUE method [36]. In addition
 558 to the uncertainties due to the π^0 reconstruction, there
 559 is an overall normalization uncertainty of 9.7% [32] that
 560 accounts for the limited accuracy with which the $p+p$
 561 MB trigger efficiency (see Table II) is known. This un-
 562 certainty is common to all $p+p$ measurements.

563 In Figure 3, the combined π^0 p_T spectrum from $p+p$
 564 collisions (2005, 2008, 2015) is compared to the earlier
 565 published result. The combined result is in excellent
 566 agreement with data taken in 2005, but has significantly
 567 improved statistics and extends the p_T range up
 568 to 25 GeV/ c . The systematic uncertainties are slightly
 569 reduced with respect to those of the 2005 data alone.

570 Also shown in Figure 3 are next-to-leading order pQCD
 571 calculations [37] with two different fragmentation func-
 572 tions (BKK and KKP FF) and for three different scales
 573 $\mu = p_T/2$, p_T , and $2p_T$. Within the assumed range of
 574 scales both fragmentation functions are consistent with
 575 the data. BKK would require a scale of $\mu = p_T$, while
 576 KKP describes the data best at a slightly larger scale.

577 B. Small system p_T spectra and nuclear 578 modification factor

579 1. p_T spectra

580 Figure 4 presents π^0 p_T spectra from $p+Al$, $p+Au$,
 581 $d+Au$, and ${}^3He+Au$ from left to right, respectively. The
 582 data are presented as the invariant π^0 yield per collision
 583 as a function of p_T . The 0–100% range corresponds
 584 to the full inelastic cross section. The other centrality
 585 ranges correspond to 0–5, 0–20, 20–40, 40–60, and above
 586 60% measured percentile of the events selected according
 587 to the multiplicity measured in the BBC on the south
 588 side (heavy nucleus going side). Different centrality se-
 589 lections are scaled by factors 1/10 for visibility. The 0–
 590 5% centrality selection, which is available for ${}^3He+Au$,
 591 $p+Au$, and $p+Al$ collisions, was taken with a high multi-
 592 plicity BBC trigger and has a p_T range limited to below
 593 10 GeV/ c .

594 2. Nuclear Modification Factor

595 For a quantitative comparison across systems and cen-
 596 trality selections the nuclear modification factor is used.
 597 It is defined as:

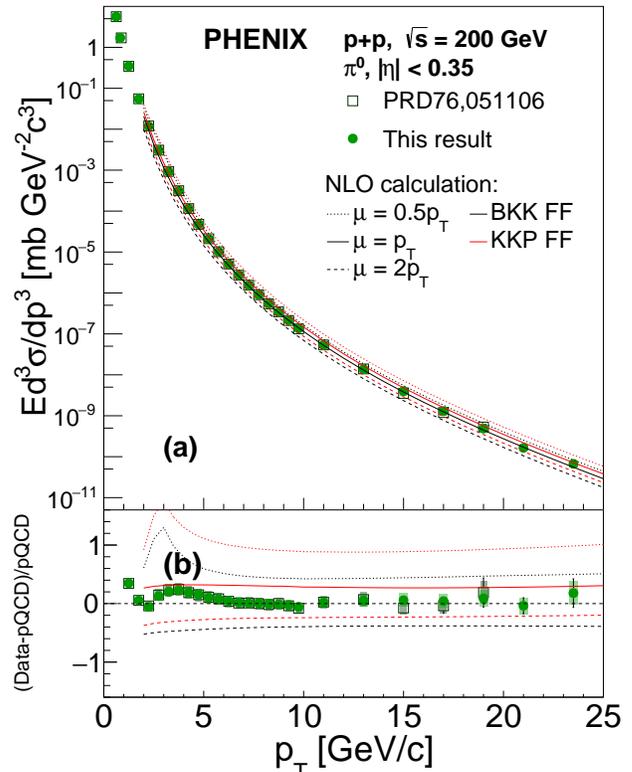

FIG. 3: Differential cross section of π^0 in $p+p$ collisions at $\sqrt{s} = 200$ GeV. The data are compared with a pQCD calculation. The lower panel shows the ratio of the data points to the NLO calculation with BKK and a scale of $\mu = p_T$.

$$R_{xA} = \frac{dN_{xA}/dp_T \times \sigma_{pp}}{\langle N_{coll} \rangle \times d\sigma_{pp}/dp_T}, \quad (1)$$

598 where dN_{xB}/dp_T is the invariant yield per $x+A$ colli-
 599 sions, $d\sigma_{pp}/dp_T$ is the invariant cross section in $p+p$
 600 collisions, $\sigma_{pp} = 42$ mb is the inelastic $p+p$ cross section, and
 601 N_{coll} is the average number of binary nucleon-nucleon
 602 collisions given in Table II. A nuclear modification factor
 603 of $R_{xA} = 1$ at high p_T indicates that π^0 production
 604 through hard scattering processes in $x + A$ collisions is
 605 well described by a superposition of $p+p$ collisions.

606 3. R_{xA} for inelastic collisions

607 The nuclear modification factors for inclusive π^0 pro-
 608 duction from inelastic $p+Al$, $p+Au$, $d+Au$, and ${}^3He+Au$
 609 collisions are shown in Figure 5. They are calculated us-
 610 ing the $p+p$ reference from the combined 2005, 2008, and
 611 2015 data. The correlations of the systematic uncertain-
 612 ties on the π^0 reconstruction for different data sets are
 613 taken into account using the BLUE method [36]. The
 614 overall normalisation uncertainties on $p+p$ and on N_{coll}

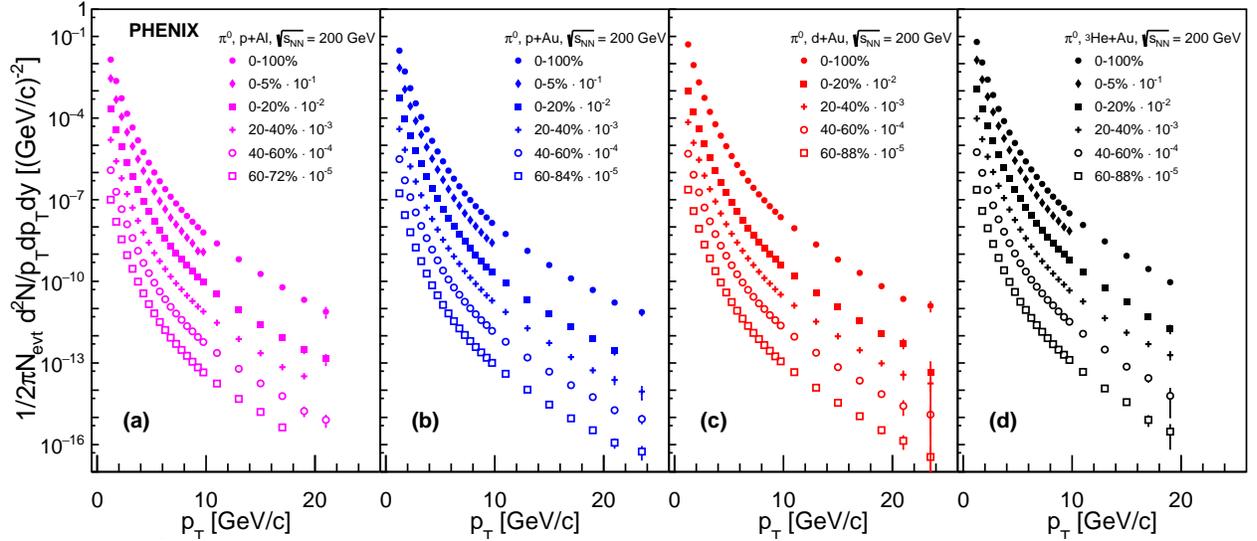

FIG. 4: Invariant yield of π^0 from (a) p +Al, (b) p +Au, (c) d +Au, and (d) ^3He +Au at $\sqrt{s_{NN}} = 200$ GeV. For each collision system the yield is shown for the inelastic cross section and for different centrality selections 0-20%, 20-40%, 40-60%, and larger than 60%. For p +Al, p +Au, and ^3He +Au an additional 0-5% centrality selection is shown, which was recorded using a dedicated high multiplicity trigger.

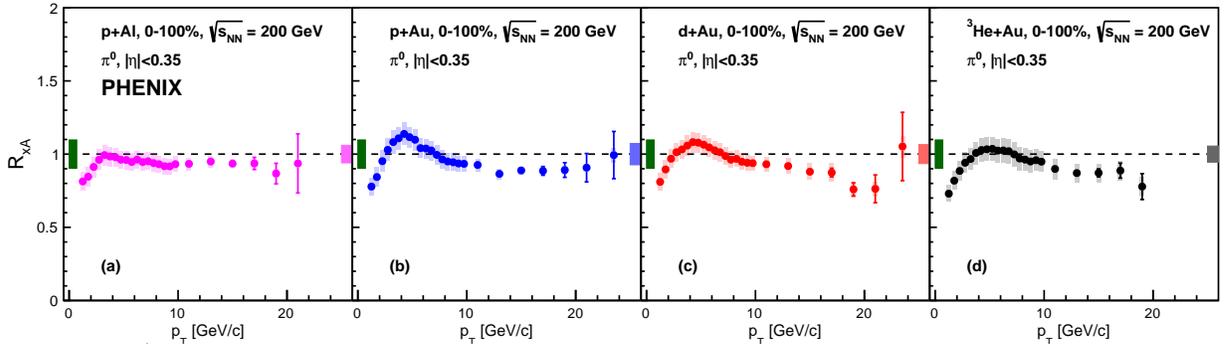

FIG. 5: Nuclear modification factors from inelastic p +Al, p +Au, d +Au, and ^3He +Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The error bars represent the statistical uncertainties, while the boxes represent the systematical uncertainties. The right boxes are the N_{coll} uncertainties from the Glauber model, while the left box represents the overall normalization uncertainty from p + p collisions.

615 are shown separately on the left and right on each panel, 630
616 respectively. 631

617 Each data set exhibits the characteristic p_T depen- 632
618 dence of the Cronin effect, an initial rise from below unity 633
619 to a peak around p_T of 4 GeV/ c , followed by a drop and 634
620 a leveling off at high p_T . The constant value at high p_T is 635
621 independent of the collision system at a value of $R_{xA} \sim$ 636
622 0.9, which is consistent with unity within the systematic
623 uncertainties on the scale and N_{coll} . The fact that R_{xA}
624 at high p_T is consistent with unity and that there is no
625 system size dependence suggest that there is little to no
626 modification of the hard scattering component in small
627 systems.

628 To investigate any possible system size dependence of 640
629 the modification at lower p_T , the peak value in R_{xA} is de- 641

630 termined as the ratio of integrated R_{xA} from 4 to 6 GeV/ c
631 divided by the integral taken above 10 GeV/ c . In these
632 ratios the systematic uncertainties largely cancel. The
633 peak values are 1.03 ± 0.018 , 1.23 ± 0.012 , 1.16 ± 0.009 ,
634 and 1.16 ± 0.02 for p +Al, p +Au, d +Au, and ^3He +Au,
635 respectively. The peak value is smallest in the smallest
636 system and most pronounced in p +Au collisions.

637 The peak values are approximately the same as those
638 calculated in fixed target p +A experiments [38] and as
639 originally predicted for RHIC energies [8, 11, 12]. How-
640 ever, the systematic trend with system size does not fol-
641 low the dependence observed at fixed target energies [5],

$$\frac{d\sigma_{xA}}{dp_T} = (xA)^{n(p_T)} \times \frac{d\sigma_{pp}}{dp_T}, \quad (2)$$

with a common exponent $n(p_T)$ for a given \sqrt{s} . Eq. 2 is re-written in terms of per event yield by using $\sigma_{xA} = xA\sigma_{pp}$, which is expected for particle production from hard scattering:

$$\frac{dN_{xA}}{dp_T} = (xA)^{n(p_T)-1} \times \frac{dN_{pp}}{dp_T}. \quad (3)$$

Comparing Eq. 3 and 1 gives a relation between R_{xA} and the exponent $n(p_T)$:

$$n(p_T) = 1 + \frac{\log(R_{xA})}{\log(xA)}. \quad (4)$$

The exponent $n(p_T)$ is calculated from the ratio of R_{pAu}/R_{pAl} and R_{HeAu}/R_{pAu} . All uncertainties on N_{coll} and the $p+p$ data cancel for the nuclear modification factor ratios. The results are shown in Figure 6. The data show that there is no universal $n(p_T)$ at $\sqrt{s_{NN}} = 200$ GeV below 8-10 GeV/c. At higher p_T , the common $n(p_T)$ underlines the similarity of R_{xA} for all collision systems.

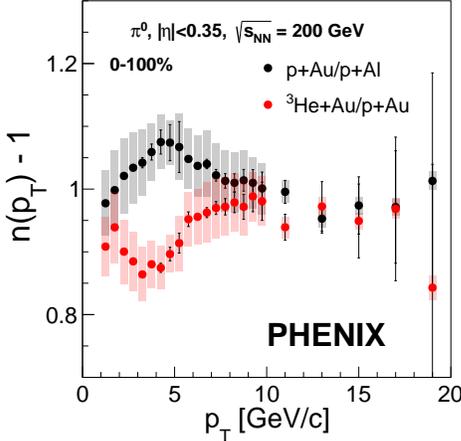

FIG. 6: Exponent according to the Eq. 4 as a function of transverse momenta extracted from $p+Au/p+Al$ and ${}^3He+Au/p+Au$ collision systems. The uncertainties from the N_{coll} calculations and from the overall normalization of $p+p$ cancel in these ratios.

4. R_{xA} Centrality Dependence

In Fig. 7, R_{xA} is shown for the different centrality selections from different collision systems. The scale uncertainty from the $p+p$ reference and, to a large extent, the

scale uncertainty due to N_{coll} only influences the scale of R_{xA} , but not the relative differences between systems. The comparison reveals clear systematic trends of R_{xA} with centrality and system size.

For $p_T > 8$ GeV/c, the R_{xA} values remain constant at similar values for the same centrality selection from different collision systems. However, the plateau value varies with centrality. R_{xA} is below unity in the more central collisions, consistent with unity in the 20–60% bin, and above or consistent with unity in the peripheral collisions. In the lower p_T range, the 0–5% and 0–20% selections exhibit a clear Cronin peak structure, similar to the inelastic collision case, but more pronounced. The peak is largest for $p+Au$. The height of the peak is system size dependent and decreases from $p+Au$, to $d+Au$, to ${}^3He+Au$, i.e. with increasing size of the projectile nucleus. Similarly, the peak is smaller for $p+Al$ than for $p+Au$, so it also seems to decrease with decreasing size of the target nucleus. In contrast, in peripheral collisions all systems follow a common trend. From central, to semi-central, to semi-peripheral collisions a gradual change is seen for each system, without apparent systematic trend across systems.

In order to better understand the trends, the average nuclear modification factor $\langle R_{xA} \rangle$ is calculated for two distinct p_T regions, above 8 GeV/c to represent the high p_T region and from $4 < p_T < 6$ GeV/c to capture the peak of R_{xA} . These $\langle R_{xA} \rangle$ are studied as function of variables characterizing centrality classes shown in Tab. II. Note that N_{coll} and N_{part} are highly correlated and follow a universal trend. $N_{part} = N_{coll} + 1$ up to an N_{coll} value of ~ 14 . For $N_{coll} > 14$, N_{part} increases slightly slower with N_{coll} . Consequently, common trends with one variable will also present themselves with respect to the other. The $\langle R_{xA} \rangle$ is calculated as follows:

$$\langle R_{xA} \rangle = \frac{\int \frac{dN_{AB}}{dp_T} dp_T}{N_{coll} \int \frac{dN_{pp}}{dp_T} dp_T} \quad (5)$$

Figure 8 shows $\langle R_{xA} \rangle$ for the two p_T regions for all measured centrality selections from all collision systems. In the top panel $\langle R_{xA} \rangle$ is plotted as function of N_{coll} and in the lower panels as function of N_{coll} per number of participating nucleons in the projectile N_{proj} .

The $\langle R_{xA} \rangle$ above 8 GeV/c exhibits no common trend as function of N_{coll} (panel b). $\langle R_{xA} \rangle$ is below N_{coll} scaling for peripheral classes and above for central classes for all collision systems. The situation changes when looking at the $\langle R_{xA} \rangle$ versus N_{coll}/N_{proj} (panel d). The collision systems involving Au as a target nucleus ($p+Au$, $d+Au$, and ${}^3He+Au$) follow a universal trend that is distinctly different from the one observed for $p+Al$. Modifications to binary scaling are approximately the same for $p+Au$ and $p+Al$ for the same centrality class, despite the difference in N_{coll} or N_{part} . The same trends are observed for any choice of p_T threshold above 7 GeV/c up to 15 GeV/c, above which statistics become limiting. There

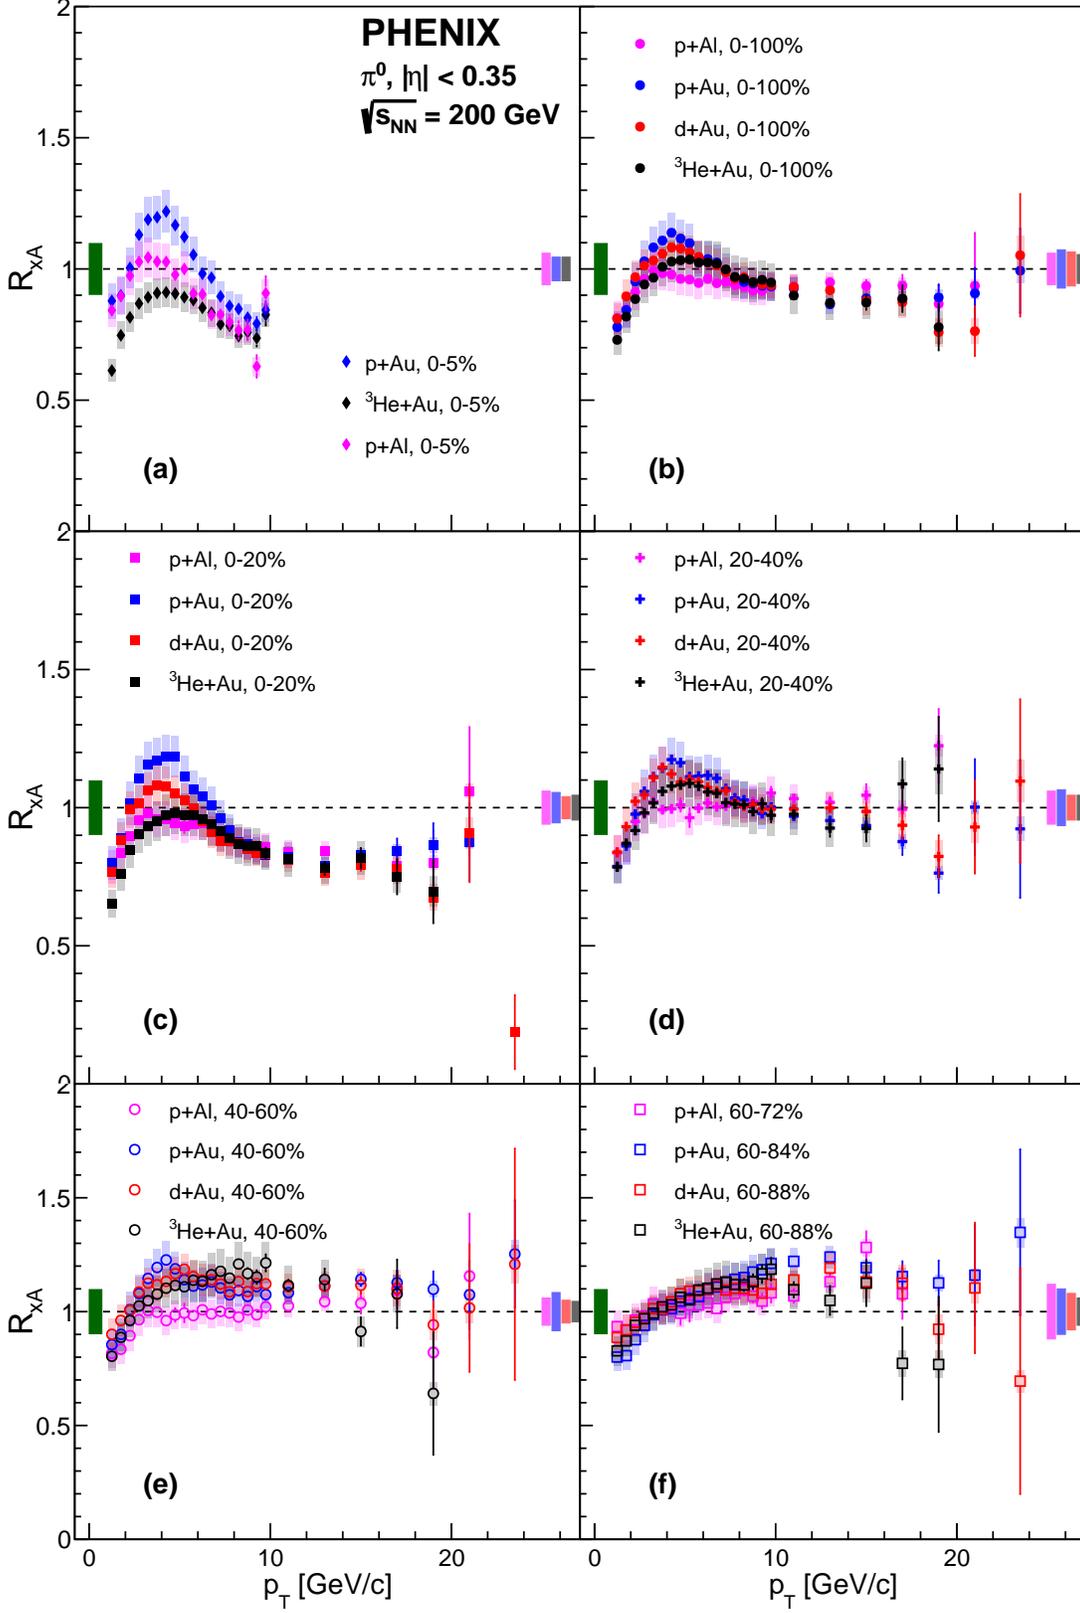

FIG. 7: Nuclear modification factors in p +Al, p +Au, d +Au, and ^3He +Au in five centrality bins and for inelastic collisions at $\sqrt{s_{NN}} = 200 \text{ GeV}$. The error bars represent the statistical uncertainties, while the boxes represent the systematical uncertainties. The right boxes are the uncertainties of the N_{coll} collisions from the Glauber model, while the left box represents the overall normalization uncertainty from $p+p$ collisions.

713 are two model independent conclusions that can be derived from the observations: (i) the underlying mechanism for the nuclear modification affects each projectile nucleus mostly independently, and (ii) the nuclear modification is not driven by the thickness of the nuclear matter traversed by the projectile.

719 Panel (a) in Fig. 8 shows $\langle R_{xA} \rangle$ as function of N_{coll} for the lower p_T range from 4 to 6 GeV/c, covering the peak in R_{xA} for all systems. The $\langle R_{xA} \rangle$ is remarkably close to binary scaling, with deviations that are visibly smaller than those observed at high p_T (see panel (b)). Another notable difference compared to the high p_T range is that all systems show similar deviations from binary scaling at the same N_{coll} . In contrast, the systems involving a Au target nucleus do not show a common trend with $N_{\text{coll}}/N_{\text{proj}}$ (panel c). These observations are qualitatively the same for any p_T window between 1 and 6 GeV/c. This suggests that the mechanism underlying the nuclear modification is different at high and low p_T with a transition in the 5 to 7 GeV/c range.

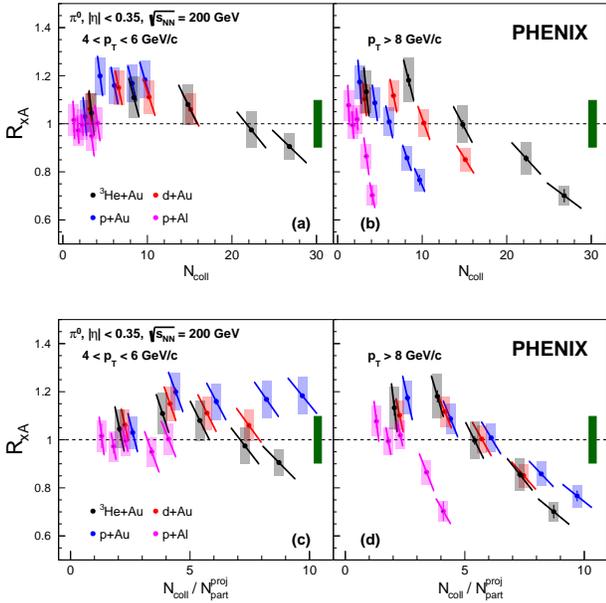

FIG. 8: Integrated R_{xA} in two different p_T regions versus the number of collisions per projectile participants. The left panel shows the region around the R_{xA} peak ($4 < p_T < 6$ GeV/c) and the right panel shows the high p_T region ($p_T > 8$ GeV/c). The statistical and systematic uncertainties are represented by error bars and boxes respectively around the data points. The tilted error bars represent the anti-correlated uncertainty on the y and x-axis due to the N_{coll} calculations. The right bar around unity represents the overall normalization uncertainty from $p+p$ collisions.

5. Model Comparison and Discussion

It is well known that the parton distribution function (PDF) of a nucleon is modified if the nucleon is within a nucleus [39]. The modifications increase with increasing number of nucleons in the nucleus. Like the PDFs themselves the nuclear parton distribution functions (nPDFs) are determined empirically by fitting a large variety of experimental data. Here three different nPDFs are considered: nNNPDFv1.0 [40], EPPS16 [41], and nCTEQ15 [42].

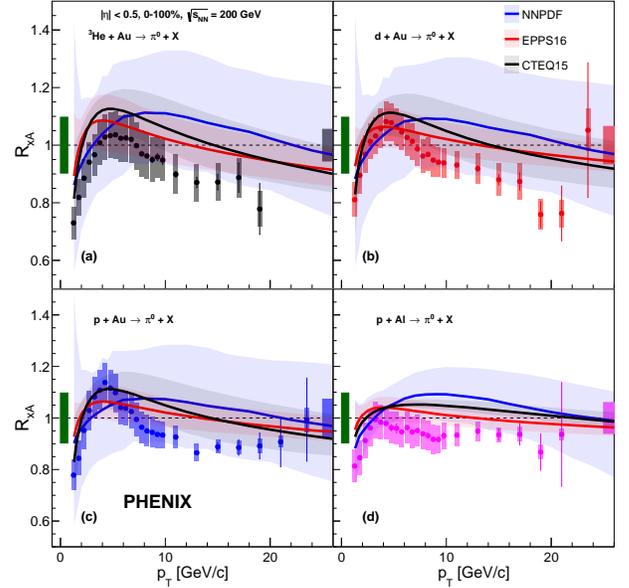

FIG. 9: R_{xA} for inelastic collisions compared to three different nuclear PDF calculations and their uncertainties. The data points include the statistical and systematic uncertainties. The left box around unity represents the overall normalization uncertainty on the $p+p$ collisions and the right box represents the uncertainty from the calculated N_{coll} .

In Figure 9, the measured nuclear modification factors for inclusive $p+Al$, $p+Au$, $d+Au$, and ^3He+Au collisions are compared to the predictions using the three different nPDFs mentioned above. The central value of the predictions is represented by a line and the uncertainties from fitting the nPDF to data are given as shaded area. Due to their large uncertainties, all three nPDFs give R_{xA} predictions consistent with the data. However, looking at the central values, the predictions are in tension with the trends of the data. For example, for the nNNPDF case an enhancement is observed from 4 to above 20 GeV/c for all systems, with a maximum near 8 GeV/c, clearly not consistent with data. Looking at individual collision systems, EPPS16 and nCTEQ16 based calculations qualitatively, but not quantitatively, capture the general trends. The tension is most clearly visible when comparing the system size dependence. Each nPDF calculation predicts an ordering of the enhancement of R_{xA} in the peak re-

761 gion: ${}^3\text{He}+\text{Au} > d+\text{Au} > p+\text{Au} > p+\text{Al}$, which is sig- 784
 762 nificant as the systematic uncertainties on the nPDFs 785
 763 within one approach are highly correlated between sys- 786
 764 tems. The ordering results from both the modification 787
 765 increasing with the target size and with the projectile 788
 766 size. In contrast, the data show the reverse ordering. 789

767 At high- p_T , the models predict an opposite, reverse order- 790
 768 ing of the suppression of R_{xA} : ${}^3\text{He}+\text{Au} < d+\text{Au} <$ 791
 769 $p+\text{Au} < p+\text{Al}$ for the same reasons. In contrast, the 792
 770 data show a larger suppression, which is fairly indepen- 793
 771 dent of the collision system. However, given the system- 794
 772 atic uncertainties on the R_{xA} scale, the nPDF predictions 795
 773 are consistent with the data at high p_T . The different 796
 774 trends, in particular at low p_T , of the nPDF calculations 797
 775 compared to the data suggest that there must be addi- 798
 776 tional physics driving the nuclear modification beyond 799
 777 the nPDFs. 800

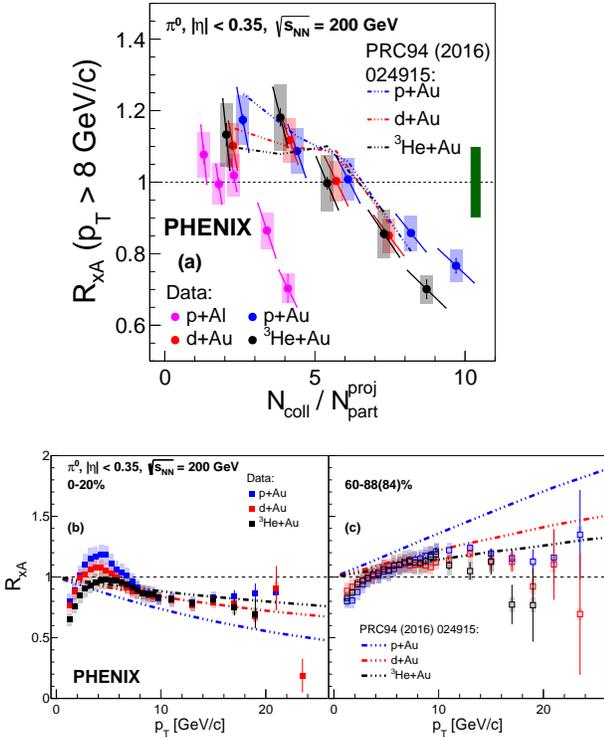

FIG. 10: The upper panel (a) shows the $\langle R_{xA} \rangle$ above $p_T = 8$ GeV/c as a function $N_{\text{coll}}/N_{\text{proj}}$. The data are compared to predictions from [43] for the consequences of high- x nucleon size fluctuations. The lower panels show the $\langle R_{xA} \rangle$ as a function of p_T for most central on left (b) and most peripheral on right panel (c) collisions.

778 The data show that at high p_T π^0 yields from small sys- 779
 780 tems are suppressed relative to $p+p$ in central event selec- 781
 782 tions, while they are enhanced for peripheral selections. 783
 784 Furthermore, for $p+\text{Au}$, $d+\text{Au}$, and ${}^3\text{He}+\text{Au}$, the $\langle R_{xA} \rangle$ 785
 786 values for $p_T > 8$ GeV/c are consistent with a super- 787
 788 position of independent collisions of the projectile nucle-

784 ons. At the same time, $p+\text{Au}$ and $p+\text{Al}$ show nearly the 785
 786 same $\langle R_{xA} \rangle$ in the same centrality bin selection. These 787
 788 observations contradict any scenarios where parton en- 789
 790 ergy loss would be responsible for the modification, which 791
 792 would necessarily result in an ordering of R_{xA} values as 793
 794 ${}^3\text{He}+\text{Au} < d+\text{Au} < p+\text{Au} < p+\text{Al} \leq 1$ for the system 795
 796 dependence, with the suppression for each system being 797
 798 largest for central and $R_{xA} \sim 1$ for peripheral collisions. 799

800 Models that invoke nucleon size variations have been 801
 802 proposed to explain the suppression/enhancement pat- 803
 804 tern seen in the data [29, 30]. These models assume 805
 806 that nucleons with high- x partons have a more compact 807
 808 color configuration and thus will produce on average less 809
 810 binary collisions and target participants at the same im- 811
 812 pact parameter as nucleons without high- x partons. As a 813
 814 consequence, events with a high p_T π^0 would typically be 815
 816 biased towards smaller multiplicity of the overall event, 817
 818 leading to an apparent enhancement in peripheral event 819
 820 selections and a suppression in central events. The calcu- 821
 822 lations from [43], which predicted jet R_{xA} for $p+\text{Au}$ 823
 824 and ${}^3\text{He}+\text{Au}$ based on a comparison to $d+\text{Au}$ data, are 825
 826 compared to π^0 $\langle R_{xA} \rangle$ above 8 GeV/c¹, see Figure 10 827
 828 (a) panel. The observed centrality dependence is quite 829
 830 consistent with the data. It can be expected that in this 831
 832 model the same event selection bias would occur in $p+\text{Al}$ 833
 834 collisions. It is important to note, however, that these 835
 836 models predict an ordering of R_{xA} with system size and 837
 838 centrality at higher p_T . For central collisions R_{xA} val- 839
 840 ues follow ${}^3\text{He}+\text{Au} < d+\text{Au} < p+\text{Au}$ and for peripheral 841
 842 collisions the ordering is reversed. This is clearly seen in 843
 844 Figure 10 (b) and (c). In contrast, such an ordering is 845
 846 not supported by the data.

816 In [31], the bias of the event selection by centrality oc- 817
 818 curs because soft particle production away from the hard 819
 820 scattering process is suppressed, caused by the depletion 821
 822 of energy available in the projectile after the hard scat- 823
 824 tering process. R_{xA} calculated for $d+\text{Au}$ with this model 825
 826 was consistent with preliminary $d+\text{Au}$ data [31] and is 827
 828 also consistent with the final data within systematic un- 829
 830 certainties. It would be interesting to see these calcula- 831
 832 tions expanded to the full variety of available data from 833
 834 small systems. 835

¹ Note that jet R_{xA} presented in [43] was converted to π^0 R_{xA} assuming $p_T(\pi^0) = 0.7p_T^{\text{jet}} = 0.7 \times 100\text{GeV} \times x_p$ and $\langle R_{xA} \rangle \sim R_{xA}(p_T)$. This procedure was discussed with the authors.

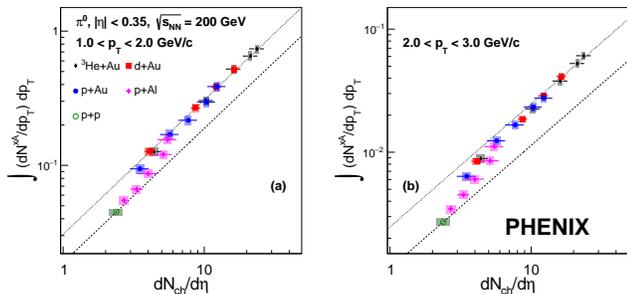

FIG. 11: Integrated yields for 1–2 GeV/c in panel (a) and 2–3 GeV/c in panel (b) as a function of charged particle multiplicity density at mid rapidity.

In recent years particle spectra from $p+p$ collisions at the LHC have been interpreted in the context of hydrodynamic models and the presence of strong radial flow [44–47], but no predictions exist for small systems at RHIC energies that could be compared to the data. If the large anisotropies of particle production seen at RHIC in $p+Au$, $d+Au$, and ^3He+Au are indeed related to hydrodynamic expansion of the collision volume, as suggested in [24], then the same systems must also exhibit radial flow since the anisotropy would be a geometry driven modulation of radial flow. The effects of radial flow are typically most prominent at p_T below a few GeV/c, where soft particle production mechanisms dominate. In the presence of radial flow the π^0 yield would be shifted towards higher momentum by the velocity field. Accordingly, when comparing the shape of the π^0 momentum spectra from $x+A$ to that from $p+p$, a depletion of the yield at the lowest p_T is expected, while at higher p_T the yield would be enhanced with a transition below 0.5 GeV/c. Since the p_T range of the π^0 data starts at 1 GeV/c, only the region where an enhancement would be expected can be studied here.

In order to look for possible indications of radial flow the integrated yields are calculated for two p_T ranges, 1–2 and 2–3 GeV/c, for all systems and event selections. The results are plotted in Figure 11 as function of the charged particle multiplicity density $dN_{ch}/d\eta$ at mid rapidity for the corresponding system and event selection. Also shown on each panel are two lines indicating integrated yields proportional to $dN_{ch}/d\eta$. The lower line is anchored to the $p+p$ point following a trend of unchanged shape of the spectra, and the other one matches the yield for the 0–20% ^3He+Au selection. While the peripheral $p+Al$ events follow the $p+p$ trend, all other selections show higher integrated yields compared to the $p+p$ trend. Above $dN_{ch}/d\eta \sim 10$ the data tends to be proportional to $dN_{ch}/d\eta$ again but at a much higher level.

The observed trend is qualitatively consistent with the presence of radial flow in small systems. Interestingly, the surprisingly rapid transition over the range from about 3 to 10 is similar to recent observations of low p_T direct photon emission [48], which also indicates a transition from $p+p$ like emission to a significant enhancement of

direct photons at similar event multiplicities. Furthermore, the presence of radial flow could naturally explain the much larger observed Cronin effect for protons from small systems [5], which so far has eluded a quantitative understanding. However, before drawing firm conclusions, more investigations are necessary. These should include the study of heavier hadrons, like Kaons and protons.

VII. SUMMARY

In summary, this paper presents new measurements of the invariant cross section of neutral pion production from $p+p$ collisions and invariant yields from $p+Al$, $p+Au$, $d+Au$, and ^3He+Au at $\sqrt{s_{NN}} = 200$ GeV. For $p+p$ the new results extend the measured range to $p_T \sim 25$ GeV/c and improve statistical and systematic uncertainties compared to the previous measurement. NLO pQCD calculations are found to be consistent with the data as previously reported.

For $p+Al$, $p+Au$, $d+Au$, and ^3He+Au collisions at $\sqrt{s_{NN}} = 200$ GeV, π^0 p_T spectra from inelastic collisions and from centrality selected event samples were measured, including a sample of the 0–5% most central events for $p+Al$, $p+Au$, and ^3He+Au , which was recorded with a dedicated high multiplicity trigger.

At high transverse momentum ($p_T > 8$ GeV/c), where hard scattering processes are the dominant production mechanism, the nuclear modification factors for all collision systems are found to be nearly constant. For the same event selection in percent centrality, different collision systems exhibit the same constant value of R_{xA} . For the full inelastic cross section, R_{xA} is consistent with unity, pointing towards little or no nuclear modification of hard scattering processes in small systems. For the most central events, it is observed that R_{xA} is significantly below unity. However, R_{xA} increases monotonically with decreasing centrality and exceeds unity for peripheral collisions. For Au target nuclei, the $\langle R_{xA} \rangle$ above p_T of 8 GeV/c shows a common trend with N_{coll}/N_{proj} . This indicates that, for hard scattering processes, the nucleons in the small projectile nucleus interact mostly independently with the Au target. For $p+Al$ collisions, $\langle R_{xA} \rangle$ does not follow the same trend. At the same event centrality, the $p+Al$ $\langle R_{xA} \rangle$ is the same as for $p+Au$, which suggests that whatever causes the change of R_{xA} with centrality does not depend on the target nucleus.

These observations disfavor scenarios where energy loss is a significant contributor to the nuclear modification of high p_T particle production in small systems. The counter-intuitive centrality dependence is likely linked to a mismatch of the centrality selection of events using charged particle multiplicity and mapping them to a number of binary collisions using the standard Glauber model. It seems that events with a high p_T π^0 are biased towards smaller underlying event multiplicity. This might be due to physical fluctuations of the proton size

924 or simply due to energy conservation if high p_T jets are 945
925 present. 946

926 For lower p_T , R_{xA} for all systems initially increases 947
927 with p_T and reaches a peak near 4–6 GeV/ c for central 948
928 and semi-central collisions. For peripheral collisions, R_{xA} 949
929 levels off to a constant at approximately the same high 950
930 p_T value for all systems. For inelastic collisions and more 951
931 central collisions, R_{xA} resembles what has been referred 952
932 to as the Cronin effect in fixed target experiments - a 953
933 rise, followed by a peak, followed by a plateau. However, 954
934 unlike at lower energies, $p+p$ and $x+A$ π^0 cross sections 955
935 are not related by a power $(AB)^{n(p_T)}$ with a common 956
936 $n(p_T)$. Furthermore, the peak value around 4–6 GeV/ c 957
937 shows a clear system size dependence $p+Au > d+Au >$
938 ${}^3\text{He}+Au > p+Al$, where the R_{xA} peak value is well above
939 unity for $p+Au$ and drops to close to unity for $p+Al$
940 collisions. 958

941 While the shape of R_{xA} roughly resembles what is ex- 959
942 pected from the nuclear modification of PDFs, the ob- 960
943 served system size dependence has exactly the reverse 961
944 ordering of what was predicted by nPDF calculations. 961

Therefore it is likely that nPDF's are insufficient to ex-
plain the nuclear modifications in small systems.

In the same p_T region, $\langle R_{xA} \rangle$ was used to study the
dependence on centrality. For all systems, $\langle R_{xA} \rangle$ in the
range 4–6 GeV/ c follows a common trend with N_{coll} .
At high p_T , $\langle R_{xA} \rangle$ scales with $N_{\text{coll}}/N_{\text{proj}}$ for Au target
nuclei. While at lower p_T , $d+Au$ and ${}^3\text{He}+Au$ are not
a superposition of $p+Au$ like collisions. Consequently,
very different mechanisms must contribute to the nuclear
modification at high and low p_T . Radial flow is one pos-
sible mechanism to explain this trend, though further
investigation is needed that is outside the scope of this
paper.
