Upton NY 11973, USA

Abstract. The production of electron pairs with p_T between 1 and 5 GeV/c and $m < 300$ MeV has been measured at mid-rapidity in $\sqrt{s_{NN}} = 200$ GeV $p+p$ and Au+Au collisions by the PHENIX experiment at RHIC. A significant excess above the hadronic background was observed in both $p+p$ and Au+Au collisions. Treating the excess as internal conversion of direct photons, the direct photon yield in Au+Au was found to be enhanced compared to the binary-scaled $p+p$ yield. The enhancement is consistent with an exponential inverse slope of $221 \pm 23 \pm 18$ MeV and predictions from hydrodynamical models with initial temperature between 300 and 600 MeV at formation times of 0.6–0.15 fm/c.

Keywords: direct photons, nucleus-nucleus collisions, $p+p$ collisions, heavy ion, elactron pair production, PHENIX, RHIC

1. Introduction

A multitude of results from the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory (BNL) indicates the creation of a high-density, thermalized medium in ultra-relativistic collisions of heavy ions [1]. Such a medium is expected to radiate thermal photons [2], which, once produced, leave the medium unscathed. Thermal photons from the partonic phase of the collision are predicted to dominate the direct photon spectrum in the transverse momentum (p_T) range of 1–3 GeV/c as illustrated in Fig. 1 [2]. However, here direct photons are submerged in a background of hadronic decay photons, mainly from the π^0 and η. This background constitutes a major experimental challenge in the conventional, calorimeter-based measurement. It can be overcome, though, by measuring low-mass electron pairs in a mass range where electron pairs from the π^0 Dalitz decay do not contribute [3].

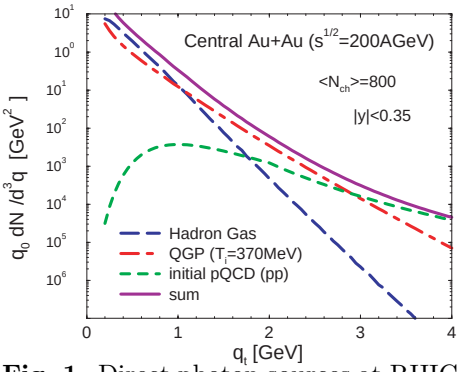

Fig. 1. Direct photon sources at RHIC [2].

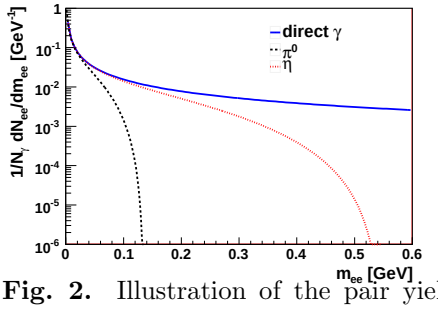

Fig. 2. Illustration of the pair yield mass dependence for direct photons as well as for π^0 and η Dalitz pairs.

The electron-pair yield above the hadronic background can be treated as internal conversion of direct photons [4].

2. Internal Conversion Method

Any source of high-energy photons also emits virtual photons with very low mass [4]. Those virtual photons then convert to low-mass e^+–e^- pairs, which can be measured (*Internal Conversion Method*). The pair yield per direct photon falls with the pair mass as:

$$\frac{d^2n_{ee}}{dm} = \frac{2\alpha}{3\pi}\frac{1}{m}\sqrt{1-\frac{4m_e^2}{m^2}}\left(1+\frac{2m_e^2}{m^2}\right)Sdn_\gamma. \quad (1)$$

Here α is the fine structure constant, m_e and m are the masses of the electron and the e^+–e^- pair, respectively, and S is a process dependent factor that goes to 1 as $m \to 0$ or $m \ll p_T$. Equation 1 also describes the relation between photons from hadron decays (e.g. $\pi^0, \eta \to \gamma\gamma$, and $\omega \to \gamma\pi^0$) and e^+–e^- pairs from Dalitz decays ($\pi^0, \eta \to e^+$–$e^-\gamma$ and $\omega \to e^+$–$e^-\pi^0$). For π^0 and η, the factor S is given by $S = |F(m^2)|^2(1-\frac{m^2}{M_h^2})^3$ [5], where M_h is the meson mass and $F(m^2)$ is the form factor. Figure 2 illustrates the pair yield mass dependence for direct photons as well as for π^0 and η Dalitz pairs. The cut-off of the π^0 pairs at the π^0 mass can be exploited to increase the signal-to-background ratio from 10%, where it is comparable to the systematic uncertainty and therefore not significant, to 50%, making a significant measurement possible. Since the measurement at low p_T is systematics limited, the simultaneous reduction in statistical significance is an acceptable trade-off[1].

[1]There are about 0.001 virtual photons with $m_{ee} > M_{\pi^0}$ for every real photon.

3. Data Set And Backgrounds

The analysis is based on two data sets: Au+Au at $\sqrt{s_{NN}}$ = 200 GeV acquired in 2004 consisting of 0.8 billion minimum bias events (4.9 pb^{-1} $p+p$ equivalent); $p+p$ at the same cms energy acquired in 2005 with 2.25 pb^{-1}. Charged tracks were measured with the Drift Chamber and Pad Chamber of the PHENIX [6] Central Arms covering $|\eta| < 0.35$ and $\Delta\phi = 2 \times \pi/2$ and identified as electrons with the Ring Imaging Čerenkov Detector (RICH) and Electromagnetic Calorimeter (EMCal). Material conversion pairs were removed by a cut on the orientation of the pair plane with respect to the magnetic field. Combinatorial background was removed by an event mixing technique, accurate to 0.25% systematic uncertainty in Au+Au.

There is additional correlated background from two sources: *cross pairs* with one electron/positron from either virtual photon in a double-Dalitz decay; *jet pairs* from two different Dalitz decays within the same jet or from back-to-back jets. These contributions can be well understood in a Monte Carlo calculation and have been subtracted.

4. Signal Extraction

After subtraction of the combinatorial background and the cross and jet pairs, the pair mass spectrum is compared to a "cocktail" of known hadronic sources [7, 8].

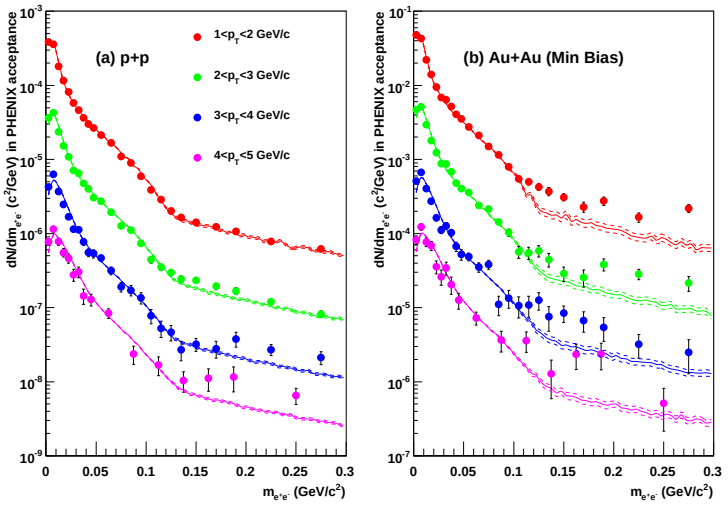

Fig. 3. Pair mass spectra for data (points) and hadronic cocktail (lines) in the PHENIX acceptance for different p_T intervals for $p+p$ (left) and Au+Au (right) [3].

Figure 3 shows this comparison for different p_T intervals for both $p+p$ and Au+Au. The cocktail is normalized to the data for $m < 30$ MeV, where the π^0 Dalitz decay dominates the yield. The "knee" at 100 MeV comes from the π^0 cut-off leading to the 80% background reduction mentioned above.

In $p + p$, the pair yield is consistent with the hadronic background for the lowest p_T interval. At higher p_T a small excess is visible for $m > m_{\pi^0}$. In Au+Au a much larger excess appears at all p_T, indicating an enhanced production of virtual photons[2].

To quantify the direct photon fraction, the mass spectrum is fit with a two-component function $f(m_{ee}) = (1-r)f_c(m_{ee}) + r f_{dir}(m_{ee})$ as illustrated in Fig. 4. Here $f_c(m_{ee})$ is the shape of the cocktail mass distribution (shown in Fig. 3), $f_{dir}(m_{ee})$ is the expected shape of the direct photon internal conversion, and r is the fit parameter. Both $f_c(m_{ee})$ and $f_{dir}(m_{ee})$ are separately normalized to the data for $m_{ee} < 30$ MeV/c^2, where their shapes are nearly identical. This preserves the meaning of r as the *real* direct photon fraction. From the agreement between

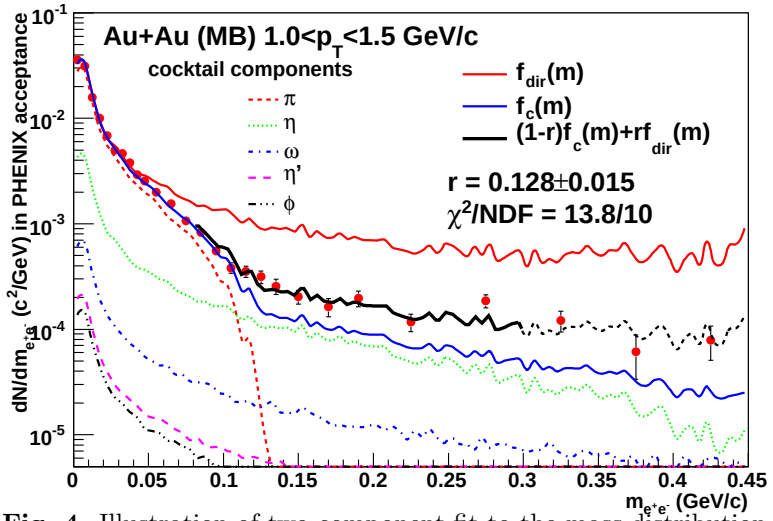

Fig. 4. Illustration of two-component fit to the mass distribution [3].

data and fit it can be concluded that the data matches the expected shape for direct photons.

The so extracted direct photon fraction, r, is plotted as a function of p_T in Fig. 5. While in case of $p + p$ the direct photon fraction is consistent with pQCD, for Au+Au r is enhanced above pQCD.

As this measurement is based on shape differences to extract the direct photon fraction, the η/π^0 ratio is the largest source of systematic uncertainty. This results

[2]This excess is in a different kinematic region (higher p_T, lower mass) than the low-mass enhancement reported in [7], which is expected to be dominated by the hadronic gas phase.

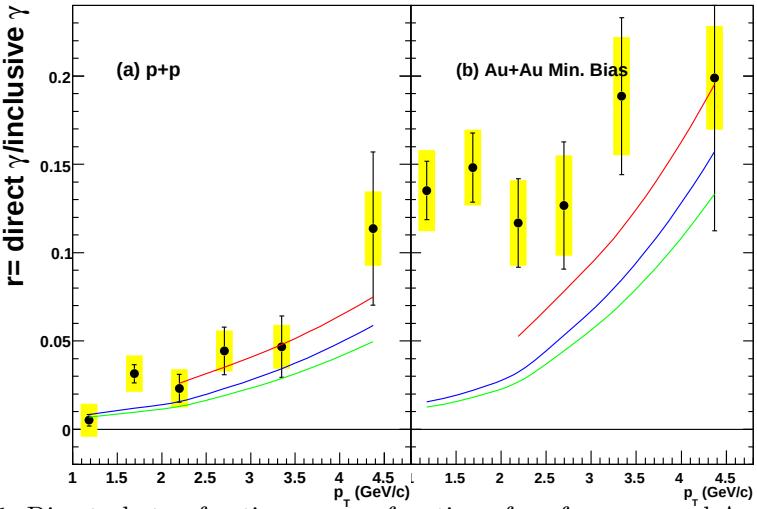

Fig. 5. Direct photon fraction, r, as a function of p_T for $p+p$ and Au+Au events compared to a pQCD calculation for three different scales. In the case of Au+Au the pQCD result is scaled by the nuclear overlap function, T_{AA} [3].

in a 7% uncertainty in $p+p$ and 17% in Au+Au. Other sources contribute only a few percent as the cocktail is normalized to the data and no absolute normalization is required.

In the next step, r is converted into the direct photon yield as $dN^{dir}(p_{\rm T}) = r \times dN^{incl}(p_{\rm T})$. The inclusive photon yield for each $p_{\rm T}$ bin is determined by $dN_\gamma^{incl} = N_{ee}^{data} \times (dN_\gamma^c/N_{ee}^c)$, where N_{ee}^{data} and N_{ee}^c are the measured and the absolutely normalized cocktail e^+–e^- pair yields, respectively, both for $m_{ee} < 30$ MeV/c^2; and dN_γ^c is the yield of photons from the cocktail. Here we use the fact that the ratio of the photon yield to the e^+–e^- pair yield for $m_{ee} < 30$ MeV/c^2 calculated from Eq. 1 is the same within a few percent for any photon source. The systematic uncertainty of γ^{incl} is 14% from the e^+–e^- pair acceptance.

5. Results

Figure 8 shows the invariant yield of direct photons as a function of p_T for $p+p$ and three different centrality classes in Au+Au. The $p+p$ data is again compared to the pQCD calculation. The calculation is consistent with the data for $p_T > 2$ GeV. A modified power law, $A_{pp}(1+p_T^2/b)^{-n}$, fits the data over the entire p_T range.

5.1. Significance of the Modified Power Law

The modified power law appears to yield an at least as good description of the data at low p_T as the pQCD calculation. What is the significance of this observation? It is obvious that the power-law behavior of hard scattering has to break down for $p_T \to 0$. For hadrons, soft production sets in with an exponential slope. This is illustrated in Fig. 6, which shows a parameterization of π^0 production in $p+p$ [

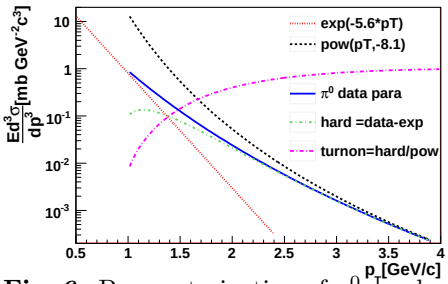

Fig. 6. Parameterization of π^0 production in $p+p$ [9] and its various contributions (for details see text).

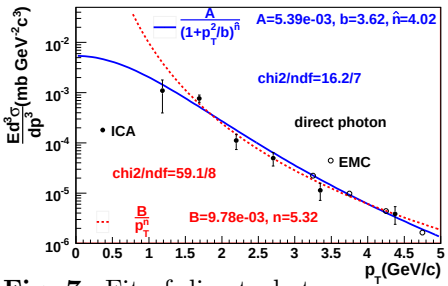

Fig. 7. Fit of direct photon cross section with both a power law and a modified power law.

9]. The parameterization is the sum of a power law and an exponential with a Woods-Saxon transition between the two. The two functions are shown separately. The exponential dies out at high p_T while the power law diverges at low p_T. The hard-scattering contribution can be understood as the difference between the data parameterization and the exponential contribution. One can see that it flattens out towards low p_T, deviating from the power law. This flattening corresponds to an onset of hard scattering as illustrated by the ratio of the hard scattering contribution to the power law.

This onset is not directly observable for hadrons as the production at low p_T is dominated by soft physics. Direct photons, however, are only produced in hard scatterings. This makes the onset of hard scattering at low p_T directly measurable. The onset has also been measured in Drell-Yan production [10].

To evaluate the statistical significance of the onset, the PHENIX data were fitted with both a power law and a modified power law. As shown in Fig. 7, the modified power law yields a smaller reduced χ^2 than the pure power law.

5.2. Au+Au Enhancement

For $1 < p_T < 3$ GeV, the direct photon invariant yield in Au+Au is enhanced above the T_{AA}-scaled modified power law that was fit to the $p+p$ data (Fig. 8). It can be well described, however, if an exponential is added. The resulting fit yields negative inverse exponential slopes of about 220 MeV[3]. If the medium were static, T could

[3]If the $p+p$ data are fit with a pure power law, T increases by 24 MeV in central events.

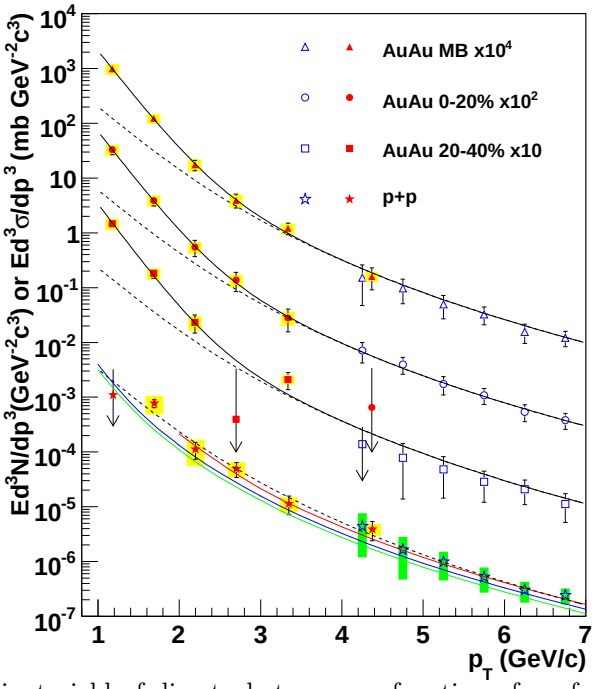

Fig. 8. Invariant yield of direct photons as a function of p_T for $p+p$ and three different centrality classes in Au+Au (solid symbols). The result of an earlier EMCal measurement is also shown (open symbols) [11, 12]. The $p+p$ data is compared to a pQCD calculation shown as three lines for different scales. The dashed line is a fit of a modified power law to the $p+p$ data. The Au+Au data are compared to the T_{AA}-scaled $p+p$ fit (dashed line). The solid line shows the result of a fit where an exponential is added to the T_{AA}-scaled $p+p$ fit [3].

be interpreted as its temperature. For a more realistic temperature estimate, the data is compared to hydrodynamical models. Models that fit the data assume initial temperatures, T_i, between 300 and 600 MeV at formation times, τ_0, between 0.6 and 0.15 fm/c, where the temperature and the formation time are anti-correlated. The $221 \pm 23(\text{stat.}) \pm 18(\text{sys.})$MeV obtained from the data alone serves as a lower limit. Even the lower limit, though, lies above the critical temperature predicted by lattice calculations.

6. Conclusion

An excess of low-mass e^+–e^- pairs above the hadronic background was observed at intermediate p_T (1 GeV $< p_T <$ 5 GeV) for both $p+p$ and Au+Au collisions. The

excess can be understood as the internal conversion of direct photons and shows the expected $1/m$ dependence. In $p+p$, the direct photon yield is consistent with the result of a pQCD calculation. In Au+Au, the yield is much larger. It is enhanced above the binary-scaled $p+p$ yield, represented by a modified power law fit to the $p+p$ data and scaled by T_{AA}. The Au+Au yield can be well described if an exponential is added to the binary-scaled $p+p$ fit. The negative inverse slope of the exponential is 221 $\pm$ 23 (stat.) $\pm$ 18 (sys.) MeV in central Au+Au. For a static medium, this could be interpreted as the temperature. For an expanding medium, it serves as a lower limit of the temperature. It is well above the critical temperature of about 170 MeV. Hydrodynamical models that fit the data assume initial temperatures, T_i, between 300 and 600 MeV at formation times, τ_0, between 0.15 and 0.6 fm/c. Together with the earlier WA98 measurement [13], this result can be interpreted as the first experimental evidence that strongly interacting matter can exceed the Hagedorn temperature of 170 MeV [14].

(Received 9 May 2009; published 31 August 2009)

We present inclusive charged hadron elliptic flow (v_2) measured over the pseudorapidity range $|\eta| < 0.35$ in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Results for v_2 are presented over a broad range of transverse momentum ($p_T = 0.2$–8.0 GeV/c) and centrality (0–60%). To study nonflow effects that are correlations other than collective flow, as well as the fluctuations of v_2, we compare two different analysis methods: (1) the event-plane method from two independent subdetectors at forward ($|\eta| = 3.1$–3.9) and beam ($|\eta| > 6.5$) pseudorapidities and (2) the two-particle cumulant method extracted using correlations between particles detected at midrapidity. The two event-plane results are consistent within systematic uncertainties over the measured p_T and in centrality 0–40%. There is at most a 20% difference in the v_2 between the two event-plane methods in peripheral (40–60%) collisions. The comparisons between the two-particle cumulant results and the standard event-plane measurements are discussed.

I. INTRODUCTION

Collisions of Au + Au nuclei at the BNL Relativistic Heavy Ion Collider (RHIC) produce matter at very high energy density [1–4]. The dynamical evolution of this hot and dense

*Deceased.
†PHENIX spokesperson: jacak@skipper.physics.sunysb.edu

medium reflects its state and the degrees of freedom that govern the different stages it undergoes [5–7]. Azimuthal anisotropy measurements serve as a probe of the degree of thermalization, transport coefficients, and the equation of state (EOS) [8–10] of the produced medium.

Azimuthal correlations in Au + Au collisions at RHIC have been shown to consist of a mixture of jet and harmonic contributions [11–14]. Jet contributions are found to be relatively small for $p_T \lesssim 2.0$ GeV/c, with away-side jet yields strongly suppressed [13]. Significant modifications to the away-side jet topology have also been reported [15–17]. The harmonic contributions are typically characterized by the Fourier coefficients,

$$v_n = \langle \cos(n[\phi - \Psi_{\mathrm{RP}}]) \rangle \quad (n = 1, 2, \ldots), \tag{1}$$

where ϕ represents the azimuthal emission angle of a charged hadron and Ψ_{RP} is the azimuth of the reaction plane defined as containing both the direction of the impact parameter vector and the beam axis. The brackets denote statistical averaging over particles and events. The first two harmonics v_1 and v_2 are referred to as directed and elliptic flow, respectively.

It has been found that at low p_T ($p_T \lesssim 2.0$ GeV/c), the magnitude and trends of v_2 are underpredicted by hadronic cascade models supplemented with string dynamics [18], but they are well reproduced by models that either incorporate hydrodynamic flow [7,9] with a first-order phase transition and rapid thermalization, $\tau \sim 1$ fm/c [19], or use a quasiparticle ansatz but include more than just 2-to-2 interactions [20].

The mass dependence of v_2 as a function of p_T has been studied using identified baryons and mesons [19,21] and empirical scaling of elliptic flow per constituent quark was observed when the signal and the p_T of the hadron were divided by the number of constituent quarks n_q ($n_q = 2$ for mesons, 3 for baryons). This scaling is most clearly observed by plotting the data as a function of transverse kinetic energy $\mathrm{KE}_T \equiv m_T - m = \sqrt{p_T^2 + m^2} - m$ [22], where m_T and m denote the transverse mass and mass of the particle, respectively. A recent study [23] finds that the constituent quark scaling holds up to $\mathrm{KE}_T \approx 1$ GeV. This indicates partonic, rather than hadronic, flow and suggests that the bulk matter collectivity develops before hadronization takes place [24–26]. Results for the v_2 of the ϕ meson further validate the observation of partonic collectivity. The ϕ is not expected to be affected by hadronic interactions in the late stages of the medium evolution because of to its small interaction cross section with nonstrange hadrons [27].

All of the v_2 measurements referenced above were performed using the event-plane method [28]. In PHENIX studies, the event plane was determined at forward and backward pseudorapidities ($|\eta| = 3.1$–3.9) with the assumption that correlations induced by elliptic flow dominate over all other nonflow correlations [19]. Nonflow correlations are those that are not correlated with the reaction plane. Common sources of nonflow correlations include jets, the near-side ridge, quantum correlations, and resonance decays. Simulation studies [19,29] have shown that the correlations from jets and dijets become negligible when the rapidity separation between the particles and the event plane is greater than three units. Thus we expect that the event plane at forward pseudorapidities $|\eta| = 3.1$–3.9 in the PHENIX experiment would not have significant jet-correlation with particles measured within the PHENIX central arm spectrometer covering the pseudorapidity window $|\eta| < 0.35$. STAR and PHOBOS Collaborations have observed that in central Au + Au collisions, there is a ridge of particles [30,31] that are correlated in azimuthal angle with a high-p_T particle and that this ridge extends to $|\eta| < 4$ (for midrapidity triggers). The ridge could produce a nonflow correlation on which we can provide information by using our v_2 measurements, which are made with different techniques and at different rapidities.

Event-by-event flow fluctuations can also affect the magnitude of the extracted flow signal [32]. This occurs because the event plane at forward pseudorapidities is reconstructed using particles from participant nucleons whose positions fluctuate event-by-event. Assuming that v_2 fluctuates according to a Gaussian distribution, the v_2 fluctuation is proportional to the fluctuation of the initial geometry. This effect scales as $1/N_{\mathrm{part}}$, where N_{part} denotes the number of participant nucleons. The difference between v_2 values obtained from different methods can be quantitatively understood in terms of nonflow and fluctuation effects [33,34].

Hence in this paper we will compare the v_2 results from the event plane determined at two different pseudorapidities with the goal of investigating the sensitivity of v_2 to nonflow and fluctuation effects. Additionally, we will extract the elliptic flow with the two-particle cumulant method, which is expected to have higher sensitivity to nonflow contributions to v_2.

In this paper, we describe the PHENIX measurements of elliptic flow (v_2) at midrapidity ($|\eta| < 0.35$) in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV obtained from a cumulant analysis of two-particle azimuthal correlations and the event-plane method over a broad range of p_T ($p_T = 0.2$–8 GeV/c) and centrality (0–60%). Section II describes the PHENIX apparatus, with an emphasis on the detectors relevant to the presented results, as well as the track selections used in the analysis. Section III gives details of the event-plane and cumulant methods as applied in PHENIX, and Sec. IV discusses their systematic uncertainties. The results from the two methods are reported in Sec. V. Section VI presents a comparison of v_2 results across different experiments and a discussion. The v_2 values obtained from the different methods are tabulated in the Appendix.

II. EXPERIMENTAL ANALYSIS

A. The PHENIX detector

The PHENIX detector consists of two central spectrometer arms at midrapidity that are designated East and West for their location relative to the interaction region, and two muon spectrometers at forward rapidity, similarly called North and South. A detailed description of the PHENIX detector can be found in Ref. [35]. The layout of the PHENIX detector during data taking in 2004 is shown in Fig. 1. Each central spectrometer arm covers a pseudorapidity range of $|\eta| < 0.35$ subtending 90° in azimuth and is designed to detect electrons, photons, and charged hadrons. Charged particles are tracked

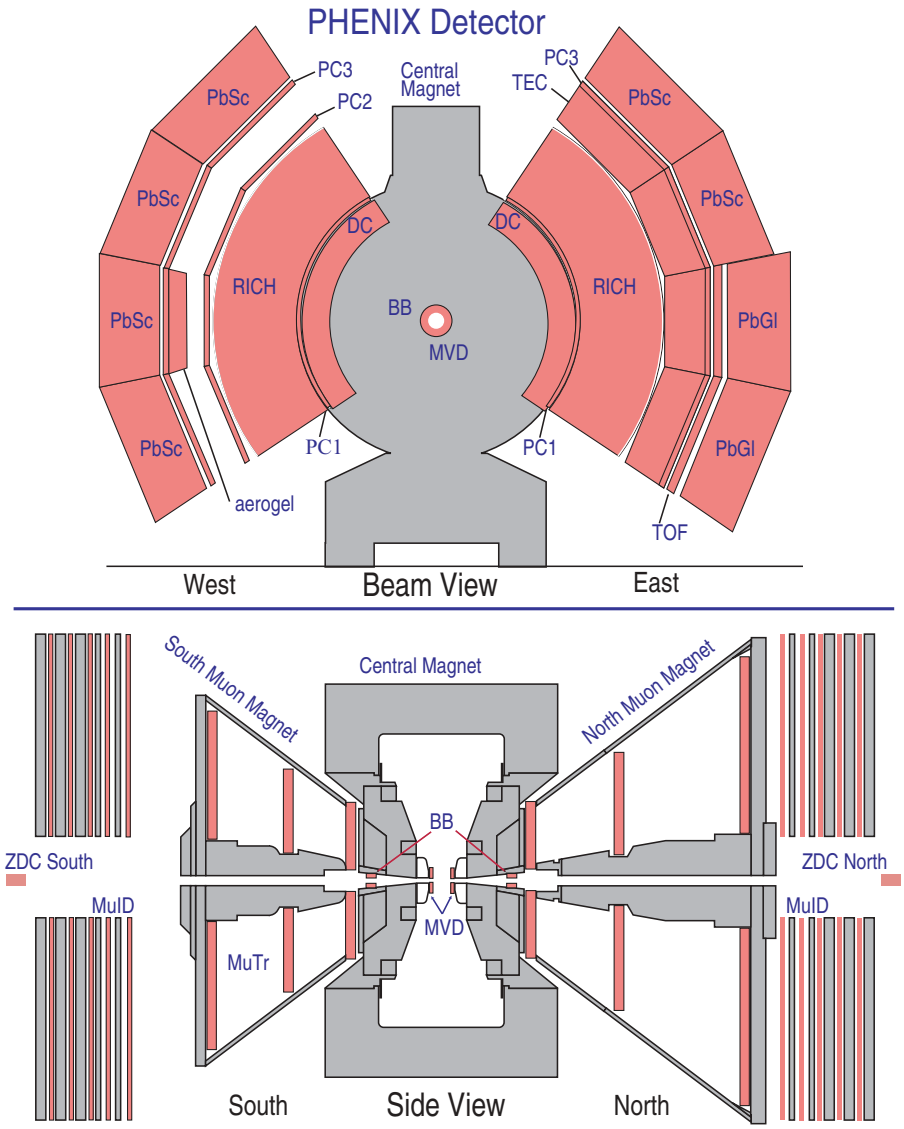

FIG. 1. (Color online) PHENIX experimental layout in 2004. Top: PHENIX central arm spectrometers viewed along the beam axis. Bottom: side view of the PHENIX muon arm spectrometers.

by drift chambers (DCs) positioned between 2.0 and 2.4 m radially outward from the beam axis and layers of multiwire proportional chambers with pad readout (two in the east arm and three in the west arm) PC1, PC2, and PC3 located at a radial distance of 2.4, 4.2, and 5 m, respectively. Particle identification is provided by ring imaging Čerenkov counters (RICHs), a time-of-flight scintillator wall (TOF), and two types of electromagnetic calorimeter (EMCAL), the lead scintillator (PbSc) and lead glass (PbGl).

The detectors used to characterize each event are the beam-beam counters (BBCs) [36] and the zero-degree calorimeters (ZDCs) [37]. These detectors are used to determine the time of the collision, the position of the collision vertex along the beam axis, and the collision centrality and also provide the event trigger. In this analysis the BBCs are also used to determine the event plane. Each BBC is composed of 64 elements, and a single BBC element consists of a 1 in. diameter mesh dynode photomultiplier tube (PMT) mounted on a 3 cm long quartz radiator. The BBCs are installed on the north and south sides of the collision point along the beam axis at a distance of 144 cm from the center of the interaction region and they surround the beam pipe. The BBC acceptance covers the pseudorapidity range $3.1 < |\eta| < 3.9$ and the full range of azimuthal angles.

The ZDCs are hadronic calorimeters located on both sides of the PHENIX detector. Each ZDC is mechanically subdivided into three identical modules of two interaction lengths. They cover a pseudorapidity range of $|\eta| > 6.5$ and measure the energy of the spectator neutrons with a 20 GeV energy resolution [37]. The shower maximum detectors (ZDC-SMDs) are scintillator strip hodoscopes between the first and second ZDC modules. This location approximately corresponds to the maximum of the hadronic shower. The horizontal coordinate is sampled by seven scintillator strips of 15 mm width, while the vertical coordinate is sampled by eight strips of 20 mm width. The active area of a ZDC-SMD is 105 mm $\times$ 110 mm (horizontal $\times$ vertical dimension). Scintillation light is delivered to a multichannel PMT M16 by wavelength-shifter fibers. The ZDC-SMD position resolution depends on the energy deposited in the scintillator. It varies from $<$3 mm, when the number of particles exceeds 100, to 10 mm for a smaller number of particles.

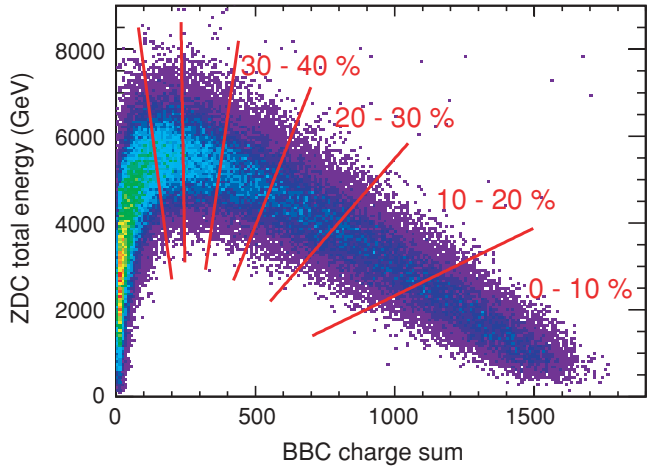

FIG. 2. (Color online) Correlation between ZDC energy and BBC charge sum for Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Solid lines represent the corresponding centrality boundaries up to 60% centrality bin.

B. Event selection

For the analyses presented here, we used approximately 850×10^6 minimum-bias triggered events. The minimum-bias trigger was defined by a coincidence between North and South BBC signals and an energy threshold of one neutron in the ZDCs. The events are selected offline to be within a z vertex of less than 30 cm from the nominal center of the PHENIX spectrometer. This selection corresponds to $92.2^{+2.5}_{-3.0}\%$ of the 6.9 b Au + Au inelastic cross section at $\sqrt{s_{NN}} = 200$ GeV [38]. The event centrality was determined by correlating the charge detected in the BBCs with the energy measured in the ZDCs, as shown in Fig. 2.

A Glauber model Monte Carlo simulation [39–41] that includes the responses of BBC and ZDC gives an estimate of the average number of participating nucleons $\langle N_{\rm part}\rangle$ for each centrality class. The simulation does not include fluctuations in the positions of the nucleons which give rise to eccentricity fluctuations. Table I lists the calculated values of $\langle N_{\rm part}\rangle$ for each centrality class.

TABLE I. Centrality classes and average number of participant nucleons $\langle N_{\rm part}\rangle$ obtained from a Glauber Monte Carlo simulation of the BBC and ZDC responses for Au + Au collision at $\sqrt{s_{NN}} = 200$ GeV. Each centrality class is expressed as a percentage of $\sigma_{\rm AuAu} = 6.9$ b inelastic cross section. Errors denote systematic uncertainties from the Glauber MC simulation.

Centrality	$\langle N_{\rm part}\rangle$
0–10%	325.2 ± 3.3
10–20%	234.6 ± 4.7
20–30%	166.6 ± 5.4
30–40%	114.2 ± 4.4
40–50%	74.4 ± 3.8
50–60%	45.5 ± 3.3

C. Track selection

Charged particle tracks are measured using information from the DC, the PC1 and PC3 detectors, and the z vertex from the BBC. The DC has 12 wire planes, which are spaced at 0.6 cm intervals along the radial direction from the beam axis. Each wire provides a track position measurement, with better than 150 μm spatial resolution in the azimuthal (ϕ) direction. The PC1 provides a space point in the ϕ and beam directions, albeit with lower resolution. This space point and the vertex position help determine the three-dimensional momentum vector by providing the polar angle for charged tracks at the exit of the DC. Trajectories are confirmed by requiring matching hits at PC3 to reduce secondary background. Tracks are then projected back to the collision vertex through the magnetic field to determine the momentum $\vec{p}$ [42]. The momentum resolution is $\delta p/p \simeq 0.7\% \oplus 1.0\% \times p$ (GeV/c). The momentum scale is known to 0.7%, as determined from the reconstructed proton mass using the TOF detector. Further details on track reconstruction and momentum determination can be found in Refs. [41,42].

The tracks reconstructed by the DC that do not originate from the event vertex have been investigated as potential background to the charged particle measurement. The main background sources include secondary particles from decays and e^+e^- pairs from the conversion of photons in the material between the vertex and the DC [41]. Tracks are required to have a hit in the PC3, as well as in the EMCAL, within at most 2σ of the expected hit location in both the azimuthal and beam directions. This cut reduces the background not originating in the direction of the vertex. To reduce the conversion background, we further require tracks to have $E/p_T > 0.2$, where E denotes the energy deposited in the EMCAL and p_T is the transverse momentum of particles measured in the DC. Since most of the electrons from photon conversion are genuine low p_T particles that were reconstructed as high p_T particles, requiring a large deposit of energy in the EMCAL suppresses the electron background [43]. We also require that there are no associated hits in the RICH. The RICH is filled with CO_2 gas at atmospheric pressure and has a charged particle threshold $\gamma_{\rm th} = 35$ to emit Čerenkov photons.

III. METHODS OF AZIMUTHAL ANISOTROPY MEASUREMENT

In this section, we introduce the methods for azimuthal anisotropy measurements as used in the PHENIX experiment. Section III A describes the event-plane method using the BBCs and ZDC-SMDs detectors, and Sec. III B describes the two-particle cumulant method.

A. Event-plane method

The event-plane method [28] uses the azimuthal anisotropy signal to estimate the angle of the reaction plane. The estimated reaction plane is called the "event plane" and is determined for each harmonic of the Fourier expansion of the azimuthal distribution. The event flow vector $\vec{Q}_n = (Q_x, Q_y)$ and azimuth of the event plane Ψ_n for the nth harmonic of the

azimuthal anisotropy can be expressed as

$$Q_x \equiv |\vec{Q}_n| \cos(n\Psi_n) = \sum_i^M w_i \cos(n\phi_i), \tag{2}$$

$$Q_y \equiv |\vec{Q}_n| \sin(n\Psi_n) = \sum_i^M w_i \sin(n\phi_i), \tag{3}$$

$$\Psi_n = \frac{1}{n}\tan^{-1}\left(\frac{Q_y}{Q_x}\right), \tag{4}$$

where M denotes the number of particles used to determine the event plane, ϕ_i is the azimuthal angle of each particle, and w_i is the weight chosen to optimize the event-plane resolution. Once the event plane is determined, the elliptic flow v_2 can be extracted by correlating the azimuthal angle of emitted particles ϕ with the event plane, i.e.,

$$v_2 = \frac{v_2^{\rm obs}}{{\rm Res}\{\Psi_n\}} = \frac{\langle\cos(2[\phi - \Psi_n])\rangle}{\langle\cos(2[\Psi_n - \Psi_{\rm RP}])\rangle}, \tag{5}$$

where ϕ is the azimuthal angle of tracks in the laboratory frame, Ψ_n is the nth-order event plane, and the brackets denote an average over all charged tracks and events. The denominator Res $\{\Psi_n\}$ is the event-plane resolution that corrects for the difference between the estimated event plane Ψ_n and true reaction plane $\Psi_{\rm RP}$.

In this paper, the second-harmonic event planes were independently determined with two BBCs located at the forward (BBC South, referred to as BBCS) and backward (BBC North, referred to as BBCN) pseudorapidities $|\eta| =$ 3.1–3.9 [19]. The difference between the two independent event planes was used to estimate the event-plane resolution. The planes were also combined to determine the event plane for the full event. A large pseudorapidity gap between the charged particles detected in the central arms and the event plane at the BBCs reduces the effect of possible nonflow contributions, especially those from dijets [29]. The measured v_2 of hadrons in the central arms with respect to the combined second-harmonic BBC event plane will be denoted throughout this paper as $v_2\{\text{BBC}\}$.

Two first-harmonic event planes were also determined using spectator neutrons at the two shower maximum detectors (ZDC-SMDs) that are sandwiched between the first and second modules of the ZDCs. Forward (ZDCS) and backward (ZDCN) SMDs which cover pseudorapidity $|\eta| > 6.5$ were used. The measured v_2 of hadrons in the central arms determined with respect to the first-harmonic ZDC-SMD event plane is denoted as $v_2\{\text{ZDC-SMD}\}$.

The pseudorapidity gap between the hadrons measured in the central arms and the ZDC-SMDs is larger than that for the BBCs, which could cause a further reduction of nonflow contributions on $v_2\{\text{ZDC-SMD}\}$. Since the ZDC-SMD measures spectator neutrons, the ZDC-SMD event plane should be insensitive to fluctuations in the participant event plane. Hence fluctuations in $v_2\{\text{ZDC-SMD}\}$ should be suppressed up to fluctuations in the spectator positions.

For completeness, two further event planes are defined: (1) a combined event plane defined by the weighted average of event planes at the forward and backward pseudorapidities for both BBCs and ZDC-SMDs, and (2) an event plane found using tracks in the central arm. The event plane at the central arms (CNT) is only used to estimate the resolution of BBC and ZDC-SMD event planes by using a three-subevent combination of the ZDC-SMD, BBC, and CNT.

1. Event-plane determination

To determine an event plane, the contribution at each azimuthal angle needs to be appropriately weighted depending on the detector used. For the BBC, we chose the weights to be the number of particles detected in each phototube, while for the ZDC-SMD, the weights were based on the energy deposited in each of the SMD strips. For the CNT event plane, the weight was taken to be proportional to p_T up to 2 GeV/c and constant for $p_T > 2$ GeV/c. For the CNT event plane, we also adopted a unit weight ($w_i = 1$) and found that the resulting CNT event-plane resolution extracted by comparing the CNT event plane with the BBC and ZDC-SMD planes was nearly identical when using the p_T-dependent or unit weights.

Corrections were performed to remove possible biases from the finite acceptance of the BBC and ZDC-SMD. In this analysis, we applied two corrections called the recentering and shift methods [28]. In the recentering method, event flow vectors are shifted and normalized by using the mean $\langle Q\rangle$ and width σ of flow vectors, i.e.,

$$Q_x' = \frac{Q_x - \langle Q_x\rangle}{\sigma_x}, \quad Q_y' = \frac{Q_y - \langle Q_y\rangle}{\sigma_y}. \tag{6}$$

This correction reduces the dependence of the event-plane resolution on the laboratory angle. Most acceptance effects were removed by the application of the recentering method. However, remaining small corrections were applied after recentering using the shift method [28], in which the reaction plane is shifted by $\Delta\Psi_n$ defined by

$$n\Delta\Psi_n(\Psi_n) = \sum_{k=1}^{k_{\rm max}} \frac{2}{k}[-\langle\sin(kn\Psi_n)\rangle\cos(kn\Psi_n) + \langle\cos(kn\Psi_n)\rangle\sin(kn\Psi_n)], \tag{7}$$

where $k_{\rm max} = 8$ in this analysis. The shift ensures that $dN/d\Psi_n$ is isotropic. When $k_{\rm max}$ was reduced to $k_{\rm max} = 4$, the difference in the extracted v_2 was negligible, and thus we include no systematic uncertainty due to the choice of $k_{\rm max}$ in our v_2 results.

Independent corrections were applied to each centrality selection in 5% increments and in 20 cm steps in the z vertex to optimize the event-plane resolution. The corrections were also done for each experimental run (the duration of a run is typically 1–3 h) to minimize the possible time-dependent response of detectors.

Figure 3 shows event-plane distributions for a subsample of the entire data set. After all corrections are applied, the event-plane distributions are isotropic.

2. Event-plane resolution

The event-plane resolution for v_2 was evaluated by both the two-subevent and three-subevent methods. In the two-subevent

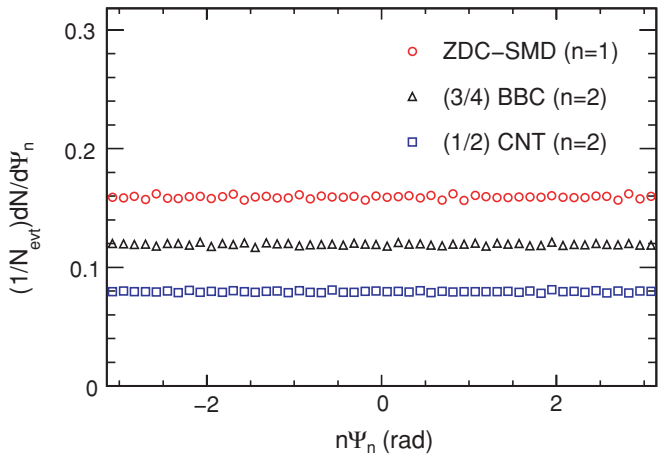

FIG. 3. (Color online) Event-plane distributions after applying all corrections for the ZDC-SMD, BBC, and CNT. The statistical error bars are smaller than the symbols. The distributions for the BBC and CNT event planes are scaled by 3/4 and 1/2 to improve visibility.

method, the event-plane resolution [28] is expressed as

$$\langle \cos\left(kn[\Psi_n - \Psi_{\mathrm{RP}}]\right)\rangle = \frac{\sqrt{\pi}}{2\sqrt{2}}\chi_n e^{-\chi_n^2/4}\left[I_{(k-1)/2}\left(\frac{\chi_n^2}{4}\right) + I_{(k+1)/2}\left(\frac{\chi_n^2}{4}\right)\right], \quad (8)$$

where $\chi_n = v_n\sqrt{2M}$, M is the number of particles used to determine the event plane Ψ_n, I_k is the modified Bessel function of the first kind, and $k = 1$ for the second-harmonic BBC event plane. For the ZDC-SMD event plane, the resolution is estimated with either $k = 1$ or 2 in Eq. (8). We will discuss the difference between these estimates in Sec. IV A.

To determine the event-plane resolution, we need to determine χ_n. Since the North and South BBCs have approximately the same η coverage, the event-plane resolution of each subdetector is expected to be the same. The same is true for the North and South ZDC-SMDs. Thus, the subevent resolution for South and North event planes can be expressed as

$$\left\langle \cos\left(2\left[\Psi_n^{\mathrm{S(N)}} - \Psi_{\mathrm{RP}}\right]\right)\right\rangle = \sqrt{\left\langle \cos\left(2\left[\Psi_n^{\mathrm{S}} - \Psi_n^{\mathrm{N}}\right]\right)\right\rangle}, \quad (9)$$

where $\Psi_n^{\mathrm{S(N)}}$ denotes the event plane determined by the South (North) BBC or ZDC-SMD. Once the subevent resolution is obtained from Eq. (9), one can calculate χ_n^{sub} using Eq. (8). The χ_n for the full event can then be estimated by $\chi_n = \sqrt{2}\chi_n^{\mathrm{sub}}$. This is then substituted into Eq. (8) to give the full-event resolution. Since the multiplicity of the full event is twice as large as that of the subevent, χ_n is proportional to $\sqrt{M}$.

In the three-subevent method, the resolution of each subevent is calculated by adding a reference event plane Ψ_n^{C} in Eq. (9):

$$\mathrm{Res}\{\Psi_l^{\mathrm{A}}\} = \sqrt{\left\langle \cos\left(2\left[\Psi_l^{\mathrm{A}} - \Psi_m^{\mathrm{B}}\right]\right)\right\rangle}\sqrt{\frac{\left\langle \cos\left(2\left[\Psi_n^{\mathrm{C}} - \Psi_l^{\mathrm{A}}\right]\right)\right\rangle}{\left\langle \cos\left(2\left[\Psi_m^{\mathrm{B}} - \Psi_n^{\mathrm{C}}\right]\right)\right\rangle}}, \quad (10)$$

where l, m, n are the harmonics of the event plane for subevents A, B, and C, respectively. The multiplicity of each subevent is not necessarily the same in Eq. (10).

The resolution of each subdetector for the BBC and ZDC-SMD can be evaluated with the three-subevent method. For the BBC event plane, the reference event plane is chosen to be the ZDC-SMD event plane and vice versa. We found that the agreement of the event-plane resolutions for BBCS and BBCN is much better than 1%, while the ZDCS and ZDCN resolutions agree within 2%.

Figure 4 shows the full-event resolution as a function of centrality. The resolution of ZDC-SMD is much smaller than that of BBC because the resolution of the first-harmonic event plane is proportional to $(\chi_1)^2$. The dashed lines are the resolutions obtained from the three-subevent method with the CNT event plane as the reference plane. For example, the BBC event-plane resolution is estimated by substituting $\Psi_l^{\mathrm{A}} \to \Psi_2^{\mathrm{BBC}}$, $\Psi_m^{\mathrm{B}} \to \Psi_2^{\mathrm{CNT}}$, and $\Psi_n^{\mathrm{C}} \to \Psi_1^{\mathrm{ZDC-SMD}}$ in Eq. (10). By including the CNT event plane, the BBC resolution increases by about 3% over that of the two-subevent method. For the ZDC-SMD, we observe the opposite effect, namely, the resolution decreases by about 8%. In Sec. VI, the resulting $v_2\{\mathrm{BBC}\}$ and $v_2\{\mathrm{ZDC\text{-}SMD}\}$, corrected by the resolution obtained using the ZDC-BBC-CNT combination, will be compared against those with the resolution determined from South-North subevents. Table II summarizes the event-plane resolutions.

3. *Correlation of event planes*

Figure 5 shows the correlation of two different event planes as a function of centrality. The first-harmonic event-plane correlation for South-North detector combinations is negative both for the ZDC-SMDs and the BBCs over all centrality bins, as shown in Fig. 5(a). This is because v_1 is an odd function of η. The magnitude of the ZDC-SMD correlation is about a factor of 2 larger than that of the BBCs for midcentral collisions. This indicates that the magnitude of v_1 and the subevent multiplicity

TABLE II. Event-plane resolutions for centrality 0–60% at $\sqrt{s_{NN}} = 200$ GeV. S-N denotes the resolutions estimated from South and North correlation of BBC and ZDC-SMD using Eqs. (8) and (9), and resolutions for ZDC-BBC-CNT are estimated from Eq. (10). The errors are statistical only.

Centrality	S-N	ZDC-BBC-CNT

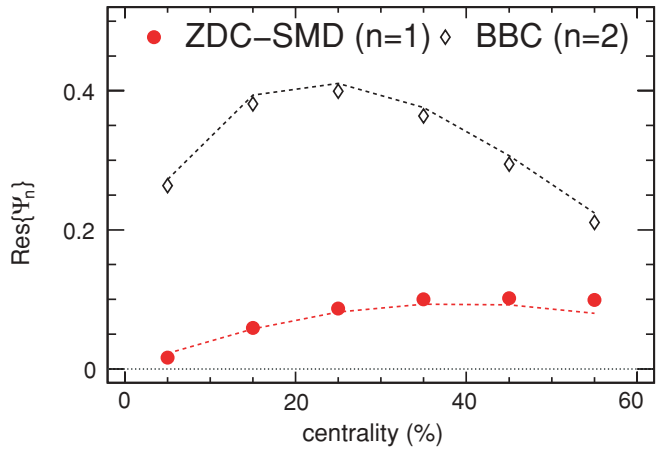

FIG. 4. (Color online) Full-event resolutions for the ZDC-SMD and BBC from the two-subevent method, Eq. (8), as a function of centrality in Au + Au at $\sqrt{s_{NN}} = 200$ GeV. The dashed lines represent resolutions from the three-subevent method with the CNT event plane as a reference. Statistical errors are smaller than the symbols.

at higher pseudorapidities are larger than those at the BBC location, since the magnitude of the correlation is proportional to $v_1^2 M$. Figure 5(b) shows the correlation of the first-harmonic event planes between BBC and ZDC-SMD. The same-side η correlation is negative, while the opposite-side η correlation is positive, which shows that the particles detected at the BBCs (dominantly charged pions emitted from participant nucleons) have the opposite sign of v_1 compared to the spectator neutrons detected at the ZDCs-SMDs.

The correlation of the mixed-harmonic event planes provides the sign of v_2, since the correlation is given by the expression [28]

$$\begin{aligned}\left\langle \cos\left(2\left[\Psi_1^{\mathrm{ZDC-SMD}} - \Psi_2^{\mathrm{BBC}}\right]\right)\right\rangle &\approx \frac{2}{\pi}\left(\mathrm{Res}\left\{\Psi_1^{\mathrm{ZDC-SMD}}\right\}\right)^2 \mathrm{Res}\left\{\Psi_2^{\mathrm{BBC}}\right\} \\ &= \pm 2\sqrt{2}\frac{2}{\pi}\left\langle \cos\left(\Psi_1^{\mathrm{ZDCS}} - \Psi_1^{\mathrm{ZDCN}}\right)\right\rangle \\ &\quad \times \sqrt{\left\langle \cos\left(2\left[\Psi_2^{\mathrm{BBCS}} - \Psi_2^{\mathrm{BBCN}}\right]\right)\right\rangle}. \end{aligned} \tag{11}$$

Three assumptions were made to obtain Eq. (11): (1) the BBC and ZDC-SMD are statistically independent, (2) the weak flow limit ($\chi_n \ll 1$) is applicable [28], and (3) the subevent multiplicity M is equal in the North-South direction for the same detector type. Thus the sign of the correlation of the mixed-harmonic event planes in Eq. (11) is determined by the term $\mathrm{Res}\{\Psi_2^{\mathrm{BBC}}\}$, which in turn determines the sign of v_2 measured at the BBC.

Figure 6 shows the mixed-harmonic correlation of the ZDC-SMD and BBC event planes as a function of centrality. The approximations in Eq. (11) provide a good description of the magnitude of the measured correlation as shown by the dashed line. The correlation is positive over all centrality bins. This result indicates that the sign of v_2 at the BBC is positive.

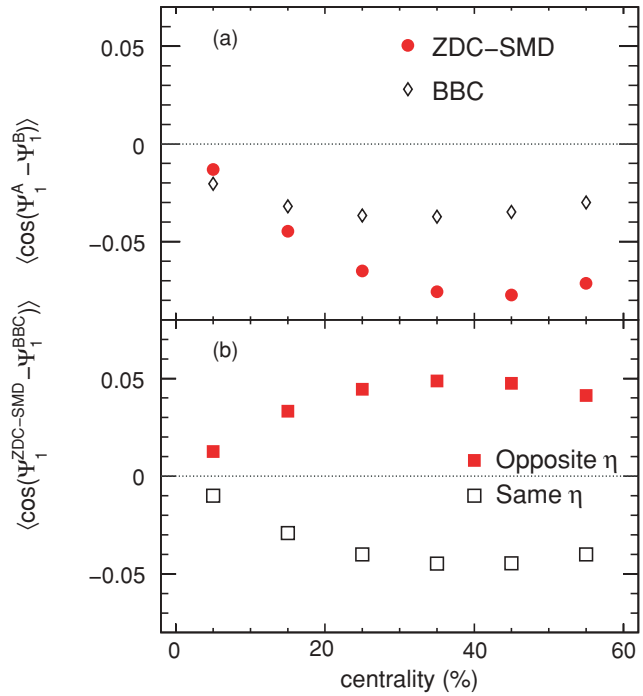

FIG. 5. (Color online) (a) Correlation of first-harmonic event planes between forward and backward ZDC-SMDs and BBCs as a function of centrality. (b) Correlation of first-harmonic event planes between ZDC-SMDs and BBCs as a function of centrality, for correlations of opposite- and same-side η subevents. Statistical errors are smaller than the symbols.

B. Cumulant method

In this section, we present the application of the cumulant method for azimuthal anisotropy measurements in PHENIX. This method uses cumulants of multiparticle correlations [44,45] to extract the azimuthal anisotropy. The cumulant method has been successfully applied in several heavy-ion experiments utilizing detectors with full azimuthal coverage (NA49, STAR) [46,47]. Here, we describe the first application

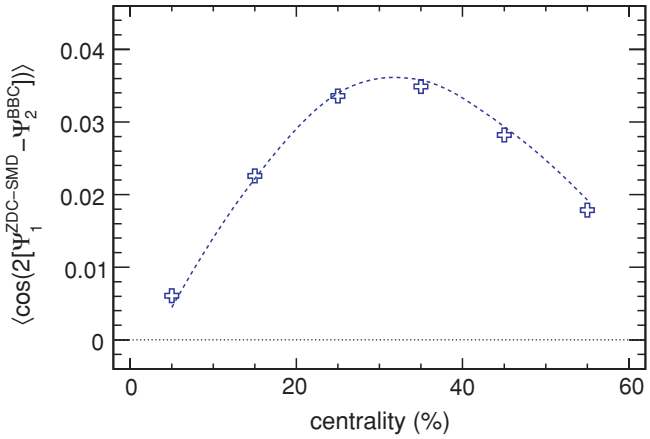

FIG. 6. (Color online) Correlation between the first-harmonic ZDC-SMD and the second-harmonic BBC event planes as a function of centrality. The dashed line shows the result obtained using Eq. (11). Statistical errors are smaller than the data symbols.

of the method for a detector with only partial azimuthal coverage. The cumulant method does not require the measurement of the reaction plane, instead the cumulants of multiparticle azimuthal correlations are related to the flow harmonics v_n, where n is the harmonic being evaluated. The cumulants can be constructed in increasing order according to the number of particles that are correlated with each other. Since PHENIX has partial azimuthal coverage, reliable extraction of azimuthal anisotropy requires the choice of a fixed number of particles from each event to avoid additional numerical errors [44].

Particles in an event are selected over a fixed (p_T,η) range where there is sufficient multiplicity. From this set, particles (called integral particles hereafter) are selected to determine the integrated flow, which is flow measured over a large (p_T,η) bin. This is done by excluding particles within small (p_T,η) bins from all available particles to avoid autocorrelations. The particles within a small (p_T,η) window (called differential particles hereafter) are used to determine the differential flow. For each event, a fixed number M of particles, chosen at random among the integral particles in the event, are used to reconstruct the integrated flow through the generating function $G_2(z)$ defined by

$$G_2(z) = \prod_{j=1}^{M}\left[1 + \frac{w_j}{M}(z^* e^{2i\phi_j} + z e^{-2i\phi_j})\right], \tag{12}$$

where w_j is the weight, chosen to be equal to 1 in our analysis, ϕ_j is the azimuth of the detected particles, and M is the multiplicity chosen for the integrated flow reconstruction. $G_2(z)$ is a real-valued function of the complex variable z. The average of $G_2(z)$ over events is then expanded in a power series to generate multiparticle azimuthal correlations. The generating function of the cumulants, defined by

$$\mathcal{C}_2(z) \equiv M(\langle G_2(z)\rangle^{1/M} - 1), \tag{13}$$

generates cumulants of azimuthal correlations to all orders, the lowest being the second order, as detailed in Sec. II B of Ref. [44]. The formulas used to compute the cumulants from which the v_2 is computed are given in Appendix B of Ref. [44]. In the case of a perfect acceptance, the relations between the anisotropy parameter v_2 and the lowest order cumulants are

$$v_2\{2\}^2 = c_2\{2\}, \tag{14}$$

$$v_2\{4\}^4 = -c_2\{4\}, \tag{15}$$

for the integrated anisotropy. Here $v_2\{2\}$ and $v_2\{4\}$ are the second- and fourth-order v_2, respectively; whereas, $c_2\{2\}$ and $c_2\{4\}$ are the second- and fourth-order cumulants. Because the typical multiplicity of charged hadrons in PHENIX, which is $\approx$40 for midcentral collisions, did not allow a reliable calculation of $v_2\{4\}$, we report here only the $v_2\{2\}$ results.

The remaining differential particles in the same event are selected in different (p_T,η) bins, and the differential cumulants are calculated from the generating function

$$\mathcal{D}_{2/2}(z) \equiv \frac{\langle e^{2i\psi} G_2(z)\rangle}{\langle G_2(z)\rangle}, \tag{16}$$

where $\langle G(z)\rangle$ denotes an average over all events, and ψ is the azimuth of each differential particle. $D_{2/2}$ denotes the second-order differential cumulant computed with respect to the second-order integral cumulant.

The differential $v_{2/2}\{2\}(p_T,\eta)$, the second-order differential v_2 with respect to the second-order integrated v_2, is calculated from the relation

$$v_{2/2}\{2\}(p_T,\eta) = \frac{d_{2/2}\{2\}(p_T,\eta)}{v_2\{2\}}, \tag{17}$$

where $d_{2/2}\{2\}(p_T,\eta)$ is the second-order differential cumulant. These relations have to be modified through acceptance corrections, which are detailed below.

1. Acceptance/efficiency corrections

The central arms detectors in PHENIX have only partial azimuthal coverage, and the implementation of the cumulant method requires an additional acceptance correction. To correct for the influence of the detector acceptance on the raw anisotropy values, we apply a correction factor using the prescription described in Ref. [44]. The acceptance and efficiency of the detector is characterized by a function $A(\phi,p_T,\eta)$, which is expressed in terms of the Fourier series as

$$A(\phi,p_T,\eta) = \sum_{p=-\infty}^{+\infty} a_p(p_T,\eta)e^{ip\phi}. \tag{18}$$

The Fourier coefficients $a_p(p_T,\eta)$ for the detector acceptance were extracted from the fit of the respective azimuthal distributions of integral and differential particles. The coefficients resulting from such fits were then used to calculate the correction factor for the raw values of the v_2 following the procedure detailed in Appendix C of Ref. [44].

Figure 7 shows a typical azimuthal angular distribution of differential particles detected in the PHENIX central arms and the corresponding Fourier fit used to correct for acceptance inhomogeneities. The Fourier fit reproduces well the overall features of the acceptance profile. This produces typical correction factors, which are in the range 1.1–1.2 for the differential flow and depend very little on centrality and p_T, as shown in Fig. 8.

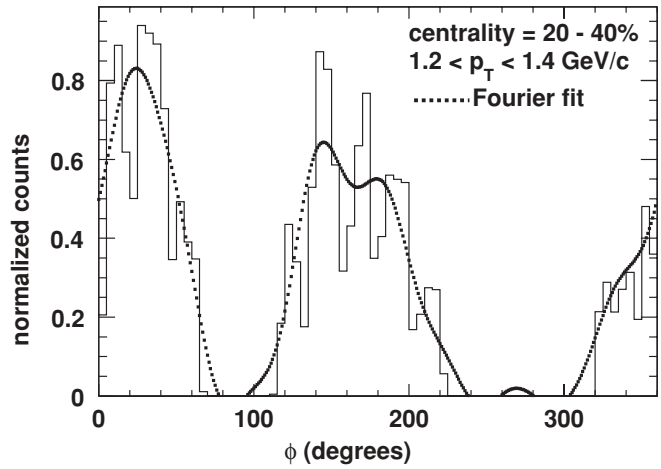

FIG. 7. Azimuthal angular distribution and corresponding Fourier fit for centrality 20–40% and p_T = 1.2–1.4 GeV/c.

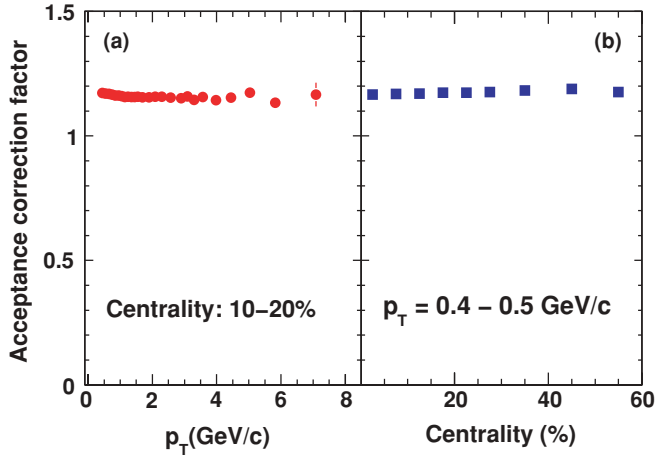

FIG. 8. (Color online) Acceptance correction factor for differential $v_2\{2\}$ as a function of (a) p_T for centrality 10–20% and (b) centrality for p_T range 0.4–0.5 GeV/c in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV.

2. *Simulations*

While Fig. 7 shows that the uneven detector acceptance is reproduced by the Fourier fit, a better test of the cumulant method is to use Monte Carlo simulations, as in Ref. [44]. For these tests, events were generated with particles having a distribution of the form $1 + 2v_1 \cos\phi + 2v_2 \cos 2\phi$, with known integrated and differential azimuthal anisotropies. The anisotropy was introduced into the events by way of a Fourier weighted selection of the azimuthal angles followed by a random event rotation designed to simulate the random orientation of the reaction plane. The multiplicity of these events was chosen to reflect the typical multiplicity measured with the PHENIX detector, and the ϕ angles were chosen from a filter that is representative of the PHENIX acceptance. We extracted Fourier components from these simulated results and applied these to extract corrected elliptic flow values.

Figure 9 shows selected results from these simulations. Corrected differential anisotropy values are compared for various input differential v_2 values, with the integrated v_2 kept fixed. The dotted line shows the trend expected if the extracted v_2 is identical to the input value used to generate the events. The good agreement between the input and extracted v_2 attests to the reliability of the analysis method within the acceptance of the PHENIX central arms.

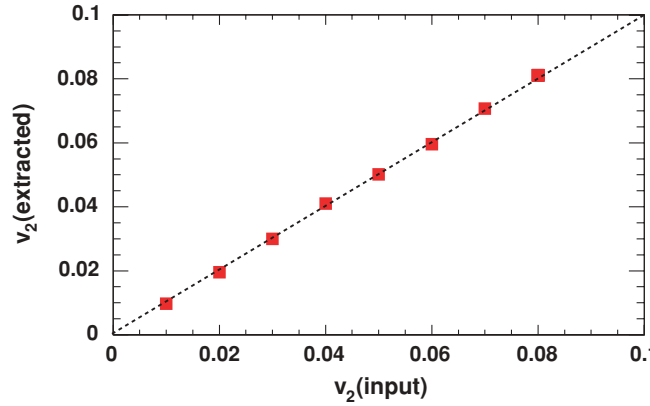

FIG. 9. (Color online) Comparison of input and extracted differential v_2 values for a fixed integrated v_2 of 8%. The dotted line indicates the expectation if input and reconstructed values are the same.

IV. SYSTEMATIC UNCERTAINTIES

In this section, we present the systematic uncertainties on the v_2 from the event-plane method (Sec. IV A) and the two-particle cumulant method (Sec. IV B). Table III lists the different sources of systematic errors for each method. The errors in Table III are categorized by type:

(i) point-to-point error uncorrelated between p_T bins,
(ii) p_T correlated, all points move in the same direction but not by the same factor,
(iii) an overall normalization error in which all points move by the same factor independent of p_T.

TABLE III. Systematic uncertainties given in percent on the $v_2\{\text{ZDC-SMD}\}$, $v_2\{\text{BBC}\}$, and $v_2\{2\}$ measurements. The ranges correspond to different systematic errors for different centrality bins.

Error source	Percentage error		Type
	$v_2\{\text{BBC}\}$	$v_2\{\text{ZDC-SMD}\}$	
Background contribution	<5% in $p_T < 4$ GeV/c		B
	5–30% in $p_T > 4$ GeV/c		B
Event-plane calibration	1–5%		C
Event-plane determination	1–4%	1–16%	C
Acceptance effect on event planes	1%	1–25%	C
	$v_2\{2\}$		
Fixed multiplicity	5%		B
Integrated p_T range	3–8%		B
Background correction	6–10%		B

A. Event-plane method

1. Background contributions

To study the influence of background on our results, we varied one of the track selections while keeping other cuts fixed and investigated the effect on v_2 in the following two cases: (i) the PC3 and EMCAL matching cuts, $\pm 1.5\sigma$ and $\pm 2.5\sigma$ matching cuts, and (ii) $E > 0.15 p_T$ and $E > 0.25 p_T$. For both conditions, we found that the difference of the v_2 is 1–2% for $p_T < 4$ GeV/c, and 5–20% for $p_T > 4$ GeV/c depending on p_T and centrality.

The effect of the RICH veto cut has also been studied. Since the contribution of charged π increases without the RICH veto cut, the p/π ratio decreases at high p_T. Thus, the v_2 for charged hadrons could be modified due to the difference of v_2 between protons and π in the range $4 < p_T < 8$ GeV/c. We found that v_2 is 10–20% different without the RICH veto cut for $p_T > 4$–5 GeV/c, where the charged π starts firing the RICH.

One of the remaining sources of background contribution comes from the random tracks that are accidentally associated with the tracks in PC3. These random tracks have been estimated by swapping the z coordinate of the PC3 hits and then by associating those hits with the real tracks. Figure 10 shows the comparison of the radial PC3 matching distribution between the real and random tracks for $6 < p_T < 8$ GeV/c. The signal-to-background ratio S/B is evaluated in the $\sigma_{\mathrm{PC3}} < 2$ window and is ~52 for $6 < p_T < 8$ GeV/c in centrality 0–60%.

The ratio of real and random tracks with and without the $E/p_T > 0.2$ cut is shown as a function of p_T for centrality 0–60% in Fig. 11. The $E/p_T > 0.2$ cut reduces the random tracks and improves the S/B ratio by a factor of ≈10–24 for $p_T > 4$ GeV/c. Since random tracks are not expected to be correlated with the event plane, we assume that their $v_2 = 0$ and evaluate the systematic uncertainty on v_2 to be less than 2% for $p_T > 4$ GeV/c, increasing to 5% for $p_T < 0.5$ GeV/c.

There is a finite residual background contribution even after the $E/p_T > 0.2$ has been applied, as observed in Fig. 10. The residual backgrounds have been estimated by fitting the σ_{PC3}

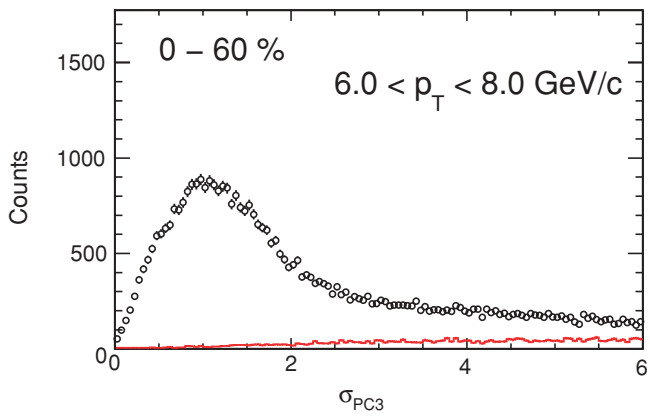

FIG. 10. (Color online) Radial PC3 matching distribution for real (open circles) and random (solid lines) tracks for $6 < p_T < 8$ GeV/c in centrality 0–60%.

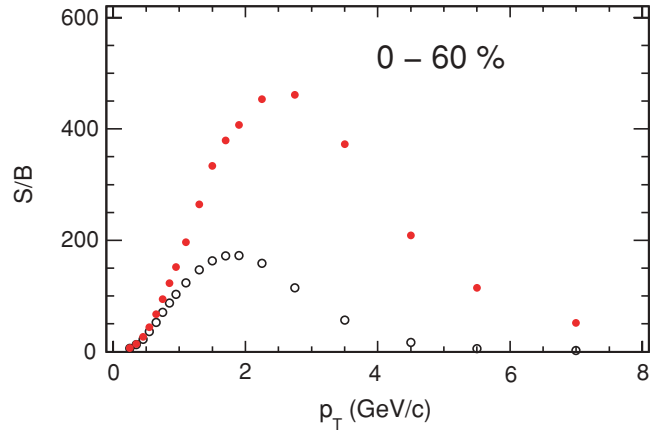

FIG. 11. (Color online) Ratio of real S to random B tracks as a function of p_T in centrality 0–60%. Solid and open circles show the S/B ratio with and without $E/p_T > 0.2$, respectively.

with a double Gaussian while requiring that the signal and residual background σ_{PC3} distribution have the same mean. For the highest p_T bin, we found that the signal-to-background ratio is ~5 for $\sigma_{\mathrm{PC3}} < 2$. The systematic error on v_2 is evaluated by comparing the measured v_2 with that of the signal

$$v_2^S = \left(1 + \frac{B}{S}\right) v_2 - \frac{B}{S} v_2^B, \tag{19}$$

where v_2^S, v_2^B and v_2 are, respectively, v_2 of signal, background estimated for $\sigma_{\mathrm{PC3}} > 3$, and measured within the 2σ matching window. The systematic uncertainties are less than 5% for $p_T < 4$ GeV/c, and ~5–10% for higher p_T. All the above systematic errors are added in quadrature, and the overall systematic error from the background contribution is estimated to vary from <5% for $p_T < 4$ GeV/c to ~30% for higher p_T.

2. Event-plane calibrations

The procedures used in the determination and calibration of event planes are the dominant sources of systematic errors on v_2 and are discussed in the following sections.

Different calibration procedures of the BBC event plane were extensively studied for previous Au + Au data sets [19]. We followed the same procedure to study the systematic errors on the BBC and ZDC-SMD event planes. Systematic uncertainties from the shift methods on $v_2\{\mathrm{BBC}\}$ are ~1–5% depending on the centrality. The systematic errors on the $v_2\{\mathrm{ZDC\text{-}SMD}\}$ are 1–2% larger than those on $v_2\{\mathrm{BBC}\}$ for centrality 10–30% and 50–60%, although those are still less than 5%.

3. Event-plane determination

Figure 12 shows the comparison of $\langle v_2 \rangle$ for different subdetectors with respect to the BBC and ZDC-SMD event planes as a function of centrality. Systematic errors are estimated by taking the maximum difference of the v_2 from the South and North event planes to that from the combined

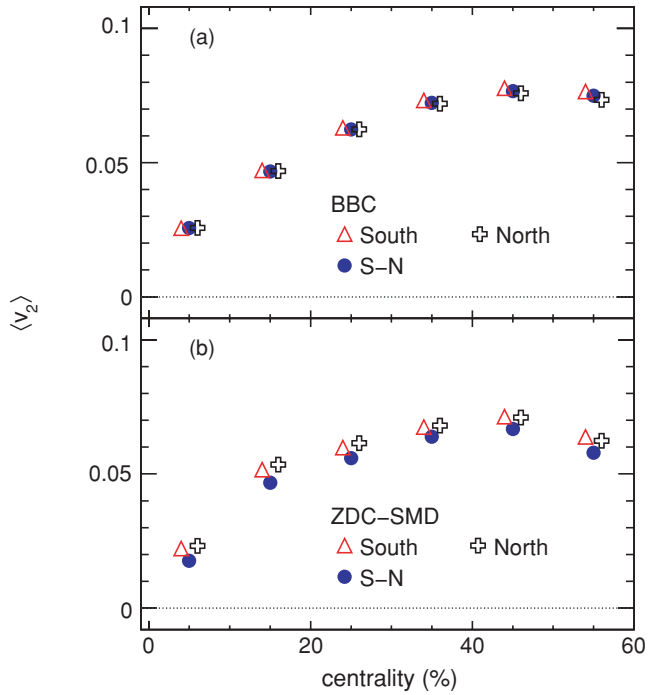

FIG. 12. (Color online) Comparison of $\langle v_2 \rangle$ averaged over $0.2 < p_T < 8$ GeV/c as a function of centrality for the (a) BBC and (b) ZDC-SMD event planes from South and North subdetectors and from combined South-North (S-N) event planes. Results from South and North event planes are shifted in the x direction to improve visibility. Only statistical errors are shown and they are smaller than the symbols.

South-North event plane scaled by $2/\sqrt{12}$ for each centrality. Systematic errors range from 1–4% for the BBC, and 1–16% for the ZDC-SMD event planes depending on the centrality bins.

4. Effect of nonuniform acceptance on v_2

In this subsection, we discuss the effect of nonuniform acceptance on the measured v_2. In practice, the imperfect azimuthal acceptance of the BBC or ZDC-SMD or the central arms could induce an azimuthal-dependent event-plane resolution and/or smear the magnitude of v_2. To study the possible effect of nonuniform acceptance, the measured v_2 is decomposed into X and Y components [48]:

$$v_2^{\mathrm{X}} = \frac{\sqrt{2}}{a_4^+} \frac{\langle \cos(2\phi) \cos\left(2\Psi_n^{\mathrm{A}}\right) \rangle}{\mathrm{Res}\left\{\Psi_n^{\mathrm{A}}; \mathrm{X}\right\}},$$
$$v_2^{\mathrm{Y}} = \frac{\sqrt{2}}{a_4^-} \frac{\langle \sin(2\phi) \sin\left(2\Psi_n^{\mathrm{A}}\right) \rangle}{\mathrm{Res}\left\{\Psi_n^{\mathrm{A}}; \mathrm{Y}\right\}}, \tag{20}$$

where ϕ denotes the azimuthal angle of hadrons measured in the central arms and $a_4^{\pm} = 1 \pm \langle \cos(4\phi) \rangle$ are the acceptance correction factors of the measured v_2 in the central arms. The coefficient $a_4^{\pm}$ should be unity in the case of perfect azimuthal acceptance. $\mathrm{Res}\{\Psi_n^{\mathrm{A}}; \mathrm{X}\}$ and $\mathrm{Res}\{\Psi_n^{\mathrm{A}}; \mathrm{Y}\}$ denote the event-plane resolution for v_2^{X} and v_2^{Y}, respectively, and are expressed as

$$\mathrm{Res}\left\{\Psi_l^{\mathrm{A}}; \mathrm{X}\right\} = \sqrt{\left\langle \cos\left(2\Psi_l^{\mathrm{A}}\right) \cos\left(2\Psi_m^{\mathrm{B}}\right) \right\rangle} \times \sqrt{\frac{\left\langle \cos\left(2\Psi_n^{\mathrm{C}}\right) \cos\left(2\Psi_l^{\mathrm{A}}\right) \right\rangle}{\left\langle \cos\left(2\Psi_m^{\mathrm{B}}\right) \cos\left(2\Psi_n^{\mathrm{C}}\right) \right\rangle}},$$
$$\mathrm{Res}\left\{\Psi_l^{\mathrm{A}}; \mathrm{Y}\right\} = \sqrt{\left\langle \sin\left(2\Psi_l^{\mathrm{A}}\right) \sin\left(2\Psi_m^{\mathrm{B}}\right) \right\rangle} \times \sqrt{\frac{\left\langle \sin\left(2\Psi_n^{\mathrm{C}}\right) \sin\left(2\Psi_l^{\mathrm{A}}\right) \right\rangle}{\left\langle \sin\left(2\Psi_m^{\mathrm{B}}\right) \sin\left(2\Psi_n^{\mathrm{C}}\right) \right\rangle}}, \tag{21}$$

where l, m, n are the harmonics of event planes for subevents A, B, and C, respectively. Another acceptance effect from the difference between $\mathrm{Res}\{\Psi_n^{\mathrm{A}}; \mathrm{X}\}$ and $\mathrm{Res}\{\Psi_n^{\mathrm{A}}; \mathrm{Y}\}$ is discussed below.

Figure 13 shows the acceptance correction factor $a_4^{\pm}$ as a function of p_T in the central arms for centrality 0–60%. The p_T dependence is parametrized by

$$a_4^{\pm}(p_T) = 1 \mp \left(p_0 e^{-p_1 p_T} + \frac{p_2}{1 + e^{(p_T - p_3)/p_4}} + p_5 \right), \tag{22}$$

where $p_n (n = 0, 1, \ldots, 5)$ are free parameters. From the fit, we get $p_0 = 0.131$, $p_1 = 1.203$, $p_2 = 0.029$, $p_3 = 0.640$, $p_4 = 0.096$, and $p_5 = -0.097$. There is no centrality dependence of the acceptance corrections in the measured centrality range, and these same correction factors are applied for all centrality bins.

Figure 14 shows the raw $v_2\{\mathrm{BBC}\}$ as a function of p_T in the 20–60% centrality bin. v_2^{Y} is systematically higher than v_2^{X} for $p_T > 1$ GeV/c as shown in Fig. 14(a). Figure 14(b) shows that v_2^{X} and v_2^{Y} agree with each other after dividing v_2^{obs} by $a_4^{\pm}$, the remaining difference between them being accounted

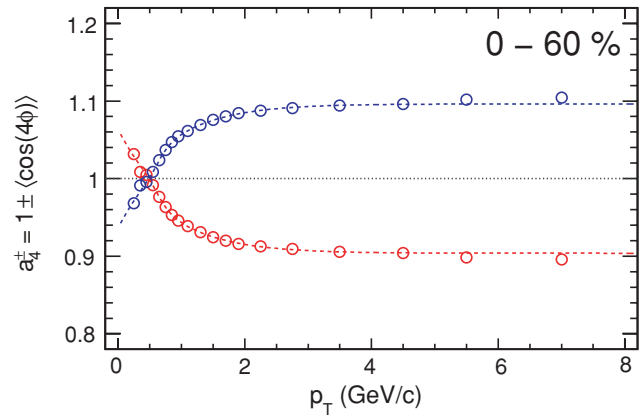

FIG. 13. (Color online) Acceptance correction factors $a_4^{\pm}$ in the central arms as a function of p_T for centrality 0–60%. Correction factors become unity for a perfect azimuthal acceptance. Statistical errors are smaller than the symbols.

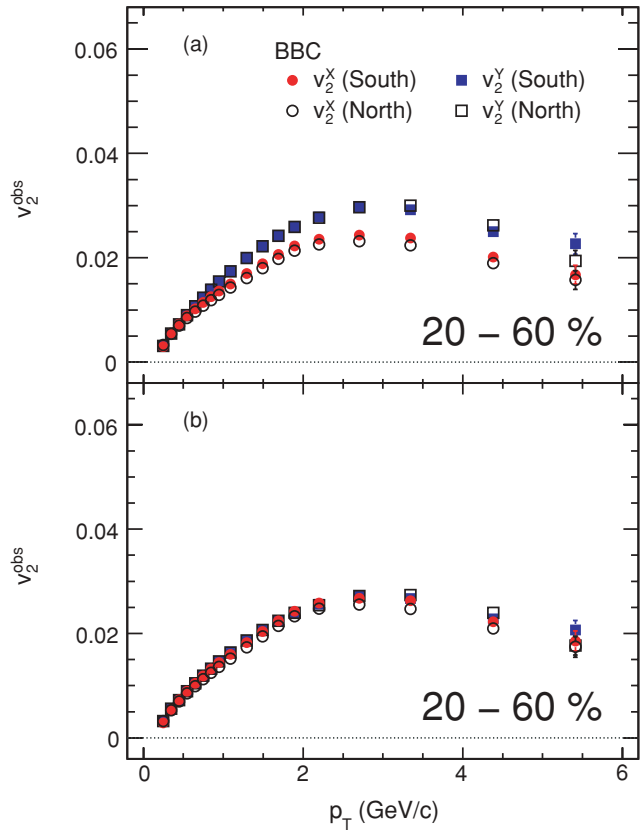

FIG. 14. (Color online) (a) Raw $v_2\{\text{BBC}\}$ without the acceptance correction as a function of p_T in centrality 20–60% for v_2^X and v_2^Y with the South and North BBC event planes. (b) Same comparison, but with the acceptance correction.

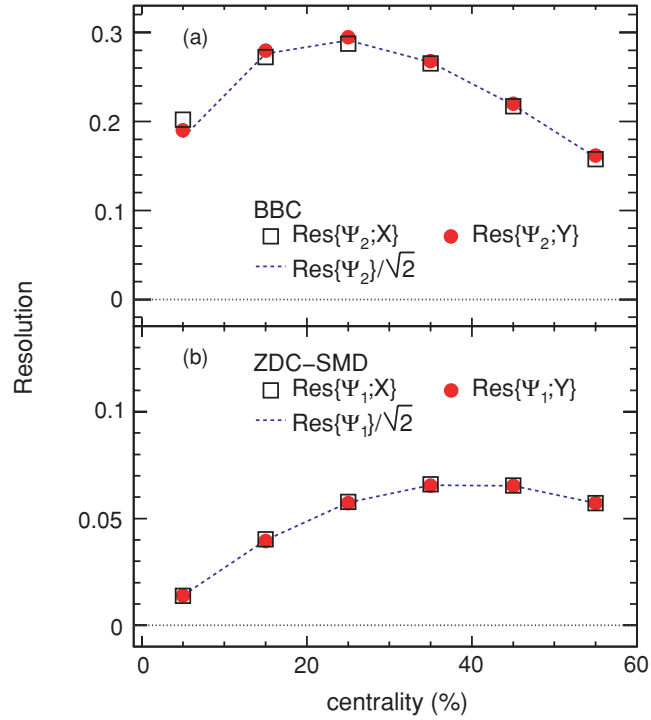

FIG. 15. (Color online) Comparison of $\text{Res}\{\Psi_n;\text{X}\}$ and $\text{Res}\{\Psi_n;\text{Y}\}$ with $\text{Res}\{\Psi_n\}$ for the (a) BBC event plane ($n = 2$) and (b) ZDC-SMD event plane ($n = 1$) as a function of centrality. The resolutions are calculated by using Eq. (21) with the ZDC-SMD, BBC, and CNT event planes. $\text{Res}\{\Psi_n\}$ is divided by $\sqrt{2}$ in order to compare $\text{Res}\{\Psi_n;\text{X}\}$ and $\text{Res}\{\Psi_n;\text{Y}\}$. Only statistical errors are shown and are smaller than symbols.

for as a systematic error. For the ZDC-SMD event plane, we observed a similar trend for v_2^X and v_2^Y.

A possible nonuniform acceptance of the BBC and ZDC-SMD could lead to the difference between $\text{Res}\{\Psi_n;\text{X}\}$ and $\text{Res}\{\Psi_n;\text{Y}\}$. If the azimuthal coverage of both detectors is perfect, $\text{Res}\{\Psi_n;\text{X}\}$ and $\text{Res}\{\Psi_n;\text{Y}\}$ should be identical. Therefore, the effect of the acceptance of the detector on the event-plane resolution can be assessed by comparing $\text{Res}\{\Psi_n;\text{X}\}$ and $\text{Res}\{\Psi_n;\text{Y}\}$.

Figure 15 shows $\text{Res}\{\Psi_n;\text{X}\}$ and $\text{Res}\{\Psi_n;\text{Y}\}$ of the BBC and ZDC-SMD as a function of centrality. The resolutions are calculated by using Eq. (21) with the ZDC-SMD, BBC, and CNT event planes. $\text{Res}\{\Psi_n;\text{X}\}$ was comparable to $\text{Res}\{\Psi_n;\text{Y}\}$ for both the BBC and ZDC-SMD event planes. They also agreed, within statistical errors, with the expected resolution, namely, the full-event resolution scaled by $1/\sqrt{2}$. We also evaluated $\text{Res}\{\Psi_n;\text{X}\}$ and $\text{Res}\{\Psi_n;\text{Y}\}$ of BBC and ZDC-SMD for the two-subevent method. $\text{Res}\{\Psi_2^{\text{BBC}};\text{X}\}$ was consistent with $\text{Res}\{\Psi_2^{\text{BBC}};\text{Y}\}$. However, for the ZDC-SMD event plane, $\text{Res}\{\Psi_1^{\text{ZDC-SMD}};\text{Y}\}$ ($\text{Res}\{\Psi_1^{\text{ZDC-SMD}};\text{X}\}$) was systematically higher (lower) by about 30% than the expected resolution when the resolutions were calculated with $k = 1$ in Eq. (8). The difference between $\text{Res}\{\Psi_1^{\text{ZDC-SMD}};\text{X}\}$ and $\text{Res}\{\Psi_1^{\text{ZDC-SMD}};\text{Y}\}$ for the two-subevent method is attributed to the nonuniform acceptance between horizontal (x) and vertical (y) directions of the ZDC-SMD. Those resolutions of the ZDC-SMD were consistent with each other using $k = 2$. For $k = 2$, the nonuniform acceptance in the azimuthal directions cancels out, since $\text{Res}\{\Psi_1^{\text{ZDC-SMD}};\text{X, Y}\}$ contains both $\langle\cos(\Psi)\rangle$ and $\langle\sin(\Psi)\rangle$ terms. Thus, $\text{Res}\{\Psi_1^{\text{ZDC-SMD}};\text{X, Y}\}$ should be the same and consistent with that from the expected resolution.

The comparison of v_2^X and v_2^Y with v_2 with respect to the BBC and ZDC-SMD event planes is shown in Fig. 16. The maximum difference of v_2^X and v_2^Y relative to $v_2\{\text{BBC}\}$ is about 2% for the centrality range 20–60% and is independent of centrality. Systematic uncertainties are evaluated by scaling the maximum difference by $2/\sqrt{12}$. The same comparison is also made for $v_2\{\text{ZDC-SMD}\}$ as shown in the bottom panel in Fig. 16. The systematic errors range from 1–25% and strongly depend on the centrality, as well as on the corrections by the different event-plane resolutions. v_2^X and v_2^Y are ~10–25% different from $v_2\{\text{ZDC-SMD}\}$ in the 0–20% centrality bin because of the very low resolution. This systematic uncertainty is denoted as "Acceptance effect on event planes" in Table III.

B. Cumulant method

The potential sources of systematic errors on the cumulant measurements are detailed below.

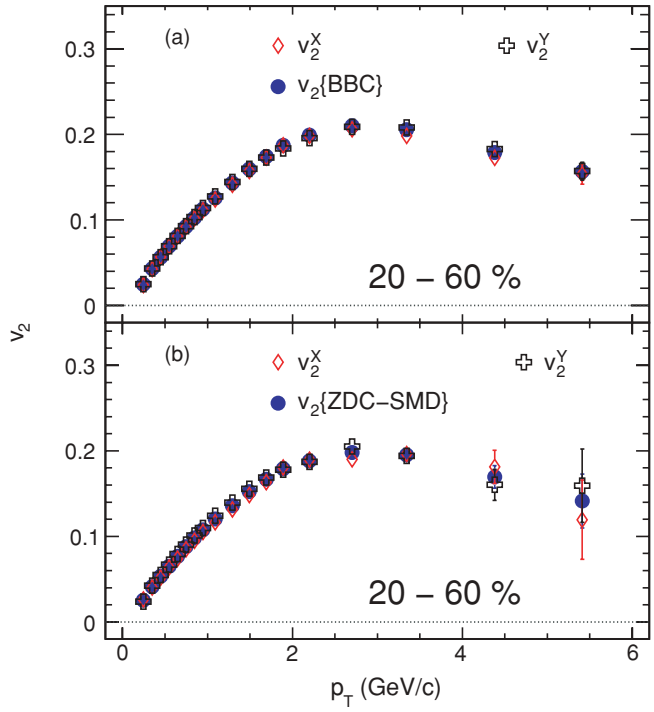

FIG. 16. (Color online) Comparison of v_2^X and v_2^Y with the total v_2 for the (a) BBC and (b) ZDC-SMD event planes as a function of p_T for the centrality bin 20–60%. Res$\{\Psi_n; X\}$ and Res$\{\Psi_n; Y\}$ are calculated by the combination of the ZDC-SMD, BBC, and CNT event planes. Acceptance corrections are included into v_2^X and v_2^Y. Error bars denote statistical errors.

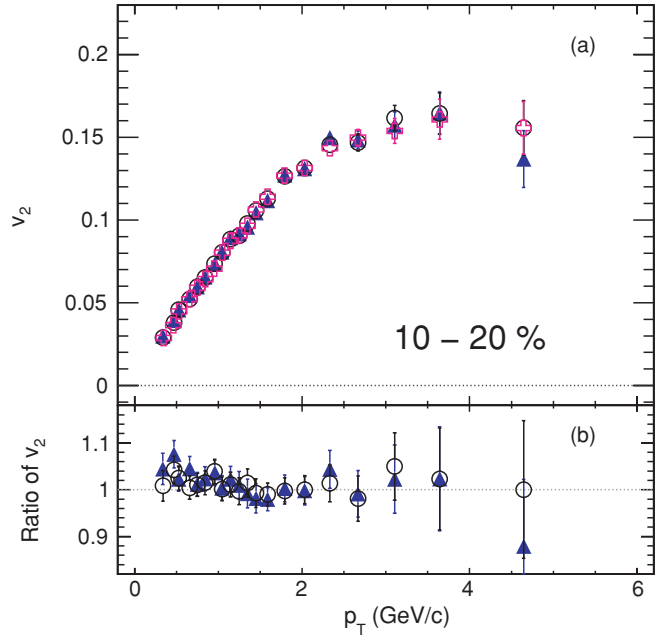

FIG. 17. (Color online) (a) $v_2\{2\}$ as a function of p_T for centrality 10–20% in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV for different fixed multiplicity cuts, corresponding to 60% (filled triangles), 70% (open circles), and 80% (open crosses) of the mean multiplicity. (b) Ratio of $v_2(p_T)$ for the two lowest multiplicity cuts to $v_2(p_T)$ for 80% of the mean multiplicity.

1. *Fixed multiplicity cut*

Following Ref. [44], a fixed multiplicity is used to reconstruct the integrated flow to avoid introducing additional errors arising from a fluctuating multiplicity. In our analysis, the systematic errors were estimated by varying the fixed multiplicity cut used for the reconstruction of the integrated flow and studying its effect on the differential flow values.

Figure 17(a) shows the variation of v_2 with p_T for integral multiplicity cuts equal to 60%, 70%, and 80% of the mean multiplicity for the centrality bin 10–20%, which corresponds to 17, 20, and 22 particles, respectively. The ratio of the differential v_2 values, shown in Fig. 17(b), is used to estimate the systematic error on our measurements, which is ∼5%.

2. *p_T range for integrated flow*

To assess the influence of the p_T range used to estimate the integrated flow on the differential flow, we chose different p_T ranges over which the integral particles were selected. Differential v_2 results were obtained for three p_T ranges: 0.25–2.0, 0.25–1.5, and 0.3–1.5 GeV/c. The systematic error from this source is estimated to be 3–8% depending on centrality and p_T.

3. *Background contribution*

The procedures followed for studying the background contribution to $v_2\{2\}$ were the same as for the event-plane method. After background subtraction, the systematic error is calculated by determining the difference between the v_2 obtained from using 2σ and 3σ association cuts. We determined that the overall systematic error due to these differences is 6–10% depending on p_T and centrality.

V. RESULTS

A. p_T dependence of v_2

The p_T dependence of v_2 has been instrumental in revealing the hydrodynamic properties of the matter formed at RHIC [19,21]. In this context, it is important to compare the p_T dependence of v_2 from different methods to establish the robustness of our v_2 measurements. This comparison is displayed in Fig. 18, which shows the differential charged hadron v_2 as a function of p_T from the event-plane and cumulant methods for different centrality bins in the range 0–60% in Au + Au at $\sqrt{s_{NN}} = 200$ GeV. $v_2\{2\}$ increases up to $p_T \approx 3$ GeV/c and saturates at 0.1–0.25, depending on centrality, for higher p_T. On the other hand, $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$ reach their maximum value at $p_T \approx 3$ GeV/c, and decrease for higher p_T.

The differences between $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$ are independent of p_T within systematic errors in the measured centrality range. $v_2\{\text{ZDC-SMD}\}$ is consistent with $v_2\{\text{BBC}\}$ within systematic errors in the 0–40% centrality range,

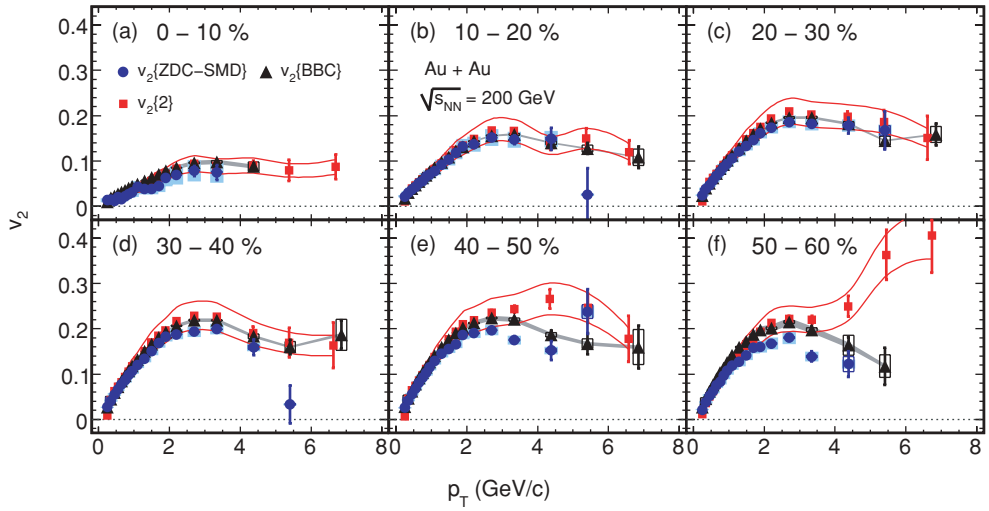

FIG. 18. (Color online) Charged hadron $v_2(p_T)$ in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV from the two-particle cumulant method (filled squares), the BBC event plane (filled triangles), and the ZDC-SMD event plane (filled circles) for the indicated centralities. Error bars denote statistical errors. The type B systematic uncertainties are represented by the open boxes for the $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$, and by the solid lines for the $v_2\{2\}$. The gray bands and blue boxes represent the type C systematic uncertainties on the $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$, respectively.

but it is ∼10–20% smaller than $v_2\{\text{BBC}\}$ in the 40–60% centrality range. These results could indicate that the influence of nonflow effects on $v_2\{\text{BBC}\}$ is small and within the systematic errors, because nonflow effects are not expected to influence $v_2\{\text{ZDC-SMD}\}$. The difference between $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$ in peripheral collisions could be attributed to nonflow contributions that might be proportionally larger in more peripheral collisions.

The cumulant and event-plane v_2 agree well within systematic uncertainties in the centrality range 0–40%. In more peripheral collisions, there may be some differences developing above $p_T \simeq 4$ GeV/c. Correlations between particles from jets affect the cumulant results, but have less influence on $v_2\{\text{BBC}\}$, as explained in Ref. [29], where it was shown that the smaller the rapidity gap between the leading particle from a jet and the event plane, the greater the v_2 of the leading particle of the jet.

To illustrate more clearly the differences between the different methods, Fig. 19 shows the ratio of $v_2\{\text{ZDC-SMD}\}$ and $v_2\{2\}$ to $v_2\{\text{BBC}\}$. The results from the three methods are comparable in magnitude within systematic errors, except for the central and peripheral bins where the largest deviations occur. In addition, $v_2\{2\}$ and $v_2\{\text{ZDC-SMD}\}$ show different behaviors at $p_T > 3$ GeV/c, with $v_2\{2\}$ being larger, and $v_2\{\text{ZDC-SMD}\}$, smaller than $v_2\{\text{BBC}\}$.

B. Centrality dependence of v_2

Figure 20 shows the N_{part} dependence of v_2 from different methods for charged hadrons in the range $1.0 < p_T <$

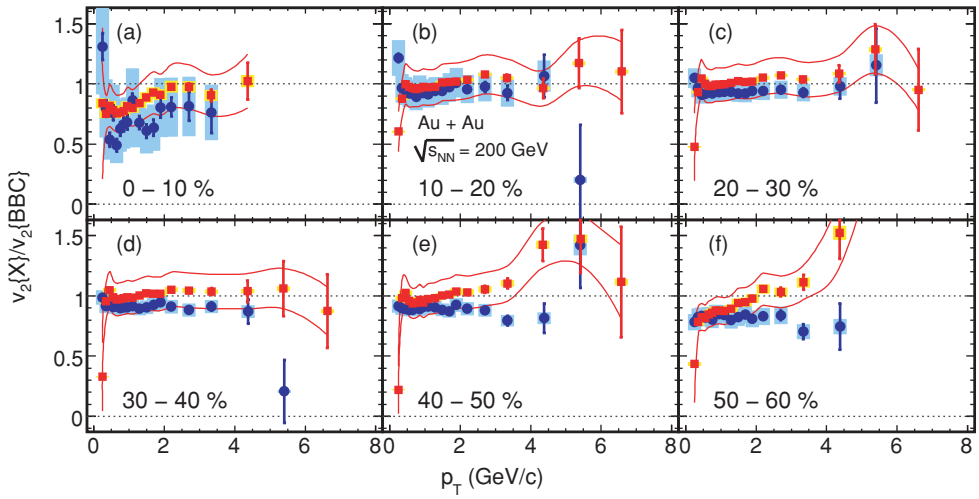

FIG. 19. (Color online) Ratio of v_2 to $v_2\{\text{BBC}\}$ as a function of p_T for six centrality bins over the range 0–60% in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Data symbols are the same as in the Fig. 18. Error bars denote statistical errors. The solid red lines represent the type B systematic errors on the $v_2\{2\}$. The blue and yellow bands represent type C systematic uncrtainties on $v_2\{\text{ZDC-SMD}\}$ and $v_2\{2\}$.

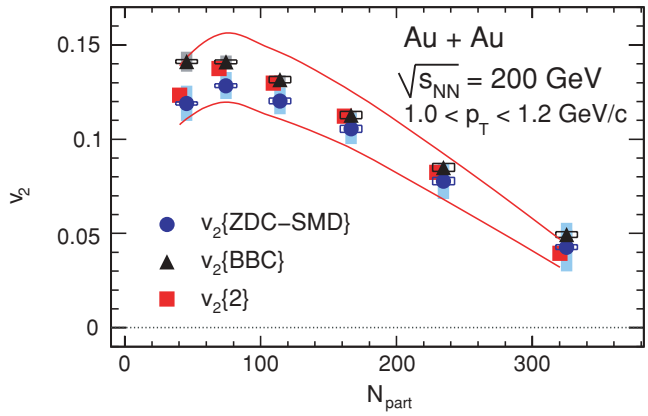

FIG. 20. (Color online) Comparison of charged hadron v_2 at $1 < p_T < 1.2$ GeV/c as a function of N_{part} for $v_2\{\text{BBC}\}$, $v_2\{\text{ZDC-SMD}\}$, and $v_2\{2\}$ in Au + Au at $\sqrt{s_{NN}} = 200$ GeV. The error bars represent statistical errors. The open boxes represent type B systematic uncertainties on $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$. Type B systematic uncertainties on $v_2\{2\}$ are represented by solid red lines. The gray and blue bands represent type C systematic errors on $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$, respectively. $v_2\{2\}$ values are shifted in the x axis to improve the plot.

1.2 GeV/c. v_2 is observed to increase with decreasing N_{part} and then decrease slightly for $N_{\text{part}} \lesssim 75$. Note that v_2 values obtained with the different methods agree well within systematic errors for all centralities. This is p_T dependent, as shown in Fig. 18.

C. Pseudorapidity dependence of v_2

Figure 21 compares the pseudorapidity dependence of the v_2 of charged hadrons within the η range (± 0.35) of the PHENIX central arms for different p_T selections. It can be

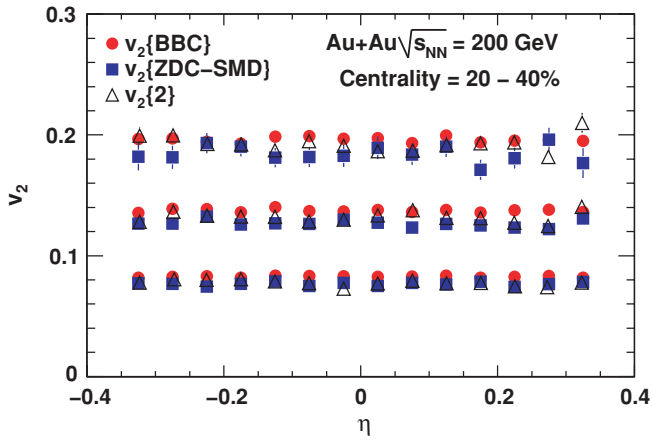

FIG. 21. (Color online) Anisotropy parameter v_2 as a function of pseudorapidity within the PHENIX central arms using event planes from the BBC and ZDC-SMD, and from the two-particle cumulant method for centrality 20–40%. The results are shown for three p_T bins, which are from top to bottom: 2.0–3.0, 1.2–1.4 and 0.6–0.8 GeV/c. Only statistical errors are shown.

observed that v_2 is constant over the η coverage of the PHENIX detector, and the constancy does not depend on p_T. This is not the case when the v_2 is measured far from midrapidity, where the PHOBOS and STAR Collaborations observe a drop in v_2 for $|\eta| > 1.0$ [49,50].

VI. DISCUSSION

A. Effect of CNT event-plane resolution

Figure 22 shows the comparison of $v_2\{\text{ZDC-SMD}\}$ and $v_2\{\text{BBC}\}$ as a function of p_T corrected either by the resolution from South-North correlations from the same detectors or by the resolution from ZDC-SMD-CNT correlations in the 20–60% centrality bin. Figures 22(a) and 22(b) compare the v_2 obtained by using two different corrections from the South-North and ZDC-BBC-CNT subevents for the BBC and ZDC-SMD event planes. The v_2 from the South-North subevent is consistent with that from the ZDC-BBC-CNT subevent, within systematic uncertainties. The small difference between South-North and ZDC-BBC-CNT subevents is attributed to the difference between the event-plane resolution, as shown in Fig. 4. Figures 22(c) and 22(d) compare $v_2\{\text{ZDC-SMD}\}$ with $v_2\{\text{BBC}\}$ for the South-North and ZDC-BBC-CNT subevents. The data points in Figs. 22(c) and 22(d) are the same as in Figs. 22(a) and 22(b). Figure 22(c) shows that $v_2\{\text{ZDC-SMD}\}$ is about 10% smaller than $v_2\{\text{BBC}\}$ for the South-North subevent. The ratio of $v_2\{\text{ZDC-SMD}\}$ to $v_2\{\text{BBC}\}$ is found to be independent of p_T except for $6 < p_T < 8$ GeV/c. If jets are the dominant source of nonflow, one expects its contribution to v_2 to become larger at higher p_T. The constant ratio suggests that the nonflow contribution from jets is small, and v_2 fluctuations may affect $v_2\{\text{BBC}\}$ below $p_T \approx 6$ GeV/c, since the effect of fluctuations is expected to be independent of p_T. $v_2\{\text{ZDC-SMD}\}$ agrees with $v_2\{\text{BBC}\}$ within systematic uncertainties for the ZDC-BBC-CNT subevent, as shown in Fig. 22(d). The event-plane resolution from the ZDC-BBC-CNT subevents includes the effect of nonflow contributions and v_2 fluctuations, since the CNT and BBC event planes are sensitive to both effects, though nonflow effects especially from jets could be negligible in the BBC event plane, as discussed earlier. The consistency between v_2 from the ZDC-SMD and BBC event planes may suggest that $v_2\{\text{ZDC-SMD}\}$ becomes sensitive to v_2 fluctuations when the BBC and CNT event planes are included in the estimation of resolution.

B. Comparison with other experiments

It is instructive to compare measurements made by different experiments at RHIC. Figure 23 shows a comparison of the p_T dependence of charged hadron v_2 in the 20–60% centrality range between PHENIX and STAR experiments [51]. The relative systematic errors on the STAR $v_2\{2\}$ and $v_2\{4\}$ measurements range up to 10% for $p_T < 1$ GeV/c, with the lowest p_T bin having the largest error ~10%, while they are of the order of 1% above 1 GeV/c [51]. The $v_2\{2\}$ from PHENIX is lower than that from STAR, but they are comparable within

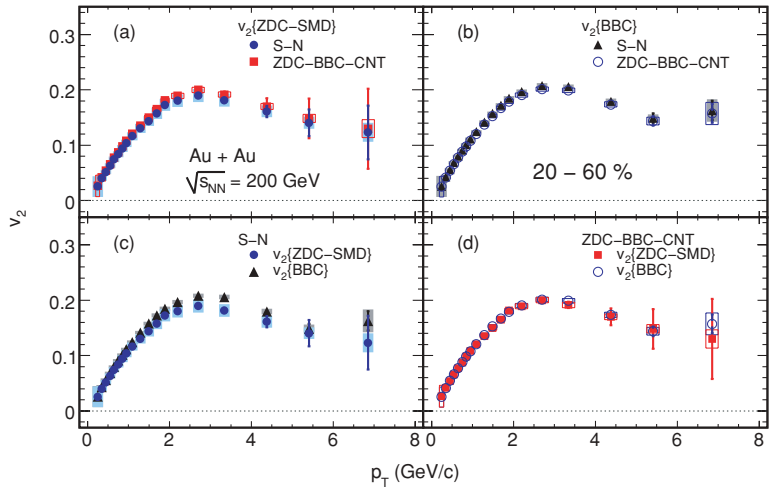

FIG. 22. (Color online) (a) Comparison of the $v_2\{\text{ZDC-SMD}\}$ obtained from the S-N and ZDC-BBC-CNT subevents as a function of p_T in the 20–60% centrality range. (b) Same comparison as (a), but for the $v_2\{\text{BBC}\}$. (c) Comparison of v_2 between BBC and ZDC-SMD event planes from the S-N subevent as a function of p_T in centrality 20–60%. (d) Same comparison as (c), but from the ZDC-BBC-CNT subevent. Error bars denote statistical errors. Open boxes and shaded bands describe the quadratic sum of type B and C systematic uncertainties from the S-N and ZDC-BBC-CNT subevents, respectively.

systematic uncertainties, as shown in Fig. 23(a). Figure 23(b) compares $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$ with $v_2\{4\}$, obtained from four-particle cumulants, as measured in STAR. For

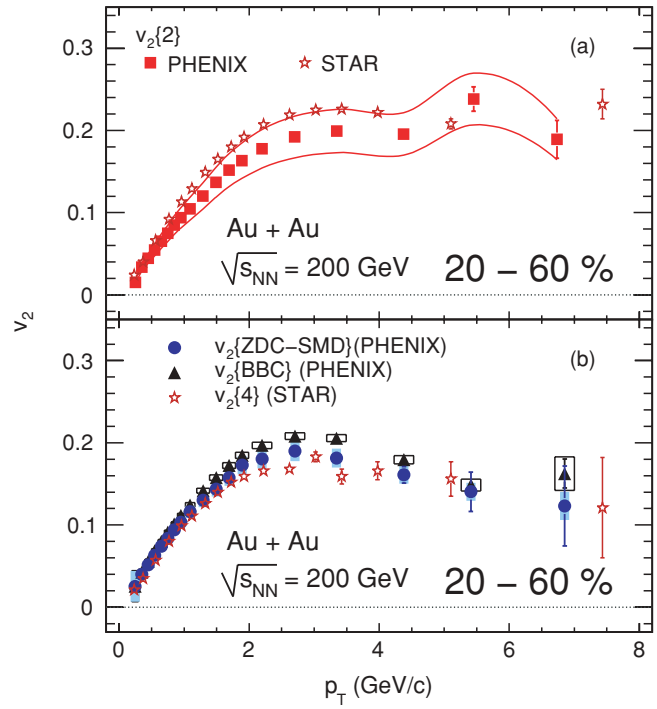

FIG. 23. (Color online) (a) Comparison of charged hadron $v_2\{2\}$ between PHENIX and STAR experiments as a function of p_T in centrality 20–60%. Solid lines represent the quadratic sum of type B and C systematic errors on the PHENIX $v_2\{2\}$. (b) Comparison of charged hadron v_2 from four-particle cumulant $v_2\{4\}$ at STAR with the PHENIX $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$ as a function of p_T in centrality 20–60%. Open boxes and shaded bands represent the quadratic sum of type B and C systematic errors on the $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$, respectively. STAR results are taken from Ref. [51]. Systematic errors on the STAR v_2 are not plotted, see text for more details.

$p_T > 2$ GeV/c, the STAR $v_2\{4\}$ is systematically smaller than the PHENIX event-plane v_2, while $v_2\{\text{ZDC-SMD}\}$ is lower than $v_2\{\text{BBC}\}$. However, the three sets of measurements are consistent within systematic errors. The order of v_2, that is, $v_2\{\text{BBC}\} > v_2\{\text{ZDC-SMD}\} > v_2\{4\}$, could be explained by the effect of flow fluctuations [33,52] if other nonflow contributions are small.

Figure 24 compares our charged hadron v_2 from the BBC and ZDC-SMD event planes to v_2 from a modified event-plane method [49], labeled $v_2\{\text{EP}_2\}$, from the STAR experiment for three centrality bins in the range 10–40%. Particles within $|\Delta\eta| < 0.5$ around the highest p_T particle were excluded for the determination of the modified event plane in order to reduce some of the nonflow effects at high p_T. We find that $v_2\{\text{BBC}\}$ agrees well with $v_2\{\text{EP}_2\}$ over the measured p_T range, whereas $v_2\{\text{ZDC-SMD}\}$ is generally slightly smaller than $v_2\{\text{EP}_2\}$.

VII. SUMMARY

In summary, we have presented PHENIX elliptic flow measurements for unidentified charged hadrons from the event plane and the two-particle cumulant methods as a function of p_T and centrality at midrapidity ($|\eta| < 0.35$) in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The first-harmonic ZDC-SMD event plane is used to measure v_2 and is compared with v_2 from the second-harmonic BBC event plane in order to understand the possible nonflow contributions as well as the effect of v_2 fluctuations on $v_2\{\text{BBC}\}$.

The comparison between v_2 from two-particle cumulant and event-plane methods shows that they agree within systematic errors. However, nonflow effects from jet correlations begin to contribute to the two-particle cumulant v_2, especially for peripheral collisions and at high p_T.

In contrast, nonflow effects on $v_2\{\text{BBC}\}$ are very small. The measured $v_2\{\text{BBC}\}$ values decrease by about 3% when the central arm event plane is included in the estimate of the BBC reaction plane resolution. This could be due to a

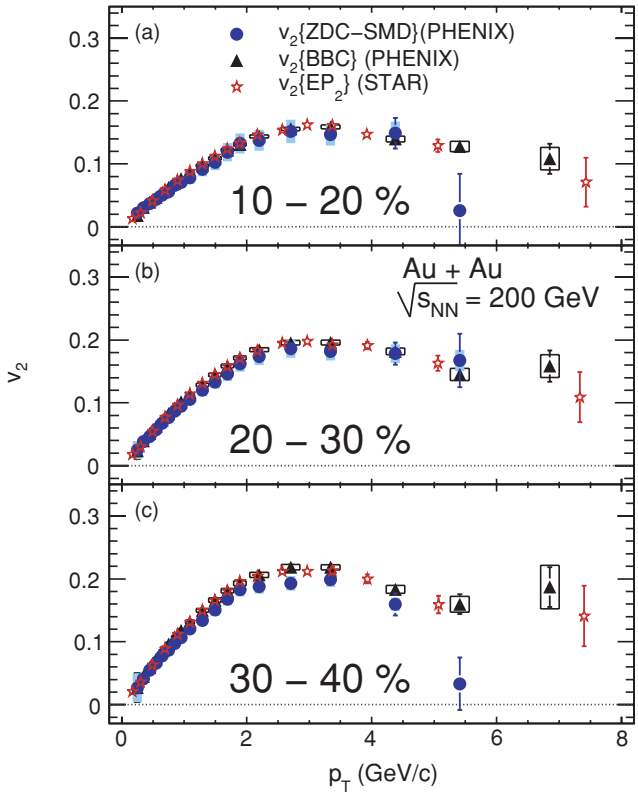

FIG. 24. (Color online) Comparison of the PHENIX $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$ with the STAR v_2 from the modified event-plane method for charged hadrons [49] as a function of p_T in three centralities. Open boxes and shaded bands represent the quadratic sum of type B and C systematic errors on $v_2\{\text{BBC}\}$ and $v_2\{\text{ZDC-SMD}\}$, respectively.

partial compensation of the nonflow effects on the measured v_2, though the results of $v_2\{\text{BBC}\}$ with and without the CNT event-plane resolution are consistent within systematic errors. The strongest evidence that nonflow effects on $v_2\{\text{BBC}\}$ are small comes from the observation that $v_2\{\text{ZDC-SMD}\}$ is comparable to $v_2\{\text{BBC}\}$ within systematic uncertainties in the 0–40% centrality range, and is only ∼5–10% smaller than $v_2\{\text{BBC}\}$ for the 40–60% centrality bin. The magnitude of this difference could indicate the level at which nonflow effects such as jets or the ridge could impact the measured flow. However, the PHOBOS Collaboration has observed the ridge to be strongest in central collisions [31] where we observe that $v_2\{\text{ZDC-SMD}\}$ is comparable with $v_2\{\text{BBC}\}$. For collisions that are more peripheral than 40% centrality, PHOBOS observes no ridge [31], so it is unlikely that our observation that $v_2\{\text{ZDC-SMD}\}$ is ∼5–10% smaller than $v_2\{\text{BBC}\}$ for the 40–60% centrality bin is caused by the ridge. Moreover, the difference between $v_2\{\text{ZDC-SMD}\}$ and $v_2\{\text{BBC}\}$ is independent of p_T in the measured centrality range.

Because of the large pseudorapidity gap between the event plane and the particles detected in the central arms spectrometer, and the first-harmonic event plane from directed flow by spectator neutrons, $v_2\{\text{ZDC-SMD}\}$ is considered to provide an unbiased measure of the elliptic flow. Within systematic uncertainties, the measured $v_2\{\text{ZDC-SMD}\}$ from PHENIX is consistent with v_2 from the four-particle cumulant method measured by the STAR experiment in the 20–60% centrality bin, and it is also consistent with the STAR v_2 from a modified event-plane method in 10–40% centrality bins. These comparisons (1) further demonstrate the validity of the $v_2\{\text{ZDC-SMD}\}$, because both STAR results aim to minimize the nonflow effects, (2) reinforce the robustness of the BBC event-plane method at RHIC, and (3) confirm previous studies of the influence of jets on the measured v_2 for different rapidity gaps. Hence, $v_2\{\text{BBC}\}$ can be used to infer constraints on the hydrodynamic behavior of heavy-ion collisions at RHIC.

(Received 29 March 2009; published 18 August 2009)

The momentum distribution of electrons from semileptonic decays of charm and bottom quarks for midrapidity $|y| < 0.35$ in $p + p$ collisions at $\sqrt{s} = 200$ GeV is measured by the PHENIX experiment at the Relativistic Heavy Ion Collider over the transverse momentum range $2 < p_T < 7$ GeV/c. The ratio of the yield of electrons from bottom to that from charm is presented. The ratio is determined using partial $D/\bar{D} \to e^{\pm}K^{\mp}X$ (K unidentified) reconstruction. It is found that the yield of electrons from bottom becomes significant above 4 GeV/c in p_T. A fixed-order-plus-next-to-leading-log perturbative quantum chromodynamics calculation agrees with the data within the theoretical and experimental uncertainties. The extracted total bottom production cross section at this energy is $\sigma_{b\bar{b}} = 3.2^{+1.2}_{-1.1}(\text{stat})^{+1.4}_{-1.3}(\text{syst})\mu b$.

DOI: 10.1103/PhysRevLett.103.082002 PACS numbers: 13.85.Qk, 13.20.Fc, 13.20.He, 25.75.Dw

Measurements of heavy flavor production (charm and bottom) in $p + p$ collisions present stringent tests for perturbative quantum chromodynamics (pQCD) calculations. For instance, while bottom production at the Tevatron is well described by next-to-leading order (NLO) pQCD [1], the cross section for charm production at high p_T, though compatible within the theoretical uncertainties, is higher than the preferred theoretical value by ~50% [2]. Measurement of heavy flavor in $p + p$ collisions also provides an important baseline for study of the medium created in relativistic heavy-ion collisions. The PHENIX experiment at the Relativistic Heavy Ion Collider (RHIC) has measured single electrons from the semileptonic decay of heavy flavor at midrapidity in $p + p$ and Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [3,4]. Strong suppression of the single electron yield at high p_T, which includes contributions from both charm and bottom decays, was observed in central Au + Au collisions [4]. This effect is conventionally attributed to energy loss by the parent parton in the medium [5]; one also expects the energy loss suffered by bottom quarks to be significantly less than that suffered by charm quarks due to the difference in their masses [6,7]. Clearly, for both pQCD comparisons and the heavy-ion reference, one wants to disentangle the yields of charm and bottom at RHIC energies.

In this Letter, we present the yield ratio of single electrons from bottom to those from heavy flavor at midrapidity in $p + p$ collisions at $\sqrt{s} = 200$ GeV, using partial $D/\bar{D} \to e^{\pm}K^{\mp}X$ (K unidentified) reconstruction. The data were collected with the PHENIX detector [8] in the 2005 and 2006 RHIC runs using its two central arm spectrometers. Each spectrometer covers $|\eta| < 0.35$ in pseudorapidity and $\Delta\phi = \pi/2$ in azimuth. The arms include drift chambers (DC) and pad chambers (PC1,2,3) for charged particle tracking, a ring imaging Čerenkov detector (RICH) and an electromagnetic calorimeter (EMCal) for electron identification and triggering. Beam-beam counters (BBCs), covering pseudorapidity $3.1 < |\eta| < 3.9$, measure the position of the collision vertex along the beam (z_{vtx}) and provide the interaction trigger. In the 2005 run, helium bags were placed in the space between the beam pipe and DC to reduce photon conversions. The bags were removed in 2006.

Two data sets are used for the analysis: (i) a minimum bias (MB) data set recorded with the BBC trigger, and (ii) an electron enriched sample, recorded with a level-1 "ERT" trigger requiring a combination of EMCal and RICH information in coincidence with the BBC trigger. The BBC trigger cross section is 23.0 ± 2.2 mb [9]. The BBC trigger selects ~53% of inelastic $p + p$ collisions and $(79 \pm 2)\%$ of hard scattering events, such as those with high-p_T particles at midrapidity. The latter efficiency is approximately p_T and particle independent, which was verified by the observed ratio of high-p_T pion and eta yields with and without the BBC trigger, and confirmed with a Monte Carlo simulation [9,10]. After selection of good runs and a vertex cut of $|z_{\text{vtx}}| < 25$ cm, an integrated luminosity ($\int Ldt$) in the ERT data of 1.77 pb^{-1} in the 2005 run and 4.22 pb^{-1} in the 2006 run are used for this analysis.

Charged particle tracks are reconstructed using the DC and PC1. The momentum resolution is ~1% at

$p_T \sim 1$ GeV/c, and the momentum scale is calibrated within 1%. Electron identification (eID) is performed using the RICH and EMCal. The purity of the electron sample is better than 99% for $1 < p_T < 5$ GeV/c [3]. Our previous measurement [3] determined the spectrum of the single electrons from heavy flavor in the 2005 run. Inclusive electron spectra from the 2005 run and the 2006 run are consistent within 5% after taking into account a contribution from the increased photon conversion due to the absence of the helium bags.

The spectrum of the single electrons from heavy flavor is determined using the "cocktail method" [3,4]. The electron spectrum from all known sources except semileptonic decay of heavy flavor is calculated using a Monte Carlo simulation and subtracted from the inclusive spectrum in the cocktail method. The dominant source of background is the π^0 Dalitz decay. The cocktail also includes contributions from quarkonium (J/ψ, Υ) and the Drell-Yan process, which were neglected in our previous measurements [3,4]. These contributions are negligible (smaller than 1% in background) for $p_T < 1$ GeV/c, but become significant at high p_T (above 10% for $p_T > 2.5$ GeV/c) [11]. The signal to background ratio increases with increasing p_T, approaching unity for $p_T \sim 3$ GeV/c [3].

The systematic uncertainties of the inclusive electron spectrum includes the uncertainty in luminosity (9.6%), geometrical acceptance (3%), eID efficiency (2%), and the ERT trigger efficiency (4% at $p_T > 2$ GeV/c). The uncertainty in the cocktail method is p_T dependent (3% at $p_T \sim 2$ GeV/c, increasing to 9% at 9 GeV/c).

The ratio of $(b \to e)$ to $[(c \to e) + (b \to e)]$ is extracted from the correlation between the heavy flavor electrons and associated hadrons [12,13]. The extraction is based on partial reconstruction of the $D/\bar{D} \to e^{\pm}K^{\mp}X$ decay. The invariant mass of unlike charge-sign electron-hadron pairs reveals a correlated signal below the D meson mass of ~ 1.9 GeV/c^2, because of the charge correlation in the D decays. Pairs are formed between a trigger electron ($2.0 < p_T < 7.0$ GeV/c) and an oppositely charged hadron ($0.4 < p_T < 5.0$ GeV/c). The hadron p_T is required to be less than 5 GeV/c, because pions also emit Čerenkov photons in the RICH above 5 GeV/c. The acceptances of positive and negative charged particles are forced to be identical by a geometrical acceptance cut. Since the momentum range of good charged kaon identification is limited, K identification is not performed but the mass of all reconstructed hadrons is set to be that of the K. Most e^+e^- pairs are then removed by an electron veto cut for the hadrons. The reconstructed mass of e^+e^- pairs has a clear peak at low mass. The remaining background e^+e^- pairs are removed by requiring $M_{ee} > 80$ MeV/c^2, where the pair mass is calculated assuming both particles in the pair are electrons.

Depending on the origin of the trigger electrons, the inclusive reconstructed electron-hadron pairs are (i) unlike-sign pairs from charm, (ii) unlike-sign pairs from bottom, (iii) combinatorial background where the electron is a background electron and (iv) background from unlike-sign hadron-hadron pairs due to hadron contamination in the electrons. The main background source is the combinatorial background (iii) and almost all background electrons are from e^+e^- pair creation. Like-sign electron-hadron pairs are used to subtract this background. Since electrons from e^+e^- pair creation and hadrons do not contribute to charge correlated signals, subtraction using like-sign pairs cancels out completely the combinatorial background where the trigger electron is from e^+e^- pair creation (iii). Only the negligibly small (<1%) contribution from K^0_{e3} decay is not canceled out by the subtraction in the background (iii). The contribution from

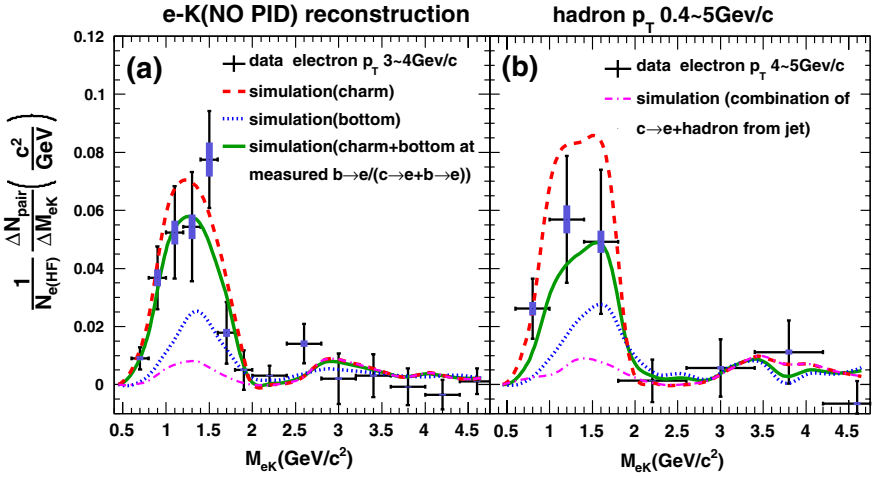

FIG. 1 (color online). Comparison of data to a PYTHIA and EVTGEN [14,15] simulation of the invariant mass distributions in PHENIX acceptance for the reconstructed signal in the 2006 run. The electron p_T range is 3.0–4.0 GeV/c (a) and 4.0–5.0 GeV/c (b). The ratios, $(b \to e)/[(c \to e) + (b \to e)]$, in solid lines are 0.26 (a) and 0.63 (b). Error bars (boxes) indicate statistical (systematic) uncertainties.

hadron contamination (iv) is also less than a 1% effect due to the excellent electron identification. After the subtraction, the reconstructed pairs include a contribution from bottom (ii) due to not identifying K. The contribution from bottom (ii) is much smaller than that from charm (i) due to the bottom decay modes and kinematics. The reconstructed pairs also contain a signal from partial reconstruction of heavy flavor hadrons and a contribution from a combination of heavy flavor electrons and hadrons from jet fragmentation. The ratio of the yield of unlike-sign pairs to that of like-sign pairs is about 1.1 for invariant masses (M_{eK}) below 1.9 GeV/c^2.

The fraction of bottom contribution to the electrons from heavy flavor is obtained as follows:

$$\frac{b \to e}{(c \to e) + (b \to e)} = \frac{\epsilon_c - \epsilon_{\rm data}}{\epsilon_c - \epsilon_b}, \quad (1)$$

where $\epsilon_{\rm data}$ is the tagging efficiency in real data and $\epsilon_{c(b)}$ is the tagging efficiency for charm (bottom) production. These are defined as

$$\epsilon_{\rm data} \equiv \frac{N_{\rm pair}}{N_{e({\rm HF})}} = \frac{N_{c\to{\rm tag}} + N_{b\to{\rm tag}}}{(c \to e) + (b \to e)}, \quad (2)$$

$$\epsilon_c \equiv \frac{N_{c\to{\rm tag}}}{c \to e}, \qquad \epsilon_b \equiv \frac{N_{b\to{\rm tag}}}{b \to e}, \quad (3)$$

where $N_{e({\rm HF})}$ is the number of measured heavy flavor electrons. $N_{\rm pair}$ is the number of background subtracted unlike-sign electron-hadron pairs for invariant mass within $0.4 < M_{eK} < 1.9$ GeV/c^2, which corresponds to the mass range of charmed hadrons. Here, $N_{c(b)\to{\rm tag}}$ is the number of reconstructed signals within $0.4 < M_{eK} < 1.9$ GeV/c^2 for charm (bottom) production.

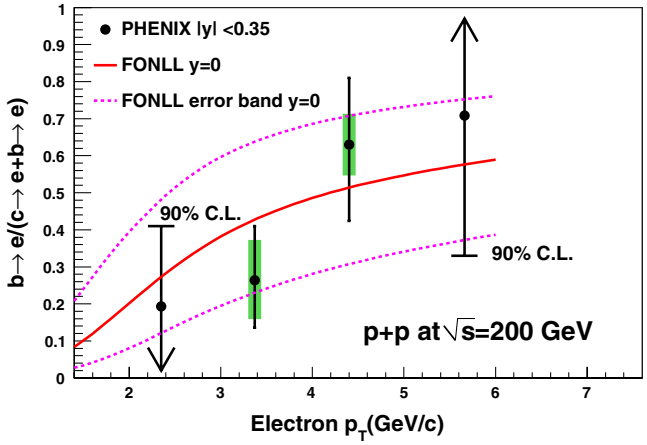

FIG. 2 (color online). $(b \to e)/[(c \to e) + (b \to e)]$ as a function of electron p_T compared to a FONLL calculation [20]. The points show the experimental result. Vertical arrows are used to indicate upper and lower limits. The solid line is a FONLL prediction and the dotted lines represent the uncertainty of this FONLL prediction.

Figure 1 shows the M_{eK} distribution of the reconstructed signals, which is normalized by the yield of heavy flavor electrons ($N_{e({\rm HF})}$) in the range $3 < p_T < 4$ GeV/c [panel (a)] and $4 < p_T < 5$ GeV/c [panel (b)]. The tagging efficiency in real data, $\epsilon_{\rm data}$, is determined by the integration of the M_{eK} distribution in Fig. 1 from $M_{eK} = 0.4$ to 1.9 GeV/c^2 as a function of electron p_T.

The tagging efficiencies for charm and bottom production, ϵ_c and ϵ_b, are calculated with the combination of PYTHIA and EVTGEN [14,15]. PYTHIA is used to simulate charm and bottom production in $p + p$ collisions at $\sqrt{s} =$ 200 GeV and is tuned to reproduce heavy flavor hadron ratios: $D^+/D^0 = 0.45 \pm 0.10$, $D_s/D_0 = 0.25 \pm 0.10$, $\Lambda_c/D^0 = 0.10 \pm 0.05$, $B^+/B^0 = 0.50$, $B_s/B_0 = 0.40 \pm 0.20$, and $B_{\rm baryon}/B^0 = 0.20 \pm 0.15$ [11,16–19]. The Monte Carlo simulation EVTGEN, which is suited for decays of D and B hadrons, is used to simulate the semileptonic decays. The dashed (dotted) lines in Fig. 1 show the M_{eK} distributions of the reconstructed signal for the simulated charm (bottom) production for an electron $3 < p_T < 4$ GeV/c (panel a) and $4 < p_T < 5$ GeV/c [panel (b)]. Some fluctuations in the simulated curves in Fig. 1 come from the limited statistics in the simulation, but the statistical uncertainties in the simulation are negligible compared to that of the data. $\epsilon_{c(b)}$ is determined in the same way as $\epsilon_{\rm data}$ from the M_{eK} distribution for charm (bottom) production. Since about 85% of the extracted

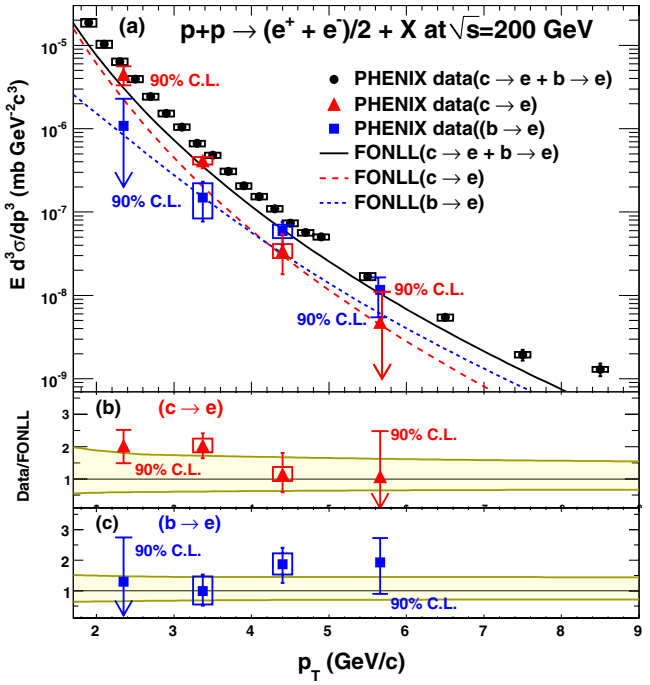

FIG. 3 (color online). (a) Invariant cross sections of electrons from charm and bottom with the FONLL calculation [20]. (b) and (c) The ratios of data points over the FONLL prediction as a function of electron p_T for charm and bottom. The shaded area shows the uncertainty in the FONLL prediction.

signal comes from partial reconstruction of heavy flavor hadrons, the tagging efficiency is determined largely by decay kinematics and $\epsilon_{c(b)}$ can be determined with good precision. The dot-dash lines in Fig. 1 show the contribution from the combination of an electron from charm and hadrons from jet fragmentation for charm production. The solid line in Fig. 1 shows the sum of the M_{eK} distributions for charm and bottom in the simulation with the ratio, $(b \to e)/[(c \to e) + (b \to e)]$, obtained with Eq. (1).

Systematic uncertainties are categorized into two parts related to (i) ϵ_{data} in the real data analysis and (ii) ϵ_c and ϵ_b in the simulation study. The dominant uncertainty in $\epsilon_{\rm data}$ is the uncertainty in the number of heavy flavor electrons (~10%). Uncertainty in $\epsilon_{\rm data}$ also includes a background subtraction uncertainty (1%–10%, p_T dependent). Category (2) includes the uncertainties in geometrical acceptance (3%) and the event generator (~8% for charm and ~9% for bottom). The event generator uncertainty is based on uncertainties, which are known in the production ratios of heavy flavor hadrons (D^+/D^0, D_s/D^0, etc.), known in the branching ratios [16–19], estimated in the momentum distribution of heavy flavor hadrons and estimated in the PYTHIA parameters.

Figure 2 shows the resulting bottom fraction, $(b \to e)/[(c \to e) + (b \to e)]$ as a function of electron p_T compared to a fixed-order-plus-next-to-leading-log perturbative QCD calculation (FONLL) [20]. In this figure, the points show the measured $(b \to e)/[(c \to e) + (b \to e)]$. For the bins with electron p_T ranges $2 < p_T < 3$ and $5 < p_T < 7$ GeV/c, 90% C.L. and mean values are shown. The solid line shows the central value of the FONLL prediction and the dotted lines show its uncertainty.

In Fig. 3, the single electron spectra for charm and bottom are measured from the ratio, $(b \to e)/[(c \to e) + (b \to e)]$, and the spectrum of the electrons from heavy flavor decays. The top panel shows the resulting single electron spectra from charm (triangles) and bottom (squares) compared to the FONLL predictions [20]. The measured spectrum of single electrons (circles) is also shown for reference. The middle (bottom) panel shows the ratio of the measured cross sections to the FONLL calculation for charm (bottom) production. The shaded area shows the uncertainty in the FONLL prediction. The larger mass makes this uncertainty smaller in the case of bottom quarks. These calculations agree with the data for bottom production within the large theoretical and experimental uncertainty. The same is true for charm within the theoretical uncertainty with a ratio of data/FONLL of ~2. A similar tendency was obtained at the Tevatron [1,2].

The electron spectrum from bottom shown in Fig. 3 is integrated from $p_T = 3$ to 5 GeV/c and gives $4.8^{+1.8}_{-1.6}(\text{stat})^{+1.9}_{-1.8}(\text{syst})$ nb. This spectrum is then extrapolated to $p_T = 0$ using the shape predicted by pQCD. PYTHIA with varying intrinsic k_T ($1.5 < k_T < 10$ GeV/c) and FONLL with varying factorization (μ_F) and renormalization (μ_R) scales ($0.5 < \mu_{F,R}/\sqrt{m^2 + p_T^2} < 2$) are used to evaluate the systematic uncertainty (12%) to this extrapolation. The extrapolation results in a bottom cross section at midrapidity of $d\sigma_{b\bar{b}}/dy\,|_{y=0} = 0.92^{+0.34}_{-0.31}(\text{stat})^{+0.39}_{-0.36}(\text{syst})\mu b$, using a $b \to e$ total branching ratio of 10 ± 1%, calculated using the heavy flavor hadron ratios described above. Using HVQMNR [21] with CTEQ5M [22] parton distribution functions (PDF's) to integrate over rapidity, the total bottom cross section is determined to be $\sigma_{b\bar{b}} = 3.2^{+1.2}_{-1.1}(\text{stat})^{+1.4}_{-1.3}(\text{syst})\mu b$. Various PDF's and bottom mass values are used to evaluate the systematic uncertainty (8%) of the rapidity extrapolation. This result is consistent with our result from the dielectron spectrum, which gave $\sigma_{b\bar{b}} = 3.9 \pm 2.5(\text{stat})^{+3}_{-2}(\text{syst})\mu b$ [23]. FONLL predicts $\sigma_{b\bar{b}} = 1.87^{+0.99}_{-0.67}\mu b$, in agreement with both these experimental results.

The fraction of bottom in heavy flavor electrons is found to be larger than 0.33 with 90% confidence level at $p_T > 5$ GeV/c. Furthermore, the assumption of no bottom suppression directly leads to a lower limit on the nuclear modification factor of single electrons, R_{AA}, of greater than 0.33 with the same confidence level. However, according to our measurements, R_{AA} is $\sim 0.25 \pm 0.05(\text{stat}) \pm 0.05(\text{syst})$ at $5 < p_T < 6$ GeV/c [4] in the 0–10% central Au + Au collisions. At the same time the current level of uncertainty in the measurement precludes us from placing significant limits on the possible energy loss of bottom quarks.

In conclusion, the ratio of the yield of electrons from bottom to that from charm has been measured in $p + p$ collisions at $\sqrt{s} = 200$ GeV. The ratio provides the first measurement of the spectrum of electrons from bottom at RHIC. FONLL calculations [20] agree with this result, which provides an important baseline for the study of heavy quark production in the hot and dense matter created in Au + Au collisions.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We acknowledge support from the Office of Nuclear Physics in DOE Office of Science, NSF and a sponsored research grant from Renaissance Technologies (USA), MEXT and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), MSMT (Czech Republic), IN2P3/CNRS, and CEA (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE (India), ISF (Israel), KRF and KOSEF (Korea), MES, RAS, and FAAE (Russia), VR and KAW (Sweden), U.S. CRDF for the FSU, US-Hungary Fulbright, and US-Israel BSF.

(Dated: March 27, 2009)

Measurements of the azimuthal anisotropy of high-$p_{\rm T}$ neutral pion (π^0) production in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV by the PHENIX experiment are presented. The data included in this paper were collected during the 2004 RHIC running period and represent approximately an order of magnitude increase in the number of analyzed events relative to previously published results. Azimuthal angle distributions of π^0s detected in the PHENIX electromagnetic calorimeters are measured relative to the reaction plane determined event-by-event using the forward and backward beam-beam counters. Amplitudes of the second Fourier component (v_2) of the angular distributions are presented as a function of π^0 transverse momentum ($p_{\rm T}$) for different bins in collision centrality. Measured reaction plane dependent π^0 yields are used to determine the azimuthal dependence of the π^0 suppression as a function of $p_{\rm T}$, $R_{\rm AA}(\Delta\phi, p_{\rm T})$. A jet-quenching motivated geometric analysis is presented that attempts to simultaneously describe the centrality dependence and reaction plane angle dependence of the π^0 suppression in terms of the path lengths of hypothetical parent partons

in the medium. This set of results allows for a detailed examination of the influence of geometry in the collision region, and of the interplay between collective flow and jet-quenching effects along the azimuthal axis.

I. INTRODUCTION

Over the past few years, experiments at the Relativistic Heavy Ion Collider (RHIC) have established that a dense partonic medium is formed in Au + Au collisions at $\sqrt{s_{NN}}$=200 GeV [1, 2, 3, 4]. This medium thermalizes very quickly [1, 5, 6, 7, 8, 9, 10, 11], is extremely opaque to the passage of high-$p_{\rm T}$ particles [12, 13], and the strong coupling of matter in the medium produces a system for which the ratio of shear viscosity to entropy (η/s) approaches zero [14, 15, 16, 17, 18]. Much of the current focus is on the extraction of key transport and thermodynamic characteristics of the matter produced in these collisions. Measurements of high-$p_{\rm T}$ parton propagation in the medium as well as medium-induced modification of the fragmentation parton spectrum and its products provide a critical tool for probing medium properties.

One of the most striking early results from RHIC was the observation of strongly suppressed production of high-$p_{\rm T}$ particles in central Au+Au events compared to appropriately scaled $p + p$ collisions [12, 13]. High-$p_{\rm T}$ partons are formed from hard scattering between the initial colliding partons, and these partons fragment into two or more jets of hadrons. When propagating through a dense volume of deconfined matter, these high-$p_{\rm T}$ partons are expected to scatter from color charges in the medium, losing energy through a combination of gluon bremsstrahlung radiation and collisional energy transfer to partons in the medium. These radiated gluons eventually fragment into hadrons at lower $p_{\rm T}$, resulting in a depletion of the observed yields of hadrons at higher $p_{\rm T}$.

A useful way to quantify the suppression of high-$p_{\rm T}$ hadrons is the nuclear modification factor ($R_{\rm AA}$) where the $p+p$ cross section is scaled by the thickness function $\langle T_{\rm AA}\rangle$ of the two Au nuclei

$$R_{\rm AA}(p_{\rm T}) = \frac{(1/N_{\rm AA}^{\rm evt})d^2N_{\rm AA}^{\pi^0}/dp_{\rm T}dy}{\langle T_{\rm AA}\rangle \times d^2\sigma_{pp}^{\pi^0}/dp_{\rm T}dy}.$$

PHENIX has measured a π^0 $R_{\rm AA}$ close to unity in both peripheral Au + Au collisions and Au+Au collisions [19, 20], consistent with the expectation that these collisions would not produce an extended, dense medium. As the collisions become more central, $R_{\rm AA}$ decreases to about 0.2, indicating a stronger parton energy loss. Furthermore, the measured π^0 $R_{\rm AA}$ is nearly constant as a function of $p_{\rm T}$, for $p_{\rm T} \gtrsim 5$ GeV/c up to the highest currently accessibly $p_{\rm T}$, 20 GeVc [19].

These data can be well reproduced by models that calculate the energy lost by the hard scattered partons as they traverse the dense medium. The amount of energy-loss depends on the density of the medium [21], so measurements of high-$p_{\rm T}$ hadron suppression provide constraints on the transport coefficient $\langle\hat{q}^2\rangle$, a measure of mean transverse momentum squared $\langle k_{\rm T}^2\rangle$ transferred by the medium to a high-energy parton. However, multiple models with different physical assumptions can reproduce the measured $R_{\rm AA}(p_{\rm T})$ [22, 23]. The different models vary widely in how they include the crucial interference terms between multiple-scattering centers as well as the interplay between inelastic, elastic and flavor-changing processes during the parton's passage.

To discriminate between these models we need to increase our experimental control of the path length, since the amount of energy lost by a high-$p_{\rm T}$ parton strongly increases with the distance traveled through the medium. A quadratic dependence on the path length is predicted for a static medium if the dominant energy-loss mechanism is the bremsstrahlung radiation of gluons surviving the destructive interference caused by multiple scattering [22, 23]. For an expanding plasma the quadratic increase should be moderated to a linear dependence [24].

The centrality dependence of $R_{\rm AA}(p_{\rm T})$ offers a probe of the path-length dependence of partonic energy loss. However, we can better test the path-length dependence by studying the azimuthal variation of the high-$p_{\rm T}$ suppression at a fixed centrality. Since the collision zone has a nearly elliptical shape in the transverse plane due to the non-central overlap of the colliding Au nuclei, partons that travel along the short axis of the nuclear overlap region lose less energy and should therefore be less suppressed. The key observable is then the two-dimensional modification factor $R_{\rm AA}(\Delta\phi, p_{\rm T})$, where $\Delta\phi$ is the angle of emission with respect to the event plane. The azimuthal dependence of the spectra can be also parameterized by a Fourier expansion, where up to second order $\frac{dN}{d\Delta\phi} = N_0[1 + 2v_2\cos(2\Delta\phi)]$, with v_2 being called elliptic flow coefficient. While both quantities characterize azimuthal asymmetries, historically and conceptually they have different roots. The notion of elliptic flow is primarily tied to lower $p_{\rm T}$ phenomena ("soft physics"), the domain where particle production is proportional to the number of participating nucleons ($N_{\rm part}$), and positive v_2 arises from the *boost* to the mean $p_{\rm T}$ in the direction where the pressure gradient is highest (along the reaction plane). Conversely, $R_{\rm AA}(p_{\rm T})$ and $R_{\rm AA}(\Delta\phi, p_{\rm T})$ are commonly used to describe high $p_{\rm T}$ behavior (hard scattering, which scales with the number of binary collisions $N_{\rm coll}$). When $R_{\rm AA}$ deviates from unity at high $p_{\rm T}$, it becomes a valuable probe of the *loss* of energy/momentum

*Deceased
†PHENIX Spokesperson: jacak@skipper.physics.sunysb.edu

in a particular direction. However, there is no clear separation between soft and hard regions, and both $R_{\rm AA}$ and v_2 are well-defined in the entire momentum range, so in this sense v_2 is sensitive to differential energy loss at high $p_{\rm T}$.

PHENIX has measured high-$p_{\rm T}$ v_2 for π^0 particles from Au+Au collisions [25]. The energy-loss models that reproduce $R_{\rm AA}(p_{\rm T})$ diverge in their predictions of the azimuthal anisotropy at high $p_{\rm T}$. They generally underpredict the observed azimuthal variation of $R_{\rm AA}(\Delta\phi)$, or equivalently, are unable to describe the $p_{\rm T}$ dependence of v_2 over the full range of $p_{\rm T}$ where one would naively expect them to be applicable [26, 27, 28]. These models include the hydrodynamical evolution of the medium, and therefore the high-$p_{\rm T}$ probe loses energy in a medium that is becoming spatially isotropic with time. Several early papers noticed that the measured v_2 values were larger than what one would expect from a completely opaque almond-shape collision zone [29, 30]. Other early energy-loss calculations came close to reproducing the measured $R_{\rm AA}(\Delta\phi)$ [31, 32], but in these the plasma expansion was not taken into account, which resulted in unrealistically strong azimuthal anisotropy. Another calculation [33] has reproduced $R_{\rm AA}(\Delta\phi)$, but in this model the Au nuclei were parameterized as hard-spheres instead of using a more realistic Woods-Saxon density profile, and this mechanism artificially increases the azimuthal dependence of the energy density.

One potential resolution of the problem with energy loss calculations not reproducing the measured azimuthal dependence of yields is a recent calculation that allowed the high-$p_{\rm T}$ parton to resonantly scatter with the medium [34] (and references therein), increasing the energy lost by a parton at plasma densities that correspond to temperatures near the critical temperature. This produces a sharper dependence of the energy-loss on the spatial variation of the medium's energy density and hence the model is able to simultaneously reproduce both $R_{\rm AA}(p_{\rm T})$ and $R_{\rm AA}(\Delta\phi)$. A critical check will be to examine whether the same parameters work for the full range of collision centralities.

In order to discriminate among all the models that attempt to reproduce $R_{\rm AA}(\Delta\phi, p_{\rm T})$, the experimental challenge is to extend the range and increase the precision of observations which can be used to test different energy-loss models. In this paper we extend the range of published data on $R_{\rm AA}(\Delta\phi)$ [25] by a) reaching higher $p_{\rm T}$, and thereby moving to a $p_{\rm T}$ region that is completely dominated by the fragmentation of hard partons and reducing the possible contribution of particles from recombination [35], b) using finer bins in centrality, thus achieving less averaging of the path length, and c) reducing the statistical and systematic uncertainties to further constrain models. We present in this article measurements using data collected during the 2004 RHIC running period. These data represent a high-statistics sample of Au + Au collisions (approximately 50 times that of the 2002 RHIC running period) and therefore extend our ability to measure $R_{\rm AA}(\Delta\phi)$ and v_2 to much higher $p_{\rm T}$ with better precision.

II. EXPERIMENTAL DETAILS

The data presented in this paper were taken by the PHENIX experiment [36] in 2004 (RHIC Run-4), and represent the analysis of 821M minimum bias Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The detectors involved in this analysis are the beam-beam counters [37] (BBC; triggering, centrality and reaction plane determination), the zero-degree calorimeter [38] (ZDC, centrality determination) and the electromagnetic calorimeter [39] (EMCal, π^0 measurement).

The BBCs are two groups of 64 hexagonal quartz Čerenkov radiator counters with photomultiplier readout surrounding the beampipe 144 cm up- and downstream ("North" and "South") from the center of the nominal collision diamond, covering the $3 < |\eta| < 3.9$ pseudorapidity range and the full azimuth. Coincidence of signals in at least two photomultiplier tubes in both BBCs served as a minimum bias trigger and according to simulations it captured 92% of all inelastic collisions. The size of the total signal in the BBCs increases monotonically with collision centrality at this $\sqrt{s_{NN}}$. The collision vertex z was calculated from the difference between the fastest timing signals in the North and South BBCs, respectively, with $\sigma < 2.0$ cm resolution. Only events with $|z| < 30$ cm were analyzed.

The ZDCs are small tungsten/scintillator hadron calorimeters with quartz fiber lightguides and photomultiplier readout, located between the beampipes at 18 m North and South from the collision point. They measure non-interacting "spectator" neutrons in a cone of about 2 mrad, and their signal is double-valued as a function of centrality (it is low in very central and very peripheral collisions but large at mid-centrality). The correlation of ZDC *vs* BBC signals resolves this ambiguity and allows a precise measurement of the true centrality for all but the most peripheral collisions.

The reaction plane (spanned by the beam direction and the impact vector of the colliding nuclei) is determined event-by-event from the azimuthal charge distribution in the BBCs, after taking into account small nonuniformities (in the response of individual radiators, PMTs, electronics, etc.), using the assumption that over a large number of events the ϕ distribution of per-event reaction planes should be uniform. Due to the large rapidity gap between the central arm ($|\eta| < 0.35$) where π^0s are measured, and the BBCs where the reaction plane is established, we assume that the reaction plane is unbiased and free from auto-correlations. However, the relatively coarse granularity of BBCs affects the resolution. Note that in this analysis precise knowledge of the reaction plane resolution, which depends strongly on centrality, is crucial. This will be discussed in detail in the next Section.

Neutral pions are measured by reconstructing their decay photons ($\pi^0 \rightarrow \gamma\gamma$) in the EMCal. The EMCal consists of 8 sectors at midrapidity ($|\eta| < 0.35$), covering a total of $2 \times 90^\circ$ in azimuth. Six sectors are lead/scintillator (PbSc) sampling calorimeter with photomultiplier readout and 5.5×5.5 cm^2 granularity, two sectors are lead/glass (PbGl) Čerenkov counters with 4×4 cm^2 granularity and photomultiplier readout. The two detectors are $18X_0$ and $16X_0$ radiation lengths deep, respectively, both ensuring essentially full containment of electromagnetic showers in the relevant energy range. The *in situ* energy resolution is well reproduced by simulation both in PbSc and PbGl: the π^0 peak positions and the widths both agree with the data to better than 1 MeV over the entire momentum range. Therefore, the error on the energy (and momentum) scale is less than 1%. Timing resolution σ_t is $\sim$ 450 ps and $\sim$ 650 ps for the PbSc and PbGl, respectively, allowing the rejection of neutrons and antineutrons up to a few GeV/c transverse momentum, which would otherwise be a major source of neutral showers up to a few GeV energy. At sufficiently high transverse momenta, decay photons from a nearly symmetric ($E_{\gamma_1} \approx E_{\gamma_2}$) decay may produce showers in the calorimeter that start to merge into one reconstructed cluster. In the PbSc this effect is first visible around $p_{\rm T} \sim 10$ GeV/c, at the upper end of the $p_{\rm T}$ region considered in this paper. Due to its higher granularity and smaller Molière-radius the PbGl is immune to this "merging" problem up to $p_{\rm T}$ $\sim$15 GeV/c. The hadronic response, timing properties and other sources of systematic errors are very different for the two calorimeter types. Therefore, when extracting the ϕ-integrated $R_{\rm AA}$, which serves as absolute normalization, the PbSc and PbGl were analyzed separately and the results combined to decrease the total systematic uncertainty.

III. DATA ANALYSIS

A. Centrality

As mentioned, the minimum-bias trigger in the Run-4 PHENIX configuration is supplied by the BBCs, and the correlation of the charge deposited in the BBCs with energy deposited in the ZDCs provided a determination of the centrality of the collision. The elliptic flow measurement presented in this paper is measured in seven bins of the centrality range 0-92%, with lowest corresponding to the most central: 0-5%, 5-10%, 10-20%, 20-30%, 30-40%, 40-50%, and 50-60%. In addition, the combined ranges 0-20%, 20-40%, 40-60%, and minimum bias bins are included. For the yields with respect to the reaction plane, the centralities presented are 0-10%, 10-20%, 20-30%, 30-40%, 40-50%, 50-60%. Finally, the $R_{\rm AA}$ versus nuclear path length result excludes the most central bin due to its smaller intrinsic ellipticity (the average path length is insensitive to $\Delta\phi$).

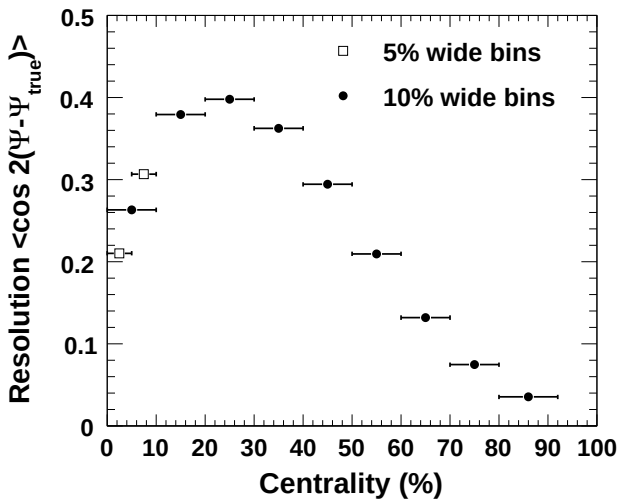

FIG. 1: Reaction plane resolution correction as a function of centrality.

B. Reaction plane determination

The technique used to determine the reaction plane on an event-by-event basis is the same used in previous PHENIX analyses [14, 40, 41]. The quartz radiators of each counter are arranged in approximately concentric circles around the beam axis. The light collected in the photo-multiplier tubes (PMTs) allows for an estimate of the number of charged particles passing through the detector.

The number of charged particles at a given PMT position, N_i, is weighted in a manner to reduce the bias of the inner rings and used to measure the orientation of the reaction plane from the formula

$$\tan(2\Psi) = \frac{\sum_i w_i N_i \sin(2\phi_i) - \langle \sum_i w_i N_i \sin(2\phi_i) \rangle}{\sum_i w_i N_i \cos(2\phi_i) - \langle \sum_i w_i N_i \cos(2\phi_i) \rangle}, \quad (1)$$

where ϕ_i is the nominal azimuth of the radiator. Subtraction of the average centroid removes biases due to various detector effects. A final flattening technique is used to remove the residual non-uniformities in the distribution of angles.

To estimate the resolution of the reaction plane measurement, we use the sub-event technique [42]. The approach consists of dividing the event up into two sub-events roughly equal in size. The two individual BBCs provide a natural sub-event division, so we analyze the distribution of event-by-event differences between the reaction plane angles measured in the north and south counters, $\Delta\Psi = \Psi_N - \Psi_S$. In the presence of pure flow, this distribution takes the form [42]:

$$\frac{dN}{d\Delta\Psi} = \frac{e^{-\chi^2}}{2}\left\{\frac{2}{\pi}(1+\chi^2) + z\left[I_0(z) + \mathrm{L}_0(z)\right] + \chi^2\left[I_1(z) + \mathrm{L}_1(z)\right]\right\}. \quad (2)$$

where $z = \chi^2 \cos(2\Delta\Psi)$ and the functions I_n and $\mathrm{L_n}$ are the modified Bessel functions of the first kind and modified Struve functions, respectively. The parameter χ describes the dispersion of the flow $\vec{Q}$ vector and thus determines the correction required for the reaction plane resolution. Since $\Delta\Psi$ represents the whole-event difference distribution and we are dealing with sub-events with roughly half the multiplicity of the event, we replace $\chi \to \chi/\sqrt{2}$ in Eq. 2 and fit this function to the measured $\Delta\Psi$ distribution to extract χ. The resulting value is then used to evaluate the resolution of the event-plane of n^{th} order [42]:

$$\langle \cos n\left(\Psi - \Psi_{RP}\right)\rangle = \frac{\sqrt{\pi}}{2}\chi e^{-\frac{\chi^2}{2}}\left[I_{\frac{n-1}{2}}\left(\frac{\chi^2}{2}\right) + I_{\frac{n+1}{2}}\left(\frac{\chi^2}{2}\right)\right] \quad (3)$$

where the true reaction plane orientation is denoted by Ψ_{RP} and the observed orientation by Ψ. Figure 1 shows the resolution correction obtained using the above-described procedure as a function of centrality. Both 5% and 10% wide bins are shown for comparison.

Eq. 2 is derived under the assumption that the azimuthal distributions are free of non-flow effects. Due to the large rapidity gap between the BBCs and the central arm region, it is expected that particles observed in the BBCs have no correlation with those measured in the central arm detectors. PYTHIA [43] studies have been used to confirm that jets observed in the central arm have negligible effect on the reaction plane measurement from the BBCs[44].

C. Neutral pion measurement

Measurement of neutral pions has played a critical role in the study of high-p_{T} phenomena at RHIC, and especially by PHENIX [12, 19, 25]. The two-particle decay channel $\pi^0 \to \gamma + \gamma$ provides a clean signal of identified hadrons out to the highest p_{T} regions.

EMCal showers are found by clustering contiguous towers with energy above a threshold energy (10 MeV) and requiring at least 50 MeV in the tower with highest energy deposit. The impact position is calculated from the positions of the participating towers weighted by the logarithm of deposited energy. The energy of the cluster is corrected for non-perpendicular incidence – the angle being derived by assuming a straight path between the actual vertex and the calculated impact point – as well as nonlinearities [25]. In high-multiplicity events such as central Au + Au collisions, there is an increasing probability for clusters to overlap (one tower accumulates energy from more than one particle), which can distort an energy measurement from a simple sum over contiguous towers. To mitigate this effect, the EMCal clustering algorithm also provides a quantity called *ecore*, which is determined by extrapolating the "core" energy represented by the central four or five towers in the cluster, assuming an electromagnetic shower profile. The energy- and impact angle- dependent shower profile is a model developed from and checked against beam test data. In this way, *ecore* provides a more realistic measurement of the shower energy, less prone to contributions from accidental overlaps (particles hitting close enough they deposit energy in the same towers) than a simple energy sum of participating towers would be. We use this *ecore* for the energy of reconstructed clusters in this analysis.

The invariant mass of a photon pair γ_i, γ_j as measured in the EMCal is calculated from the energy of the clusters and their measured position:

$$m_{\gamma_i\gamma_j} = \sqrt{(P^2_{\gamma_i} + P^2_{\gamma_j})} = \sqrt{2E_iE_j\cos(1-\theta_{ij})} \quad (4)$$

where θ_{ij} is the opening angle between the two photons and $m_{\gamma_i\gamma_j}$ is equal to the π^0 mass for photons from the decay of the same π^0. Since the photons from the π^0 are not tagged, such pairs have to be formed from each photon pair in the event where the pair momentum falls in a particular p_{T} bin, and some of these pairs might accidentally reproduce the π^0 mass as well (combinatorial background), particularly at lower p_{T} and higher centralities (multiplicities). Since π^0s cannot be uniquely identified, raw π^0 yields are extracted statistically, by subtracting the combinatorial background from the invariant mass distribution.

A well-known technique to reduce the combinatorial background is to place a cut on the energy asymmetry of the pair, as defined by:

$$\alpha = \frac{|E_1 - E_2|}{E_1 + E_2} = \beta|\cos\theta^*|. \quad (5)$$

Because the angular distribution $d\sigma/d\cos\theta^*$ of the pairs in the rest frame of the π^0 is uniform, the asymmetry distribution should be flat. However, due to the steeply falling photon spectrum, fake (non-correlated) pairs which still give the proper π^0 mass are strongly peaked towards $\alpha = 1$. A pair of clusters in the EMCal is considered a neutral pion candidate only if the pair's

asymmetry is less than 0.8. In addition, the two photons are required to be separated by at least 8 cm for the combination to be considered as a π^0 candidate.

There remains a non-trivial background contribution which passes these cuts: pairs of photons from different π^0s, or, more generally, from pairs of uncorrelated clusters which pass the photon identification cuts and accidentally give an invariant mass near the true π^0 mass. This remaining combinatorial background is estimated and subtracted using the event mixing method. The procedure involves forming pairs from different events, which will by definition be uncorrelated. Each photon candidate is combined with all the photon candidates in previous events stored in memory. In order to replicate the background from uncorrelated pairs within the same event as closely as possible in the mixed events, mixing is performed within bins of centrality, vertex z position, and reaction plane orientation. Since all events analyzed are minimum-bias, no special steps are needed to avoid the distortions of the mixed-event background by the trigger requirement. All cuts applied to the combinations of same event pairs are also applied to mixed-event pairs. The number of events buffered determines the statistics of the event-mixed distributions, chosen as a tradeoff between desired statistical accuracy and computational resources. The data presented in this article are mixed with five previous events (in each centrality, vertex, and reaction plane bin).

For a given $p_{\rm T}$ bin, the mixed-event mass distribution is normalized to the same-event distribution in a region away from the π^0 mass peak. The normalization region is 0.25–0.45 GeV/c^2 for $p_{\rm T} < 6.0$ GeV/c and 0.21–0.45 GeV/c^2 otherwise. Fig. 2 shows an example of this subtraction process for two $p_{\rm T}$ ranges in two centrality bins.

The scaled background distribution is then subtracted from the same-event pair distribution. The subtracted result thus represents a sample of real π^0s. The peak is fit to a Gaussian to determine its width and mean position. The raw yield of π^0s is determined by integrating the counts in a window of $\pm 2\sigma$ around the mean. The width and mean are recorded and parameterized as a function of $p_{\rm T}$ and centrality based upon this ϕ-integrated, large sample. The positions and widths from this parameterization are then used when we extract the (much smaller) raw yields in bins of angle $\Delta\phi$ with respect to the reaction plane. The maximum variation of the yields (multiplicities) with $\Delta\phi$ is only about a factor of 2, and therefore the means and widths are not expected to change substantially. Furthermore, the statistics are much poorer in the $\Delta\phi$ bins, which would make individual π^0 fits unreliable.

There is a residual background in the invariant mass distributions even after the mixed-event distribution has been removed, especially at lower $p_{\rm T}$ (below ~ 2 GeV/c). This is due to correlations that event mixing cannot reproduce, like the "sub-event structure" due to the presence of jets or multiple, close-by showers from an annihilating anti-neutron, or imperfections of the reconstruction algorithm, such as cluster merging, cluster splitting, and a host of other contributions. Much of the residual background is excluded by starting the fit at 0.09 GeV/c. What is left is accounted for by including a first-order polynomial in the fits to the (already background-subtracted) invariant mass distribution, and subtracting its integral from the raw π^0 yield (see Fig. 2). In the more central events, the peak deviates slightly from gaussian on the high mass side, due to overlapping clusters. The use of *ecore* mitigates this effect, and the systematic uncertainty on yield extraction arising from the remaining asymmetry has been estimated to be 3-4% [19].

D. Elliptic flow measurement

To obtain the azimuthal angle dependence of π^0 production, we measure raw π^0 yields in a given $p_{\rm T}$ bin as a function of the π^0 angle with respect to the reaction plane orientation in six equally-spaced bins of $\Delta\phi = \phi(\pi^0) - \Psi_{RP}$ covering the range $0 < \Delta\phi < \pi/2$. The π^0 yields are measured in each $\Delta\phi$ bin using the same procedure described in III C for the reaction-plane inclusive measurement except that the mass fits are not performed in each $\Delta\phi$ bin. Instead, the peak integration window is set $\pm 2\sigma$ around the mean where the width and mean are taken from the inclusive analysis. The resulting raw π^0 angular distribution $dN/d\Delta\phi$ can then be fit to determine the strength of the modulation in the yield. Because the PHENIX BBCs have uniform azimuthal coverage, the π^0 measurements have uniform acceptance in $\Delta\phi$ when averaged over a large event sample, despite the limited azimuthal acceptance of the PHENIX electromagnetic calorimeters.

Assuming elliptic flow is the dominant source of $\Delta\phi$ variation in the π^0 yields, we perform a fit to the angular distributions of the form

$$\frac{dN}{d\Delta\phi} = N_0(1 + 2v_2^{\rm meas}\cos 2\Delta\phi). \qquad (6)$$

We use an analytic linear χ^2 fitting procedure that matches the integral of Eq. 6 over each of the $\Delta\phi$ bins to the measured π^0 yield within the corresponding bin. In the definition of the χ^2 function we account for non-zero covariances between the yields in the different $\Delta\phi$ bins resulting from the limited acceptance of the calorimeters. These covariances have been evaluated separately for each $p_{\rm T}$ and centrality bin. Examples of the raw $dN/d\Delta\phi$ distributions and the results of the χ^2 fits are shown in Fig. 3. The resulting $v_2^{\rm meas}$ values are then corrected upward to account for reaction plane resolution using correction factors described in Section III B.

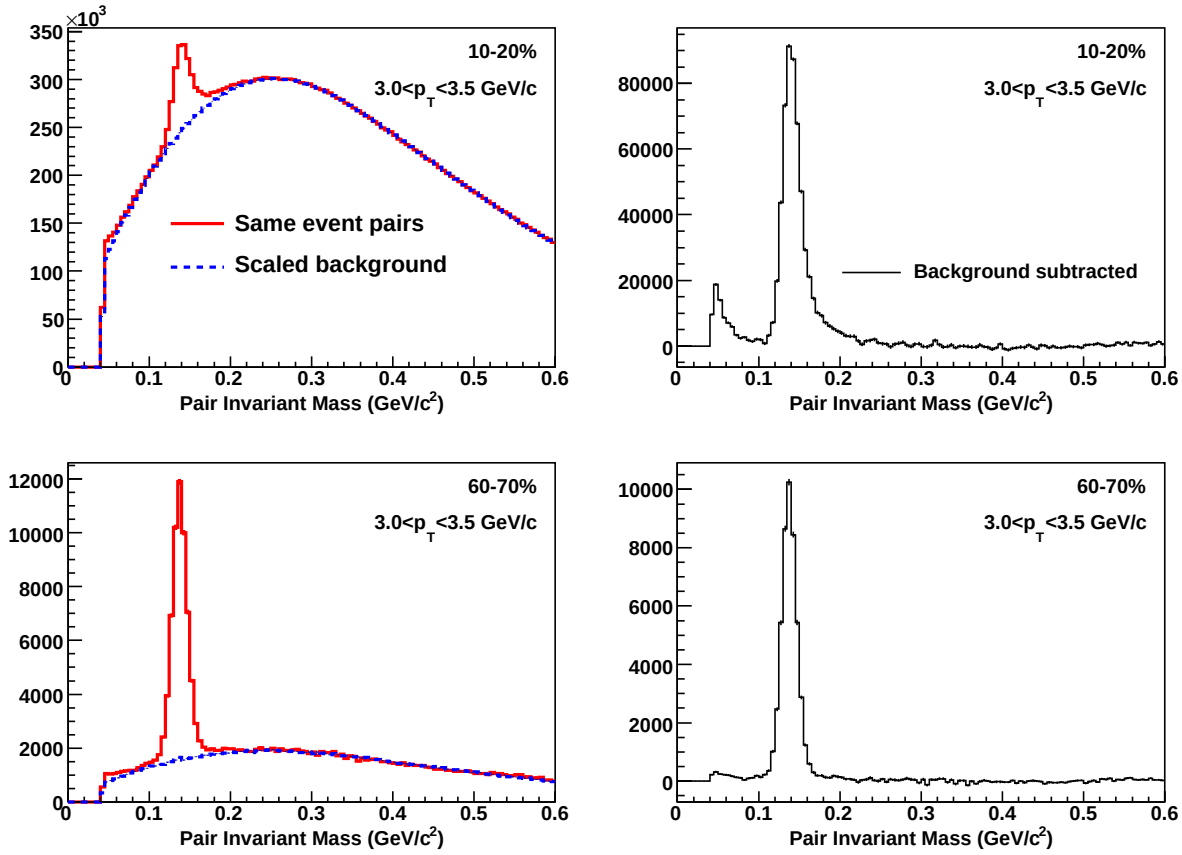

FIG. 2: Invariant mass distributions at moderate $p_{\rm T}$ and two different centralities. Left panels: same event and normalized mixed event distributions. Right panel: the subtracted distributions, which are then fitted with the sum of a first degree polynomial and a Gaussian.

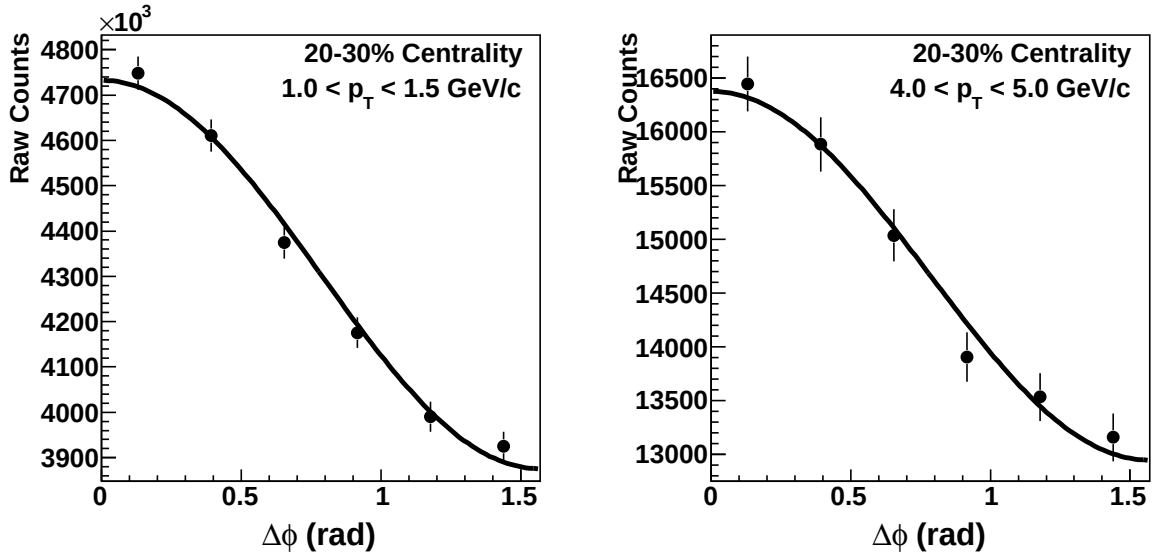

FIG. 3: Example of analytic fitting of raw $dN/d\Delta\phi$ distributions

E. $R_{\rm AA}$ ($\Delta\phi$) measurement

The nuclear modification factor $R_{\rm AA}$ has played a critical role in understanding energy loss mechanisms. $R_{\rm AA}$ is defined as

$$R_{\rm AA}(p_{\rm T}) = \frac{(1/N_{\rm AA}^{\rm evt})d^2N_{\rm AA}^{\pi^0}/dp_{\rm T}dy}{\langle T_{\rm AA}\rangle \times d^2\sigma_{pp}^{\pi^0}/dp_{\rm T}dy} \quad (7)$$

where $\langle T_{\rm AA}\rangle$ is the mean Glauber overlap function for the centrality being analyzed:

$$\langle T_{\rm AA}\rangle \equiv \frac{\int T_{\rm AA}(\mathbf{b})d\mathbf{b}}{\int (1-e^{-\sigma_{pp}^{inel}T_{\rm AA}(\mathbf{b})})d\mathbf{b}}, \quad (8)$$

from which the mean number of binary nucleon-nucleon collisions can be calculated, $\langle N_{\rm coll}\rangle = \sigma_{pp}^{inel}\langle T_{\rm AA}\rangle$.

For each $p_{\rm T}$ bin, we can calculate the ratio

$$R(\Delta\phi_i, p_{\rm T}) = \frac{N(\Delta\phi_i, p_{\rm T})}{\sum_{i=1}^{6} N(\Delta\phi_i, p_{\rm T})} \quad (9)$$

where $N(\Delta\phi_i, p_{\rm T})$ is the number of π^0s observed in the given $(\Delta\phi_i, p_{\rm T})$ bin. Since the BBC is azimuthally symmetric the PHENIX acceptance has no $\Delta\phi$ dependence, there should be no azimuthal dependence to efficiency and acceptance corrections. As a result,

$$R_{\rm AA}(\Delta\phi_i, p_{\rm T}) = R(\Delta\phi_i, p_{\rm T}) \times R_{\rm AA}(p_{\rm T}). \quad (10)$$

Thus, we can use measured inclusive $R_{\rm AA}(p_{\rm T})$ to convert $R(\Delta\phi_i, p_{\rm T})$ to $R_{\rm AA}(\Delta\phi_i, p_{\rm T})$. Since the detector efficiency and acceptance corrections are already contained in $R_{\rm AA}(p_{\rm T})$, there is no need to apply them to $R(\Delta\phi_i, p_{\rm T})$.

Prior to calculating $R_{\rm AA}(\Delta\phi_i, p_{\rm T})$ we correct the ratios $R(\Delta\phi_i, p_{\rm T})$ for the finite reaction plane resolution using an approximate unfolding technique. For a pure flow $\Delta\phi$ distribution, we can express the influence of the resolution broadening on the measured $\Delta\phi$ distribution

$$R^{\rm meas}(\Delta\phi_i, p_{\rm T}) = R^{\rm true}(\Delta\phi_i, p_{\rm T})\left[\frac{1+2v_2^{\rm meas}\cos(2\Delta\phi)}{1+2v_2^{\rm corr}\cos(2\Delta\phi)}\right], \quad (11)$$

where according to the results of Section III B $v_2^{\rm meas} = v_2^{\rm corr}/\langle\cos 2(\Psi-\Psi_{RP})\rangle$. Then, if the measured $\Delta\phi$ distribution resulted from pure elliptic flow, it could be corrected back to the true distribution by

$$R^{\rm corr}(\Delta\phi_i, p_{\rm T}) = R^{\rm meas}(\Delta\phi_i, p_{\rm T})\left[\frac{1+2v_2^{\rm corr}\cos(2\Delta\phi)}{1+2v_2^{\rm meas}\cos(2\Delta\phi)}\right]. \quad (12)$$

As shown above, the general features of the measured π^0 $\Delta\phi$ distributions are well-described by pure $\cos(2\Delta\phi)$ modulation. However, we wish to preserve in our measurements of the azimuthal dependence of the π^0 production the full shape of the measured $\Delta\phi$ distribution, including possible small non-elliptic contributions. For this purpose, the correction described in Eq. 12 applied to the data represents an approximation to a full unfolding procedure that becomes exact when the distribution is purely $\cos(2\Delta\phi)$ in form. We have checked for a few cases that a full unfolding procedure applied to the measured $dN/\Delta\phi$ distributions using singular value decomposition regulation of the response matrix reproduces the correction in Eq. 12. From the corrected ratios, $R^{\rm corr}(\Delta\phi_i, p_{\rm T})$, we use Eq. 10 to obtain $R_{\rm AA}(\Delta\phi_i, p_{\rm T})$.

IV. RESULTS

A. Elliptic flow coefficient

The results of the v_2 measurements using the methods described in Sec. III D are presented in Fig. 4 as a function of $p_{\rm T}$ for different centrality bins. The data points in the figure are plotted at the mean π^0 $p_{\rm T}$ in bins of width $\Delta p_{\rm T} = 0.5$ GeV/c for $p_{\rm T} < 4$ GeV/c and $\Delta p_{\rm T} = 1$ GeV/c for $p_{\rm T} > 4$ GeV/c. The error bars shown on the v_2 data points were obtained by multiplying the raw v_2 fit errors (see Section III D) by the same reaction plane resolution correction factor applied to the v_2 values themselves. The error bars, then, represent uncorrelated statistical errors on the measured v_2 values arising from statistical errors on the $dN/d\Delta\phi$ data points used in the fits (these errors would be categorized as Type A uncertainties in the framework described in [45] or $p_{\rm T}$-uncorrelated). Systematic errors on the v_2 measurements due to the reaction plane determination procedure and from systematic uncertainties in the reaction plane resolution correction are represented in Figs. 4,5 by filled boxes, which for most data points are similar in size or smaller than the data points (these uncertainties are classified as Type B [45] or $p_{\rm T}$-correlated).

Figure 5 shows $v_2(p_{\rm T})$ for four centrality ranges, obtained by combining data from the centrality bins shown in Fig. 4. The corrected $dN/d\Delta\phi$ distributions from individual centrality bins were summed over a given centrality range and then fit to obtain the corrected v_2 values shown in Fig. 5. The reaction plane resolution correction produces correlated errors in the corrected $dN/d\Delta\phi$ distributions for each original centrality bin, and these correlated errors persist in the summed $dN/d\Delta\phi$ distribution. These correlated errors are not included in the statistical errors for the fit to the combined $dN/d\Delta\phi$ distribution, but their impact on the final v_2 value is estimated separately by evaluating the changes in the v_2 fit parameter that result from adding to the summed $dN/d\Delta\phi$ values ±1 σ of the correlated errors. Since this estimated uncertainty results from the statistical uncertainties on the v_2 values for the original centrality bins, we include the 1σ bounds obtained from this procedure in the statistical error on the v_2 values for the combined centrality bins. Systematic errors for the combined bins are plotted similarly to those in Fig. 4.

The results presented here nearly double the $p_{\rm T}$ range of previous PHENIX π^0 v_2 measurements from RHIC

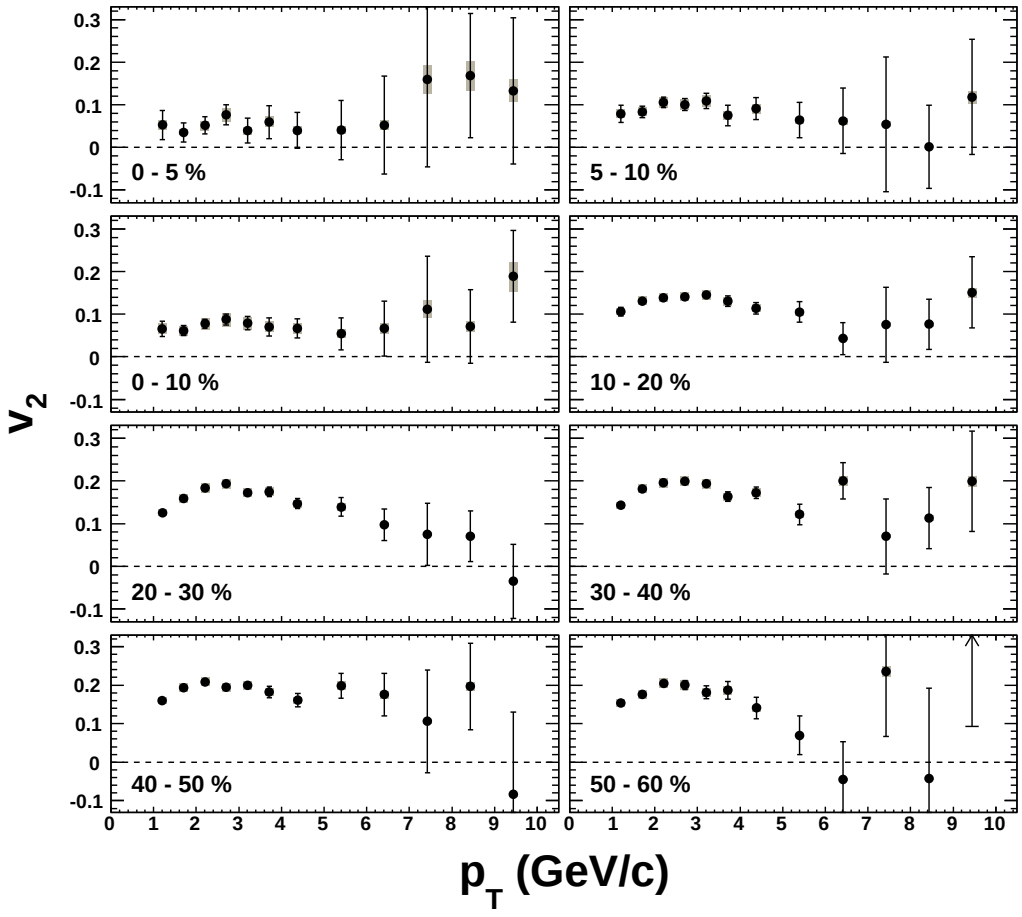

FIG. 4: π^0 v_2 versus $p_{\rm T}$ for centralities 0-5%, 5-10%, 0-10%, 10-20%, 20-30%, 30-40%, 40-50%, and 50-60%. The arrow in the 50-60% panel shows the lower limit of the uncertainty on the data point, which lies outside the bounds of the plot.

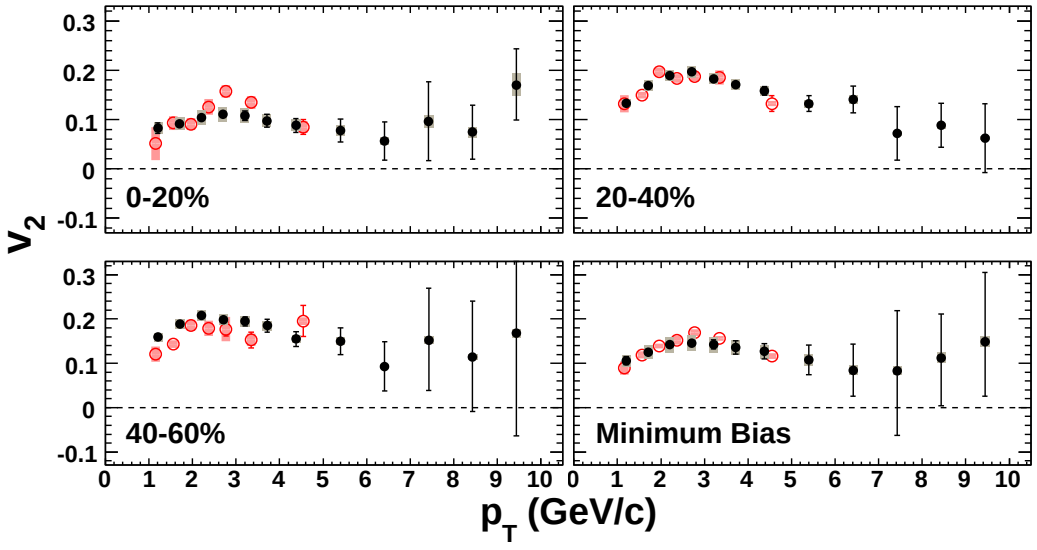

FIG. 5: (Color online) π^0 v_2 versus $p_{\rm T}$ for centralities 0-20%, 20-40%, 40-60%, and minimum bias. The closed (black) circles are data presented in this paper, and the open (red) circles are previously published results [40].

Run-2 [40]. Those measurements are shown for comparison purposes in Fig. 5. Good agreement is seen between the Run-4 measurements presented here and the Run-2 results except in the 40-60% centrality bin where the new v_2 measurements are systematically higher by $\sim 30\%$. This difference is attributed to improved reaction plane resolution corrections for the 40-60% centrality bin resulting from the combining of *corrected* $dN/\Delta\phi$ distributions from smaller centrality bins. This summing procedure better handles the rapid variation of reaction plane resolution with centrality in mid-central to peripheral collisons. Furthermore, we have cross-checked the procedure using 5% bins, verifying the combined result reproduces the data analyzed in wider bins. The previous Run 2 analysis did not have a sufficiently large data sample to allow the use of separate 40-50% and 50-60% bins, and therefore the reaction plane resolution correction was necessarily less accurate. The measured v_2 values presented in Fig. 4 and Fig. 5 are also consistent with previously published PHENIX charged pion v_2 measurements [14, 40].

The results in Figures 4 and 5 show a rapid increase of v_2 with increasing $p_{\rm T}$ at low $p_{\rm T}$, a maximum in the range $2 < p_{\rm T} < 3$ GeV/c, and then at higher $p_{\rm T}$ a decrease of v_2 with increasing $p_{\rm T}$. An increase in v_2 at low $p_{\rm T}$ is well-established [46, 47, 48] and is understood to result from the collective elliptic flow of the medium generated by the initial spatial anisotropy of the collision zone. Hydrodynamical models have been successful in quantitatively describing the pion $v_2(p_{\rm T})$ in the region $p_{\rm T} < 1.5$ GeV/c. However, it has also been well-established that the pion $v_2(p_{\rm T})$ deviates from the hydrodynamic prediction above 1.5 GeV/c, a result that is understood to imply the contribution of hard processes, distortions of the spectrum due to recombination at freeze-out, and/or effects from dispersive hadronic evolution after freeze-out. Thus, a change in the variation of v_2 with $p_{\rm T}$ near $p_{\rm T} \sim 2$ GeV/c is not unexpected. If the large v_2 values at lower $p_{\rm T}$ are interpreted as resulting from soft, collective mechanismsm, then a decrease in v_2 for $p_{\rm T} > 3$ GeV/c suggested by the data in Fig. 4 would naturally reflect an increasing contribution of hard processes with smaller v_2.

To statistically test the significance of the decrease of v_2 with $p_{\rm T}$, we show in Fig. 6 the results of linear fits to the high-$p_{\rm T}$ v_2 values for the 20-30% and 30-40% centralities. The panels on the left-hand side of Fig. 6 display a series of fits beginning at higher $p_{\rm T}$ values, the first fit starting at the $p_{\rm T}$ near the maximum v_2, $p_{\rm T} = 2.5$ GeV/c. The right-hand panels show the 1-σ limits of the functions for the three fits in the series, calculated from the 1-σ variation of the two fit parameters (and including the covariance between them). The results of the fits indicate that the decrease of v_2 with $p_{\rm T}$ at higher $p_{\rm T}$ is statistically significant, though the data points for $p_{\rm T} > 5$ GeV/c are not sufficient by themselves to establish a trend. We can state, however, that the points for $p_{\rm T} > 5$ GeV/c are consistent with the linear decrease obtained including the lower $p_{\rm T}$ points. A question we would like to answer, then, is whether the data show any indications of devation from a monotonic decrease in $v_2(p_{\rm T})$ indicating the transition to a quenching-dominated azimuthal variation.

A complete understanding of $v_2(p_{\rm T})$ over the measured $p_{\rm T}$ range therefore requires the treatment of the transition from soft to hard dominated physics. According to the above discussion, in the $p_{\rm T}$ range where v_2 is maximum, particle production is likely not dominated by hard processes and the reduction of v_2 with increasing $p_{\rm T}$ indicates increasing hard-scattering contributions (or decreasing soft contamination). Motivated by this general argument, we have attempted to describe the results in Figs. 4 and 5 by a functional form

$$v_2(p_{\rm T}) = \left(\frac{(p_{\rm T}/\lambda)^m}{1+(p_{\rm T}/\lambda)^m}\right)\left(a + \frac{1}{p_{\rm T}^n}\right). \qquad (13)$$

The first term is intended to describe a rapidly rising and saturating soft v_2 resulting from collective motion while the second term represents a rapidly falling soft/hard ratio. The additive constant in the second term represents an asymptotic v_2 that could describe a constant or slowly varying azimuthal-dependent quenching. We show in Figs. 7-8 the optimum fits to the full set of $v_2(p_{\rm T})$ values in the different centrality bins and the result of 1σ variation of the fit parameters taking into account the complete covariance matrix from the fits.

The fits to the data show that the measured $p_{\rm T}$ dependence of the π^0 v_2 is qualitatively compatible with a description of the of low and intermediate $p_{\rm T}$ region in terms of a collective flow modulation diluted by a decreasing relative soft contribution with increasing $p_{\rm T}$. Assuming this picture, it is then important to determine at what $p_{\rm T}$ the contamination from the soft production no longer dominates the measured $\Delta\phi$ variation of π^0 yield. For most of the centrality bins, the fits suggest that v_2 decreases over most of the measured $p_{\rm T}$ range albeit with a decreasing slope at higher $p_{\rm T}$. The central bins are compatible with v_2 continuing to decrease beyond the measured $p_{\rm T}$ range although the 1σ uncertainty bands also accommodate v_2 saturating within the measured range. The more peripheral bins (30-40% and 40-50%) suggest that the v_2 has reached a nearly $p_{\rm T}$ independent value by ~ 5 GeV/c. The 50-60% centrality bin has sufficient fluctuations that little can be inferred from the $p_{\rm T}$ dependence of v_2 in that centrality bin. In all of the centrality bins, the data are consistent with a smooth reduction of $v_2(p_{\rm T})$ from a maximum to a nonzero value at high $p_{\rm T}$ with that value increasing in more peripheral collisions as would be expected from quenching in an increasingly anisotropic medium. While the functional form in Eq. 13 can describe the $p_{\rm T}$ variation of v_2 within the range of the current data and within the statistical fluctuations of the data points, it is possible that this description will fail at higher $p_{\rm T}$ with improved statistics. In fact, a statistically significant deviation of $v_2(p_{\rm T})$ from the form in Eq. 13 might provide the most direct evidence of the dominance of quenching effects in

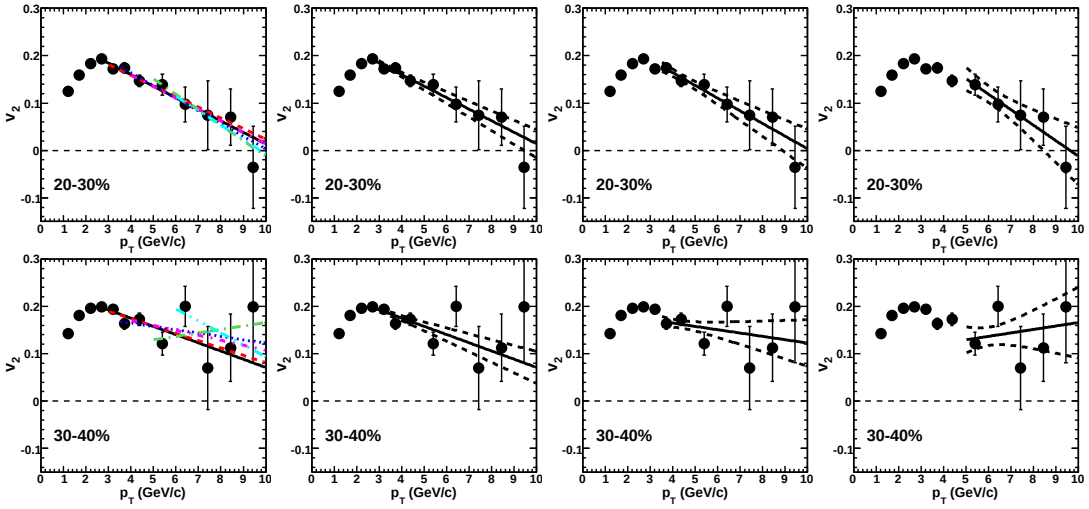

FIG. 6: (Color online) v_2 versus $p_{\rm T}$ for 20-30% and 30-40% centralities, with fits of the high-$p_{\rm T}$ data to a first order polynomial. From right to left, the first panel shows the series of fits, with each fit starting with a successively higher $p_{\rm T}$. The second, third, and fourth panels show selected fits with uncertainty bands based on the 1-σ variation of the fit parameters, including their covariance.

determining v_2.

B. Nuclear modification factor with respect to the reaction plane

The nuclear modification factor as a function of $\Delta\phi$ for six centrality bins is shown in Figs. 9-14. The closed circles represent the $\Delta\phi$-dependent measurements described in this paper while the open circles positioned at $\Delta\phi = \pi/4$ represent the inclusive $R_{\rm AA}$ measurement [19]. In both cases statistical uncertainties (i.e. Type A) are represented by the error bars. For the inclusive $R_{\rm AA}$ measurement, the total systematic uncertainties (or Type C [45]) are shown by the boxes. The upper and lower 1σ ranges of the correlated statistical uncertainties (i.e. Type B) on the $R_{\rm AA}(\Delta\phi)$ measurements resulting from the reaction plane resolution correction are shown by the (blue) solid and (red) dashed lines. For all bins except the 0-10% centrality bin a dotted line is plotted at $R_{\rm AA} = 1$ for reference. We note that by construction, the average $R_{\rm AA}(\Delta\phi)$ from the reaction plane dependent measurements must be equal to the inclusive $R_{\rm AA}$.

The results in the Figs. 9-14 show that the in-plane π^0 suppression is generally weaker and varies more rapidly with $p_{\rm T}$ than the suppression for π^0s produced at larger angles. As the collisions become more peripheral (for example, 50-60%), the small suppression seen in the inclusive $R_{\rm AA}$ almost vanishes for π^0s emitted close to the reaction plane. In a previous analysis [25], it was observed that the in-plane $R_{\rm AA}$ even exceeded unity for peripheral collisions; these data exhibit no such enhancement. However, the results presented in this article agree within systematic errors with previously reported data.

The $R_{\rm AA}(\Delta\phi)$ results are combined in Fig. 15 that shows the $p_{\rm T}$ dependence of the $R_{\rm AA}$ in each of the six $\Delta\phi$ bins included in this analysis. We use a semi-log scale so that the reduction of the $\Delta\phi$-integrated $R_{\rm AA}$ in more

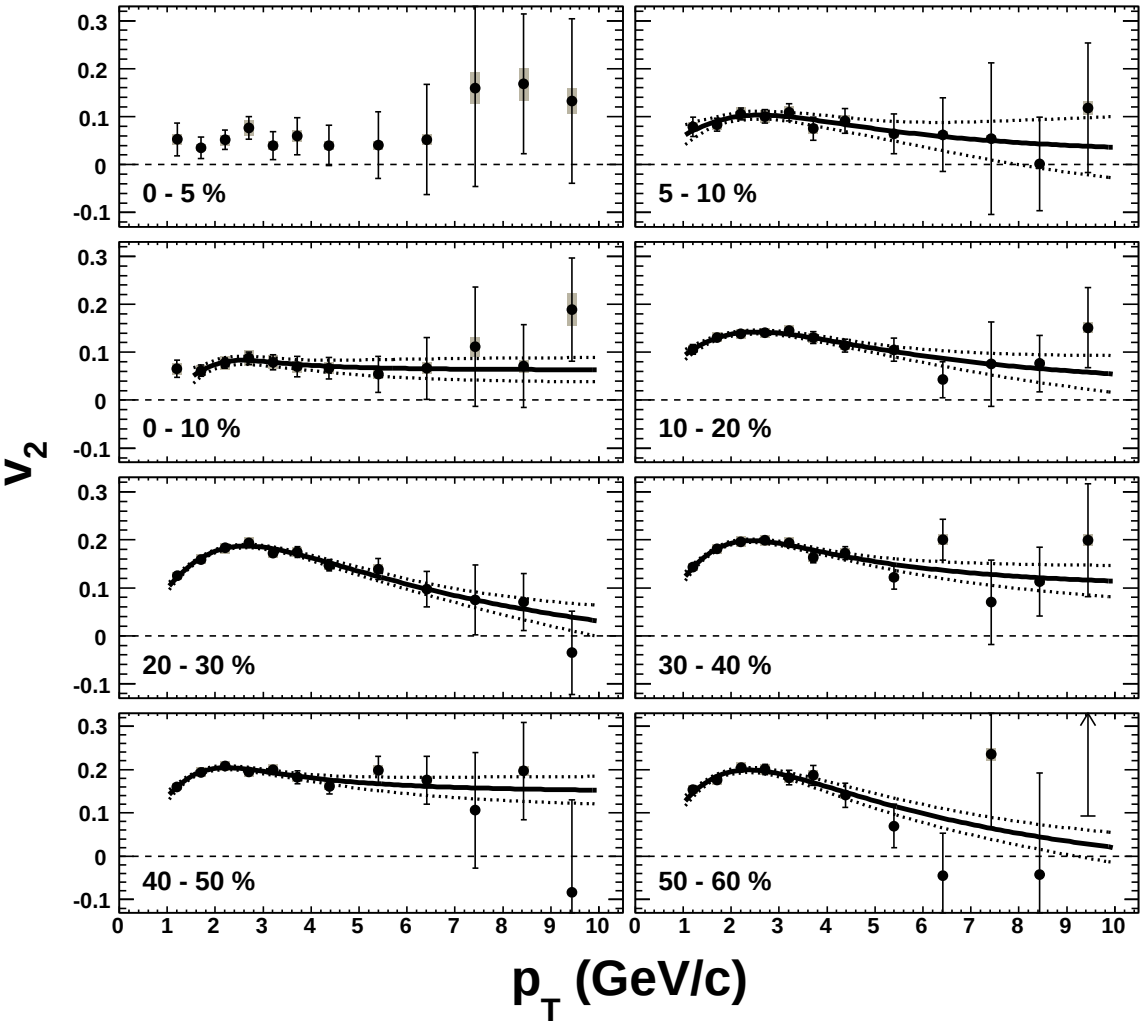

FIG. 7: π^0 v_2 versus $p_{\rm T}$ for centralities 0-5%, 5-10%, 0-10%, 10-20%, 20-30%, 30-40%, 40-50%, and 50-60%. The arrow in the 50-60% panel shows the lower limit of the uncertainty on the data point, which lies outside the bounds of the plot. The solid lines represent the fit to the data, Eq. 13. The dashed lines represent the 1 σ deviations of the fit function. See text for more details.

central collisions does not confuse the interpretation of the results. For clarity, the results from the 20-30%, 30-40%, 40-50%, and 50-60% centrality bins are shown on linear plots in Fig. 16.

The $R_{\rm AA}(p_{\rm T})$ results exhibit a peak near 2 GeV/c, which becomes more prominent for more central collisions. The peak is strongest in the 0-10% bin where there is little modulation of the $\Delta\phi$ distributions at low or high $p_{\rm T}$, so the peak cannot be directly attributed to elliptic flow. The peak in $R_{\rm AA}$ near 2 GeV/c is much weaker in the more peripheral (40-50% and 50-60%) centrality bins, particularly for π^0s produced at larger $\Delta\phi$, and the primary variation seen in these peripheral bins with increasing $\Delta\phi$ is a reduction in $R_{\rm AA}$ that is only weakly $p_{\rm T}$ dependent.

For the intermediate centrality bins (10-20% through 30-40%) the peaking in $R_{\rm AA}$ is seen in all $\Delta\phi$ bins, but is much stronger in the in-plane bins. For these intermediate centralities and for $p_{\rm T}$ values above the peak in $R_{\rm AA}$ ($p_{\rm T} \gtrsim 3$ GeV/c), the $R_{\rm AA}$ for π^0s produced at angles normal to the reaction plane is nearly constant with $p_{\rm T}$ while the $R_{\rm AA}$ for π^0s produced at small angles from the reaction plane decreases rapidly with increasing $p_{\rm T}$. The near constancy of the out-of-plane $R_{\rm AA}$ together with the rapid reduction in in-plane $R_{\rm AA}$ indicates that in the intermediate centrality bins, the v_2 and inclusive $R_{\rm AA}$ decrease simultaneously with increasing $p_{\rm T}$ such that $R_{\rm AA}(\pi/2, p_{\rm T}) = R_{\rm AA}(p_{\rm T})(1 - 2v_2)$ is approximately constant. We will argue below that a correlation between $R_{\rm AA}$ and v_2 may naturally result from the underlying physics responsible for the azimuthal variation of the particle yields. However, we observe that a simultaneous reduction in integrated $R_{\rm AA}$ and v_2 suggested by the more central $R_{\rm AA}(p_{\rm T})$ data would be contrary to

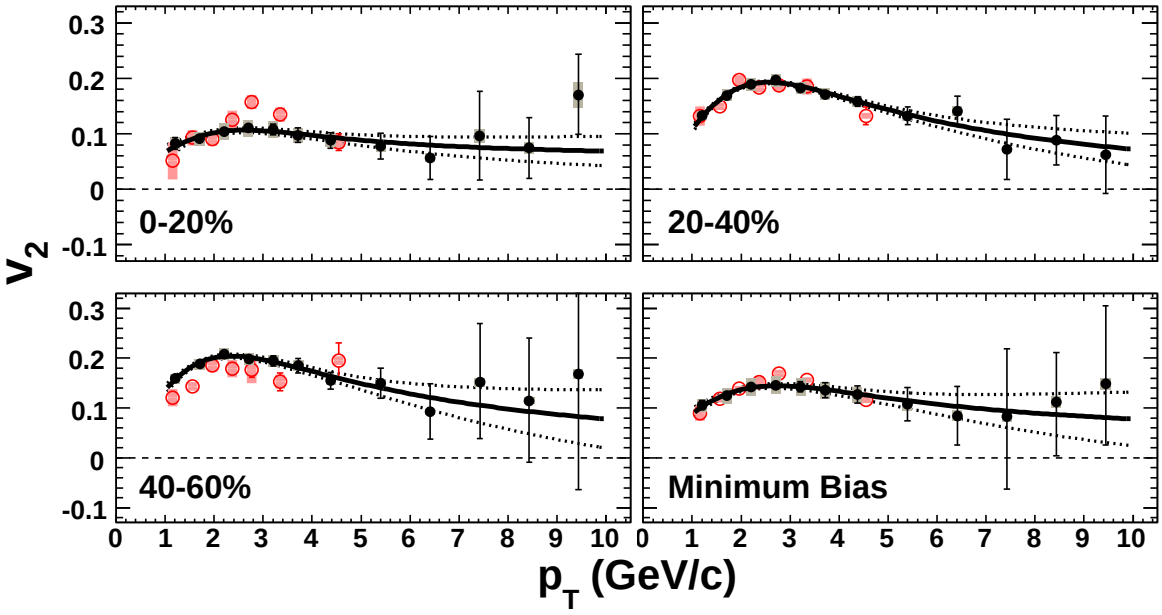

FIG. 8: (Color online) π^0 v_2 versus $p_{\rm T}$ for centralities 0-20%, 20-40%, 40-60%, and minimum bias. The closed (black) circles are data presented in this paper, and the open (red) circles are previously published results [40]. The solid and dashed lines as in Fig. 7.

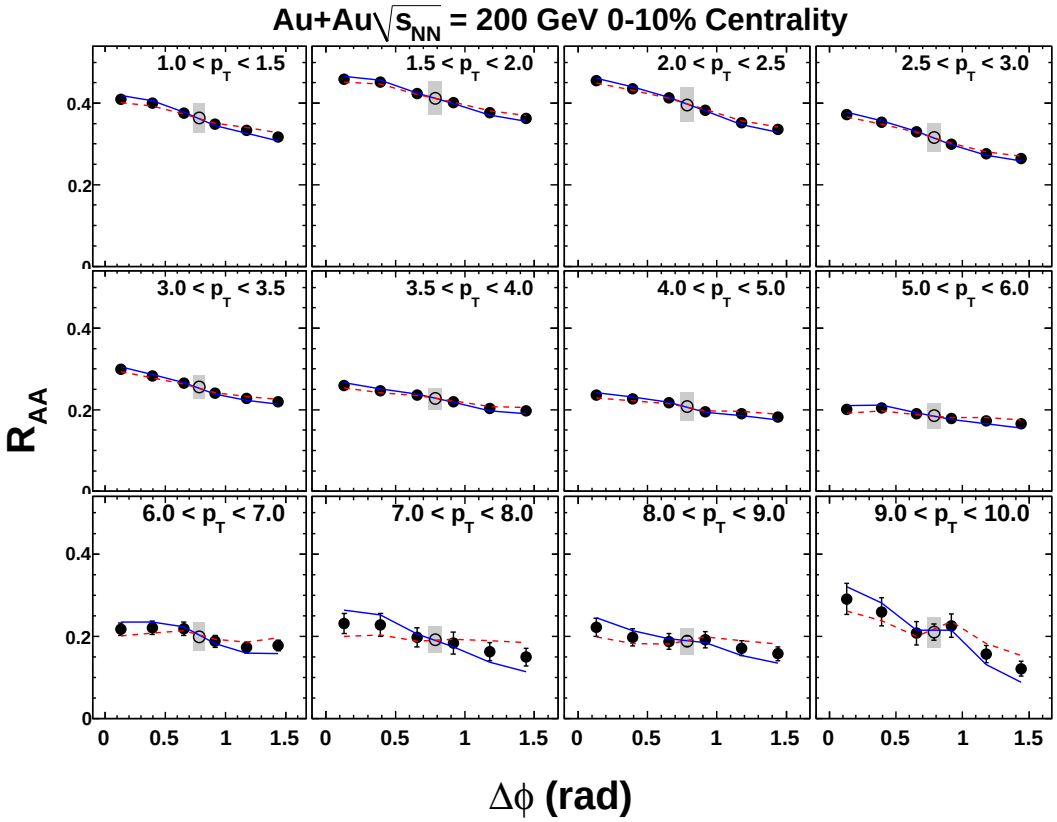

FIG. 9: (Color online) π^0 $R_{\rm AA}$ versus angle of emission with respect to the reaction plane for 0-10% centrality. The error bars denote the statistical errors, while the solid (blue) line and dashed (red) line represent the systematic error due to the resolution correction factor. The inclusive $R_{\rm AA}$ measurement is shown with the open circle, for which the error bar shows the statistical error and the box shows the systematic error.

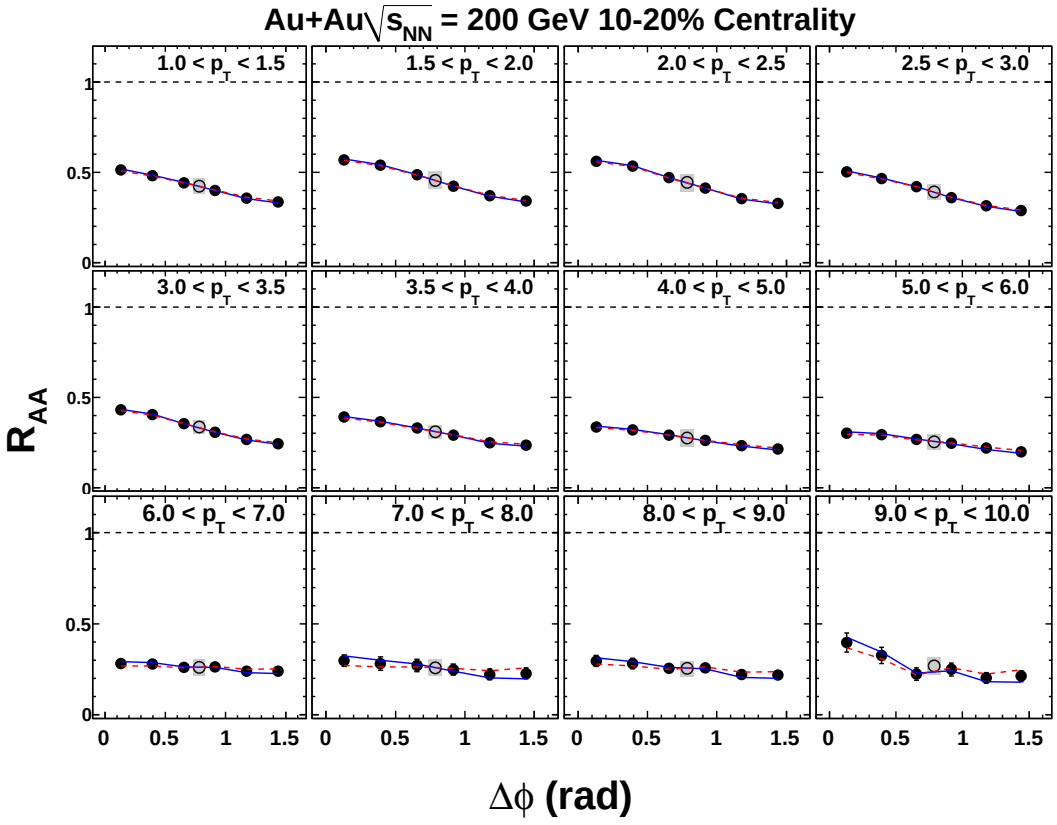

FIG. 10: π^0 $R_{\rm AA}$ versus angle of emission with respect to the reaction plane for 10-20% centrality. Colors/data points as in Fig. 9.

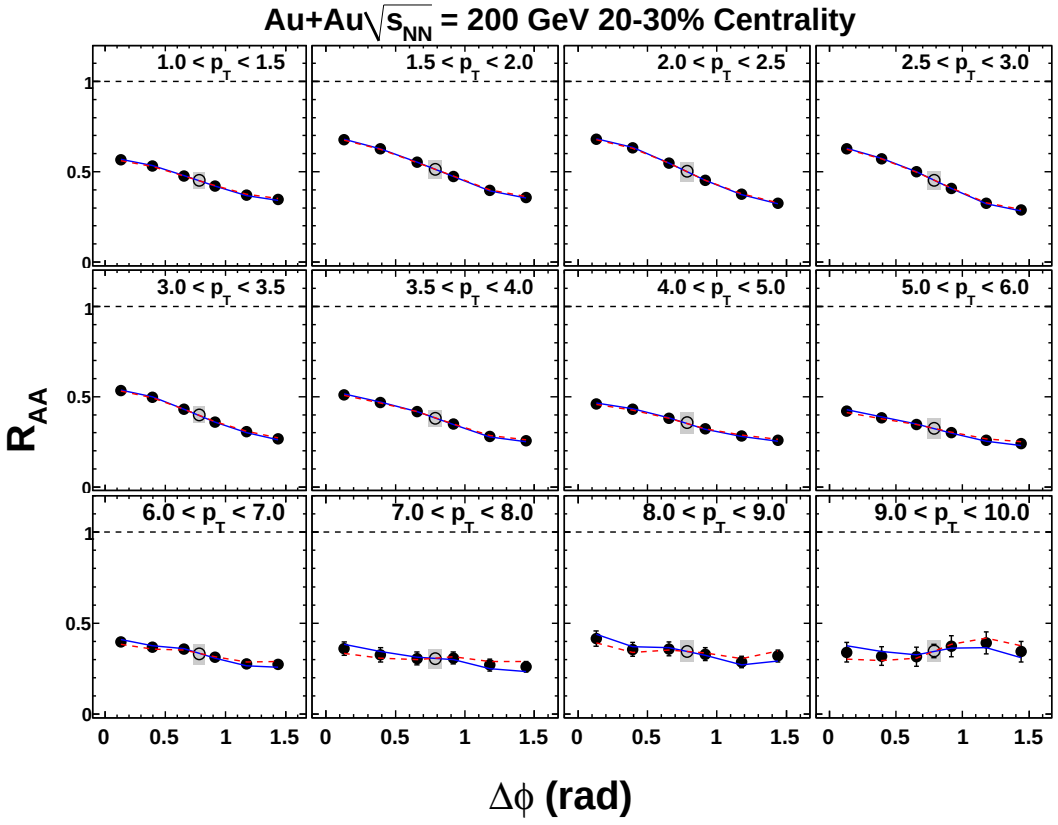

FIG. 11: π^0 $R_{\rm AA}$ versus angle of emission with respect to the reaction plane for 20-30% centrality. Colors/data points as in Fig. 9.

naive energy loss expectations since smaller $R_{\rm AA}$ would imply stronger quenching in the medium which would, in turn, imply larger variation between in-plane and out-of-plane quenching.

A similar implicit correlation between integrated $R_{\rm AA}$ and v_2 is seen in the centrality dependence of the $R_{\rm AA}(\Delta\phi)$ results. These are re-plotted in Fig. 17 as a function of $N_{\rm part}$ for three $\Delta\phi$ bins – the bins closest to and further from the reaction plane and one of the intermediate bins. For $N_{\rm part} > 100$, the out-of-plane $R_{\rm AA}$ values are nearly independent of centrality while the in-plane $R_{\rm AA}$ values decrease rapidly with increasing centrality. This result would have a natural geometric interpretation for π^0 production dominated by hard scattering and jet quenching. The length of the medium normal to the reaction plane varies only slowly with centrality except in the most peripheral collisions. Then, if the π^0 suppression is determined primarily by the path length of its parent parton in the medium, the π^0 $R_{\rm AA}$ would be nearly constant. Following the same argument, the yield for pions in the direction of the reaction plane would be much less suppressed in non-central collisions due to the short path lengths of the parent partons in the medium. However, with increasing centrality and decreasing anisotropy of the collision zone, the in-plane parton path lengths would grow to match those in the out-of-plane direction. Thus, if the π^0 suppression depended primarily on path length, the in-plane $R_{\rm AA}$ would naturally drop to match the out-of-plane values reproducing the behavior of Fig. 17. In order to better see the difference between the in- and out-of-plane behaviors, these data are also plotted on Fig. 18 with a semi-log scale.

One difficulty with this geometric interpretation of the $R_{\rm AA}(\Delta\phi)$ results given above is that the trend in the data that it is supposed to explain persists down to low $p_{\rm T}$, where the v_2 values are too large to be accounted for via perturbative or formation time based energy loss scenarios [26, 27, 28, 29, 30, 49]. That fact coupled with the pronounced peaking in $R_{\rm AA}(\Delta\phi)$ near 2 GeV/c suggests that physics other than hard scattering and jet quenching must be invoked to explain the π^0 yields at intermediate $p_{\rm T}$. However, the fact that the out-of-plane yields show less pronounced peaking near 2 GeV/c, that they vary little as a function of $p_{\rm T}$ above 3 GeV/c, and that they vary little with centrality for $N_{\rm part} > 100$ could be interpreted to imply that the π^0 suppression at angles normal to the reaction plane more directly represents the effects of quenching of hard quarks and gluons while the yield of π^0s produced more closely aligned with the reaction plane is enhanced by the collective motion of the system. That additional enhancement could either be due to soft hadrons being boosted to larger $p_{\rm T}$ values by the collec-

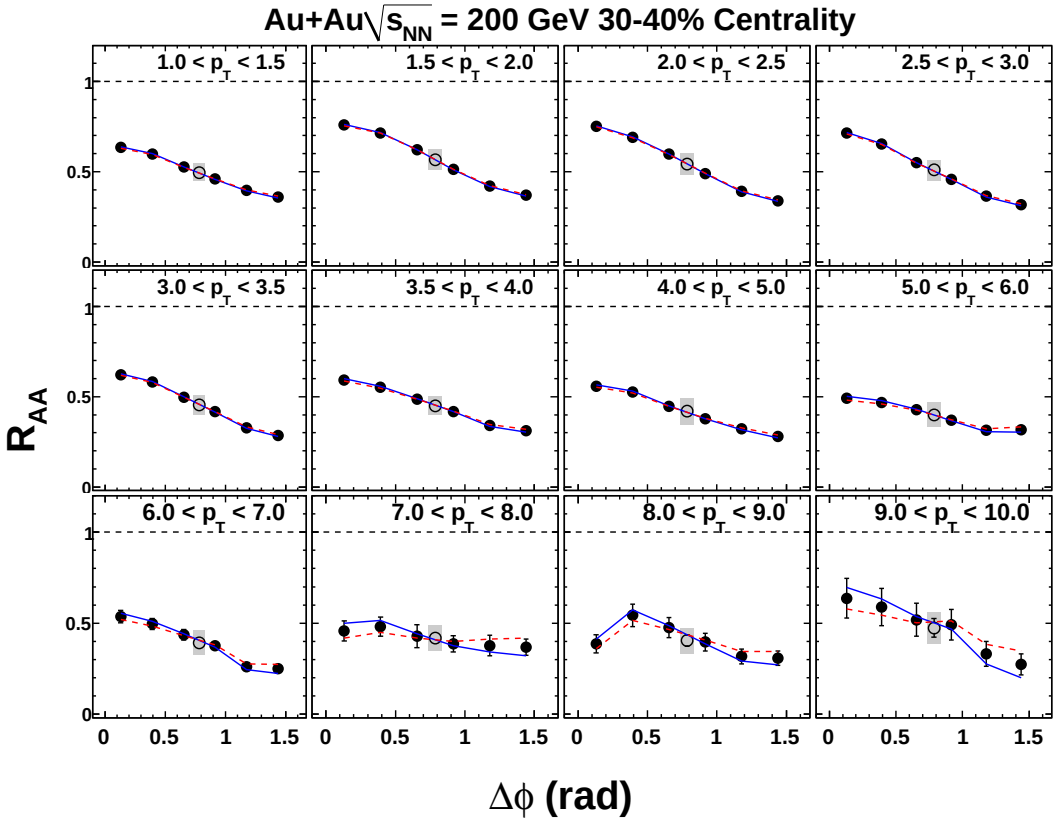

FIG. 12: π^0 $R_{\rm AA}$ versus angle of emission with respect to the reaction plane for 30-40% centrality. Colors/data points as in Fig. 9.

tive elliptic flow or could result from weaker quenching for partons moving in the direction of the flow field [27, 50]. Simultaneous description of the in-plane and out-of-plane behavior is a sensitive test of energy loss models.

The v_2 values presented in Figs. 7-8 also peak near 2 GeV/c, but the locations of the maxima in v_2 are shifted to higher $p_{\rm T}$ than the maxima in $R_{\rm AA}(\Delta\phi)$. This suggests that the two effects may not directly related, but we observe that the maxima in the $R_{\rm AA}(p_{\rm T})$ distributions in Figs. 15-16 shift to larger $p_{\rm T}$ for smaller $\Delta\phi$. To better illustrate the shift of the maxima in $R_{\rm AA}(p_{\rm T})$ we show in Fig. 19 the $R_{\rm AA}(p_{\rm T})$ values for the different $\Delta\phi$ bins and indicate the variation of the peak position obtained using polynomial fits to the first four $p_{\rm T}$ bins. For the 30-40% centrality bin, the maximum in $R_{\rm AA}(p_{\rm T})$ for $\Delta\phi < \pi/12$ is shifted by 0.4 GeV/c relative to the $5\pi/12 < \Delta\phi < \pi/2$ bin. This shift in the peak $R_{\rm AA}(p_{\rm T})$ with $\Delta\phi$ can produce a $v_2(p_{\rm T})$ that peaks higher in $p_{\rm T}$ than the inclusive $R_{\rm AA}$.

The observed shift in the peak of $R_{\rm AA}(p_{\rm T})$ with $\Delta\phi$ illustrates an important property of collective motion of the medium. The collective motion does not simply superimpose azimuthal variation on the particles produced at a given $p_{\rm T}$, it provides a $\Delta\phi$ dependent shift and/or broadening in the transverse momentum spectrum of the produced particles. The resulting distortion will be the smallest for particles produced at angles normal to the reaction plane and will be largest for particles produced in the plane. Any collective shift of soft particles to higher $p_{\rm T}$ will increase the measured $R_{\rm AA}(\Delta\phi, p_{\rm T})$ for small $\Delta\phi$ relative to large $\Delta\phi$ values producing a simultaneous increase in both the $\Delta\phi$-integrated $R_{\rm AA}$ and the v_2. With increasing $p_{\rm T}$, an expected decrease in the soft contamination would naturally explain the simultaneous reduction in v_2 and $\Delta\phi$-integrated $R_{\rm AA}$ evident in the 10-20% and 20-30% bins where the separation between the $R_{\rm AA}(p_{\rm T})$ curves for different $\Delta\phi$ bins decreases while the average $R_{\rm AA}$ also decreases. We will return to investigate this correlation again below.

The 40-50% and 50-60% centrality bins in Fig. 15 show little of the peaking near 2 GeV/c, especially in $\Delta\phi$ bins not aligned with the reaction plane. Nonetheless the v_2 values for the more peripheral bins reach the same large maximum values, $v_2 \sim 0.2$, at intermediate $p_{\rm T}$ as the v_2 values for more central bins where the peak in $R_{\rm AA}(p_{\rm T})$ is more prominent. Thus, while the peaking in $R_{\rm AA}(p_{\rm T})$ is less prominent in the more peripheral bins, the relative difference between the in-plane and out-of-plane π^0 yields in the 40-50% centrality bin is comparable to that in the 20-30% centrality bin. However, it is possible that the large $\Delta\phi$ dependence in the more peripheral bins and the apparent persistence of that variation to high $p_{\rm T}$ in

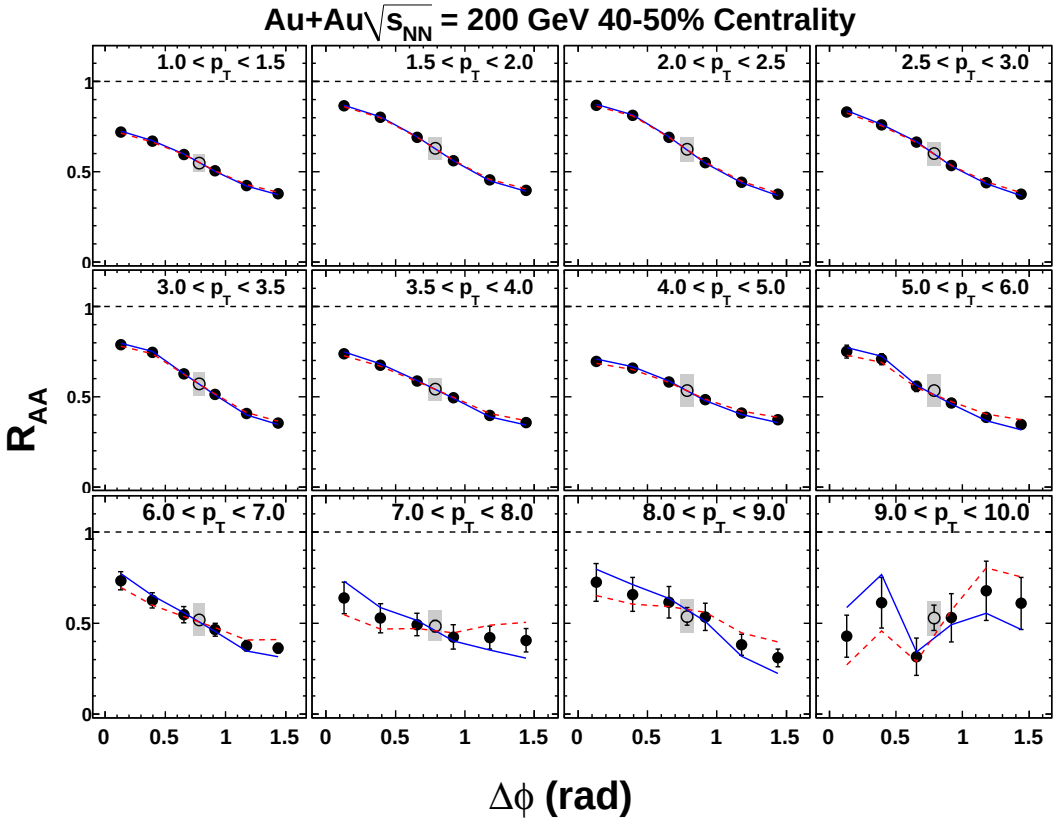

FIG. 13: π^0 $R_{\rm AA}$ versus angle of emission with respect to the reaction plane for 40-50% centrality. Colors/data points as in Fig. 9.

the 40-50% centrality bin more directly reflects the larger spatial anisotropy of the collision zone in more peripheral collisions. The question of whether the π^0 suppression measurements presented here can be understood on the basis of geometry and jet quenching will be more fully explored in the following section.

We have observed above that the $p_{\rm T}$ and centrality dependence of $R_{\rm AA}$ indicate a correlation between inclusive $R_{\rm AA}$ and v_2 such that the out-of-plane π^0 yields vary only slowly with $p_{\rm T}$ or centrality while the in-plane yields approach the out-of-plane yields with increasing $p_{\rm T}$ or increasing $N_{\rm part}$. Such a correlation between these two seemingly unrelated quantities merely indicates that the yields or $R_{\rm AA}$ of π^0's measured in-plane and out-of-plane more directly reflect the underlying physics responsible for the azimuthal variation than the $\Delta\phi$-integrated yield or $R_{\rm AA}$ and the amplitude of the $\Delta\phi$ modulation, v_2. Indeed, we have argued above that at higher $p_{\rm T}$ the centrality dependence of $R_{\rm AA}(\Delta\phi)$ may reflect the geometry of jet quenching. At intermediate $p_{\rm T}$, the $R_{\rm AA}(p_{\rm T})$ results suggest contamination of the in-plane yields by soft production and a simultaneous decrease in $R_{\rm AA}$ and v_2 with increasing $p_{\rm T}$ as the relative contribution of collective soft processes to π^0 production decreases. To more directly demonstrate the correlation that forms the basis of these arguments we show in Fig. 20 a plot of v_2 versus the inclusive $R_{\rm AA}$ for centralities from 0 to 60%. Data are displayed for $p_{\rm T} > 2$ GeV/c. The intermediate centrality bins show a correlated increase of v_2 and $R_{\rm AA}$ consistent with the discussion above and a possible saturation of v_2 for larger $R_{\rm AA}$ values. In fact, the trends for different centrality bins appear to be in general agreement. However, their exact relationship and establishing or excluding a causal connection requires further investigation.

C. Nuclear modification factor dependence on path length

The centrality of a collision fixes the geometry of the overlap region between the nuclei, and fixing the angle of emission of the particles further constrains the path length through the medium. We can use this feature to study the dependence of the nuclear modification factor on the path length traversed by the partons. We investigate the path length dependence by expanding on several methods previously described in [25]. We start with three estimators of the path length that are purely geometric, and one that includes the color density of the medium in its calculation:

1. We start by modeling the overlap region as an el-

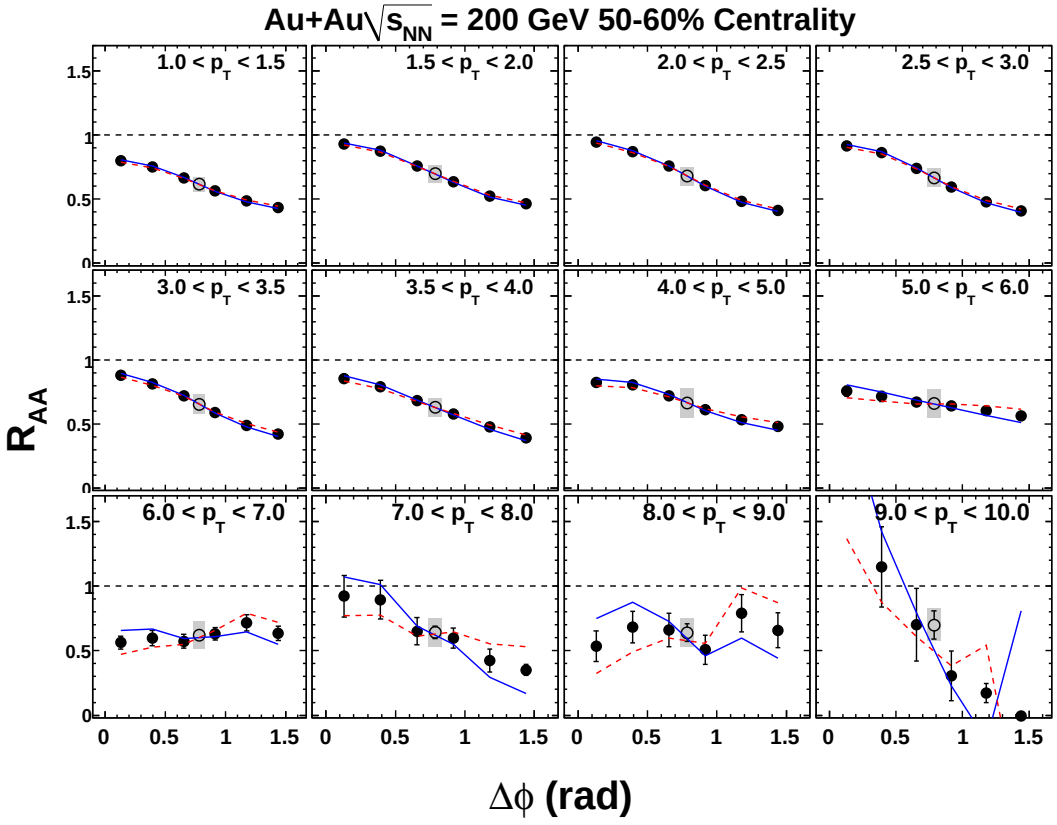

FIG. 14: π^0 $R_{\rm AA}$ versus angle of emission with respect to the reaction plane for 50-60% centrality. Colors/data points as in Fig. 9.

lipse defined by

$$\frac{x^2}{b^2} + \frac{y^2}{a^2} = 1 \tag{14}$$

where the minor axis b is oriented in the x direction and is parallel to the reaction plane. The axes a and b are fixed by the intersection in the transverse plane of two hard spheres with $R = 6.8$ fm. In terms of the spatial eccentricity $\epsilon = \langle y^2 - x^2 \rangle / \langle y^2 + x^2 \rangle$ (often used with Glauber calculations), we can express the distance from the origin to the edge of the ellipse at a given angle:

$$L_\epsilon(\Delta\phi) = \frac{b\sqrt{1+\epsilon}}{\sqrt{1+\epsilon\cos 2\Delta\phi}}. \tag{15}$$

Since this length starts at the origin, and does not take into account color density, the expression provides a very simple estimator with which we can evaluate the dependence of the $R_{\rm AA}$ on path length. We will refer to the hard sphere result as $L_{\epsilon,hs}$.

2. Instead of an ellipse strictly defined by the transverse profile of two hard spheres, we model the collision region as an effective ellipse whose dimensions are determined by equating the RMS radius and eccentricity to the corresponding quantities calculated from the transverse distribution of participant density based on standard Glauber calculations. This length, L_ϵ, is evaluated using the same expression as Eq. 15, with $b = \sqrt{x^2}$. Both quantities are determined using the PHENIX Glauber model [51].

3. For a more realistic approach, we evaluate the distance along the parton's path weighted by the participant density,

$$\rho L_{xy} = \int_0^\infty dl \rho_{\rm part}(x_0 + l\cos\Delta\phi, y_0 + l\sin\Delta\phi), \tag{16}$$

where (x_0, y_0) is the hard-scattering position and $\Delta\phi$ is the angle of the jet with respect to the x axis. The jet production point is sampled from a Monte Carlo using a weighted $T_{\rm AA}(x,y)$ distribution and a uniform $\Delta\phi$ distribution. The participant density, assumed to be proportional to the color density, is calculated from the Glauber model. The $\rho_{\rm part}$ density in Eq. 16 is modeled using a 1D Bjorken expansion,

$$\rho_c(\tau) \propto \left(\frac{\tau^2/\tau_0^2}{1+\tau^2/\tau_0^2}\right)\left(\frac{\tau_0}{\tau}\right).$$

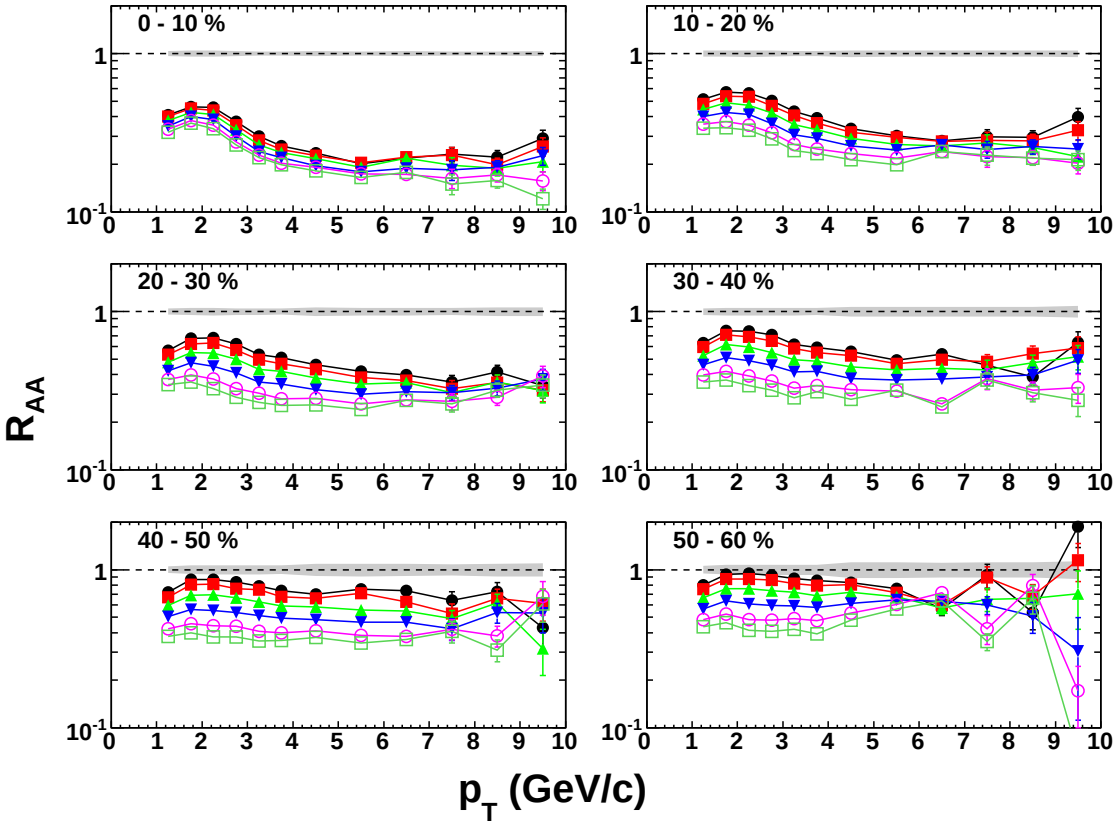

FIG. 15: (Color online) Semi-log plots of $R_{\rm AA}(p_{\rm T})$ for each $\Delta\phi$ bin, in different centrality ranges. The $\Delta\phi$ bins are represented as follows: closed (black) circles, 0-15°; closed (red) squares, 15-30°; closed (light green) triangles, 30-45°; closed inverted (blue) triangles, 45-60°; open (magenta) circles, 60-75°; and open (dark green) squares, 75-90°. The systematic error in the inclusive $R_{\rm AA}$ is represented by the grey bands. Errors due to the correction factor have been omitted for clarity.

Thus ρL_{xy} roughly represents LPM energy loss [52]. Note that ρ_c approaches the same $1/\tau$ dependence as the standard $\rho \propto \tau_0/\tau$ but differs from by a factor of 2 at $\tau = \tau_0$ (additionally this form is regular at $\tau = 0$).

4. Finally, we modify ρL_{xy} by normalizing it by the value of the participant density at the center of the collision region, $\rho_{\rm cent} = \rho_{\rm part}(0,0)$. As a result, $\rho L_{xy}/\rho_{\rm cent}$ is an estimator based on geometry alone, but also accounts for the effect of the density distribution both on the jet production point as well as the path from that point to the edge of the medium.

Figs. 21-24 show the $R_{\rm AA}$ dependence on $L_{\epsilon,hs}$, L_ϵ, ρL_{xy}, and $\rho L_{xy}/\rho_{\rm cent}$ respectively. The results shown in this paper cover the $p_{\rm T}$ range $p_{\rm T}$ = 1-10 GeV/c, not only extending the measurement presented previously but allowing a much finer binning in $p_{\rm T}$. The statistical errors in the $R_{\rm AA}$ measurements are represented by error bars (see Section IV B). The systematic errors shown in these data are on the $R_{\rm AA}$ values only, and are indicated by the filled boxes. The major contribution to the systematic error in the L_ϵ values is the determination of $N_{\rm part}$, and is at the 10-20% level.

Both the $L_{\epsilon,hs}$ and L_ϵ behavior show an interesting degree of scaling. This result is all the more unexpected because of the overly simple geometric picture they represent. Despite the simplistic picture they present, they both exhibit striking universality: the hard sphere $R_{\rm AA}(L_{\epsilon,hs})$ scales well in the low $p_{\rm T}$ region (as high as $p_{\rm T} \approx 4$ GeV/c) while $R_{\rm AA}(L_\epsilon)$ scales well to higher $p_{\rm T}$, at least one bin in $p_{\rm T}$ beyond $L_{\epsilon,hs}$ (though one might argue qualitatively this trend continues even higher when the most peripheral centrality is excluded). The more precise $p_{\rm T}$ dependence available in this data set reveals a slight deviation from the universality with L_ϵ that was previously reported [25].

By contrast, we expect the ρL_{xy} estimator to provide a somewhat more intuitive and concrete picture, as it represents a more realistic approach to the geometry and medium. Since we expect radiative energy loss to play a greater role at high $p_{\rm T}$, this should be the estimator that would provide the best scaling. In fact, at the higher $p_{\rm T}$ range, a universality does emerge, though not until $p_{\rm T} \approx 6$ GeV/c. Below that value, the measured $R_{\rm AA}$

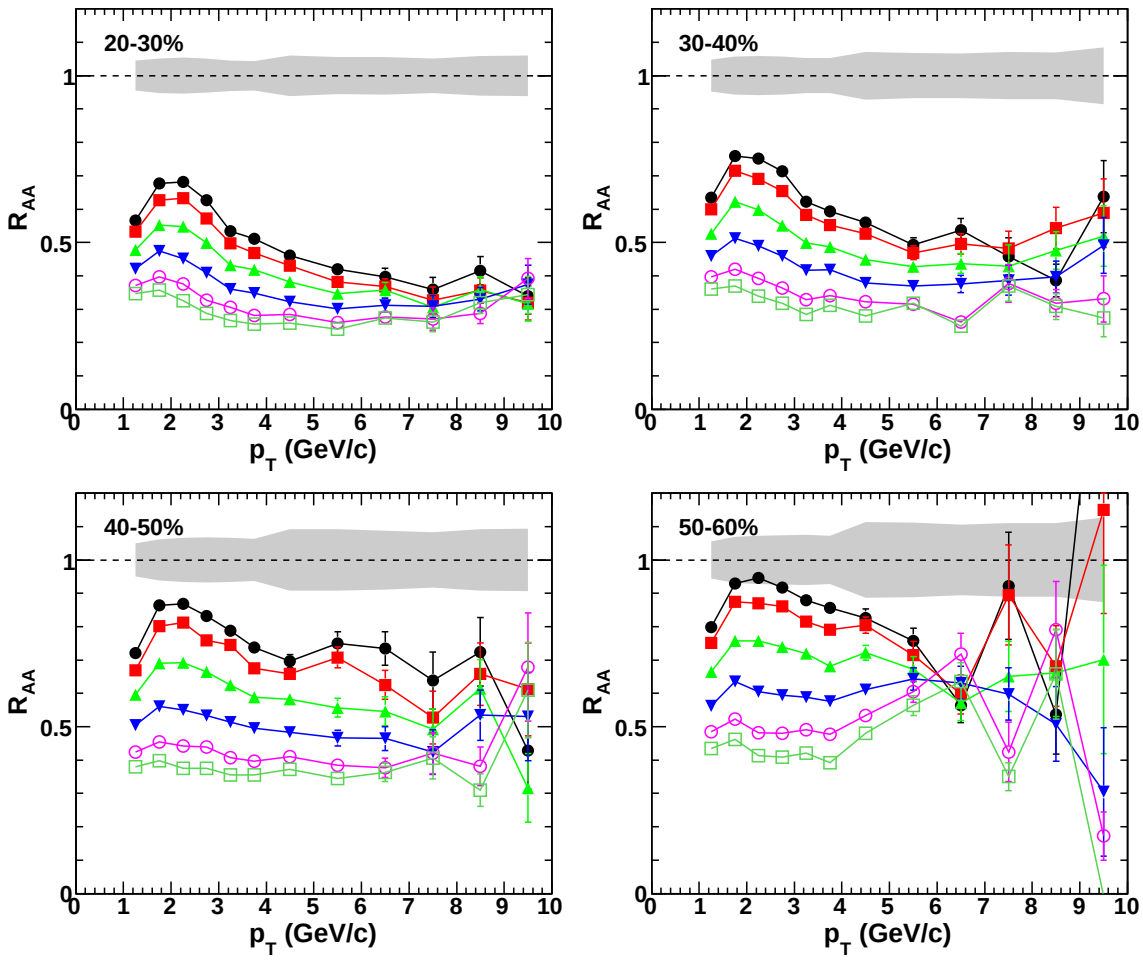

FIG. 16: (Color online) $R_{\rm AA}(p_{\rm T})$ for different $\Delta\phi$ bins in the 20-30%, 30-40%, 40-50%, and 50-60% centrality ranges. Colors/data points as in Fig. 15.

points lie on parallel, but separate, curves. When ρL_{xy} is normalized to the central density, data again exhibit a more universal dependence over a wider $p_{\rm T}$ range than what is seen with ρL_{xy} alone, as shown in Fig. 24.

When considered together these results offer a rich picture. At low to moderate $p_{\rm T}$ simple geometry may play a larger role in determining the final level of $R_{\rm AA}$ than conventionally thought. At higher $p_{\rm T}$ the scaling motivated by energy loss (ρL_{xy}) describes the data well. We note that there are three possible (and not necessarily exclusive) interpretations: 1) at low to moderate $p_{\rm T}$ the combined effects of the boost due to expansion and fragmentation are sensitive primarily to the difference in lengths traveled by the partons, and only weakly dependent on other parameters 2) we need to restrict the analysis of the π^0 $R_{\rm AA}$ to $p_{\rm T} > 5$ GeV/c to be in the range where fragmentation followed by energy loss dominates, or 3) the assumption that energy loss does not depend linearly on color density [34] is incorrect and leads a departure from scaling with ρL_{xy} at low to moderate $p_{\rm T}$.

V. SUMMARY AND CONCLUSIONS

We have presented measurements for the azimuthal anisotropy of neutral pions in Au + Au collisions at $\sqrt{s_{_{NN}}} = 200$ GeV. These measurements include the v_2 and $R_{\rm AA}(\Delta\phi)$ of π^0s as a function of transverse momentum and centrality. The v_2 has been measured from $p_{\rm T} \approx$ 1–10 GeV/c in eight centrality bins and four combined centrality bins. The $R_{\rm AA}$ has been measured in the same $p_{\rm T}$ range in six centrality bins. In addition, the $R_{\rm AA}$ dependence on effective path length through the collision region has been presented for five centralities.

The general trend seen in the $v_2(p_{\rm T})$ data is an initial increase in v_2 with increasing $p_{\rm T}$, peaking of the v_2 in the region of $2 < p_{\rm T} < 3$ GeV/c, followed by a decrease in the v_2. We have argued that such a trend implies a transition from particle production dominated by soft processes to a $p_{\rm T}$ region dominated by hard processes. In order to quantify the $p_{\rm T}$ and centrality evolution of v_2, we have fit its $p_{\rm T}$ dependence to an empirical expression that allows for such a transition. While the statistical precision of the

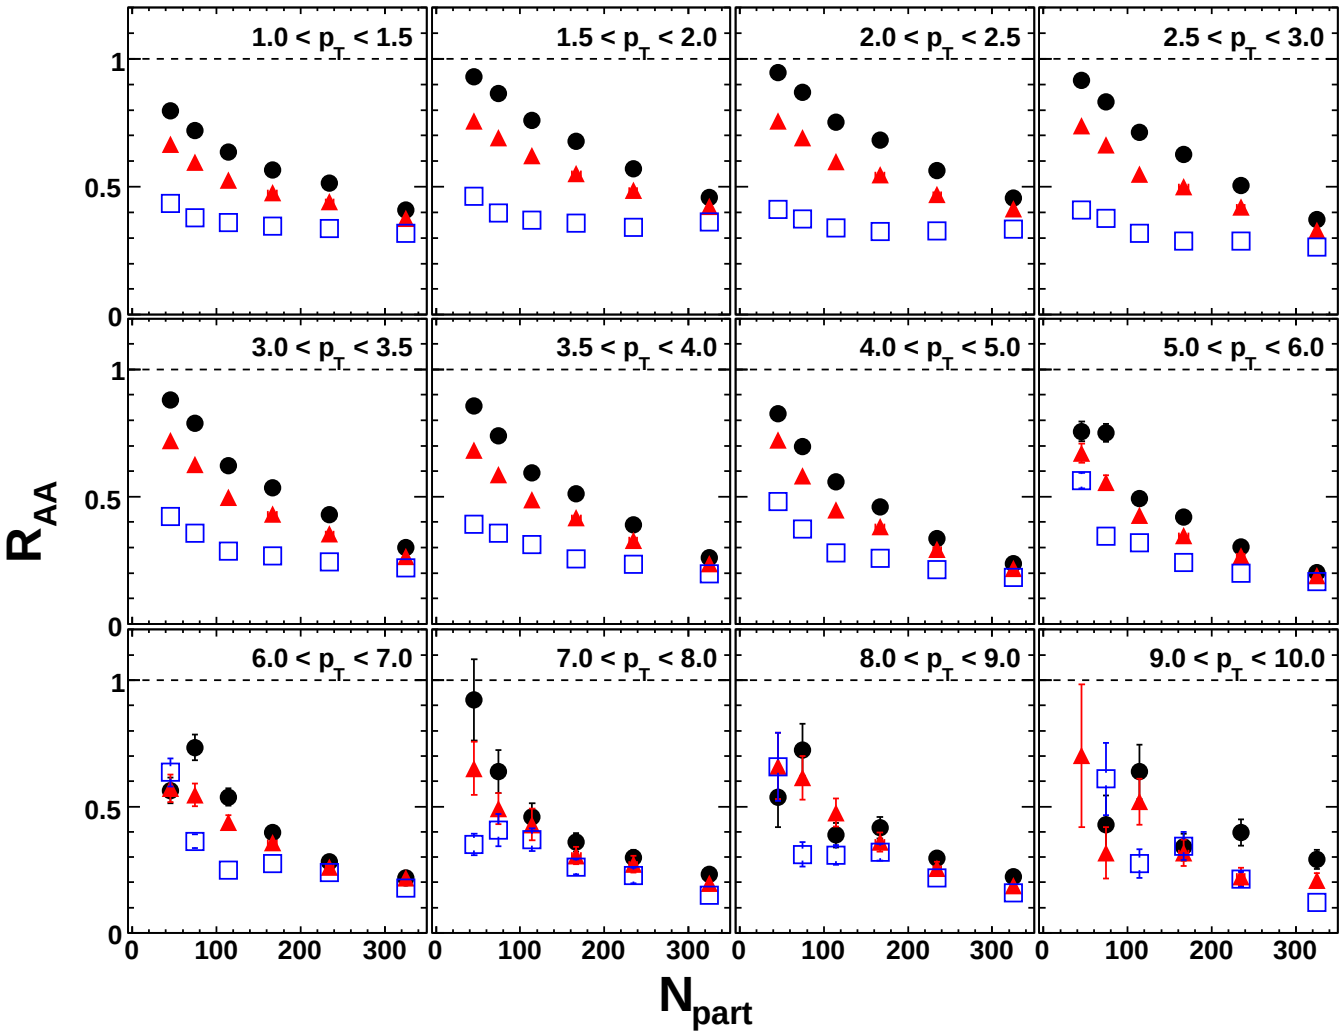

FIG. 17: (Color online) π^0 $R_{\rm AA}(N_{\rm part})$ in reaction-plane bins at fixed $p_{\rm T}$. The three bins are as follows: closed (black) circles are $R_{\rm AA}(0 < \Delta\phi < 15^\circ)$ (in plane), the closed (red) triangles are the $R_{\rm AA}(30 < \Delta\phi < 45^\circ)$, and open (blue) squares are $R_{\rm AA}(85 < \Delta\phi < 90^\circ)$ (out of plane).

high-$p_{\rm T}$ data limits the conclusions we can draw from the fits, it is clear that the data support the assumption of a decreased dominance of soft processes transitioning to an increased dominance of hard process with increasing $p_{\rm T}$. The more peripheral bins suggest that a $p_{\rm T}$-independent v_2 may be reached by $p_{\rm T} \sim 5$ GeV/c.

The differential probes represented by $R_{\rm AA}(\Delta\phi)$ provide a more sophisticated handle on the role of geometry in the collision region. For example, we see that in mid-centrality collisions the suppression of pions out-of-plane is approximately the same as the suppression in more central collisions. The data suggest that the interplay between the two main effects, namely collective flow and jet quenching, may take place not only along the expected transition in $p_{\rm T}$ from soft to hard physics, but perhaps also azimuthally, with the quenching effects being dominant along the direction normal to the reaction plane. To further shed light on the transition from soft to hard $p_{\rm T}$ regions, we have fit the maxima of mid-central $R_{\rm AA}(p_{\rm T})$ in each $\Delta\phi$ range. Between the in and out of plane directions, we observe a shift of 0.4 GeV/c in position of the peak of the spectrum.

In order to further clarify the centrality evolution of the azimuthal dependence of the π^0 suppression, we have presented the $R_{\rm AA}$ as a function of $N_{\rm part}$ in fixed $p_{\rm T}$ bins, for three directions: along the reaction plane, normal to the reaction plane, and midway between. For $N_{\rm part} \gtrsim 100$, the $R_{\rm AA}$ along the normal to the reaction plane is almost constant, a trend seen in most $p_{\rm T}$ bins. By contrast, the $R_{\rm AA}$ nearest to the reaction plane drops by almost a factor of two, converging on the out-of-plane value at the highest $N_{\rm part}$. This important feature may provide the most compelling argument for geometry as the source of suppression. Since the path length in the direction normal to the reaction plane varies slowly with centrality, we would expect the $R_{\rm AA}$ to be nearly flat. Conversely,

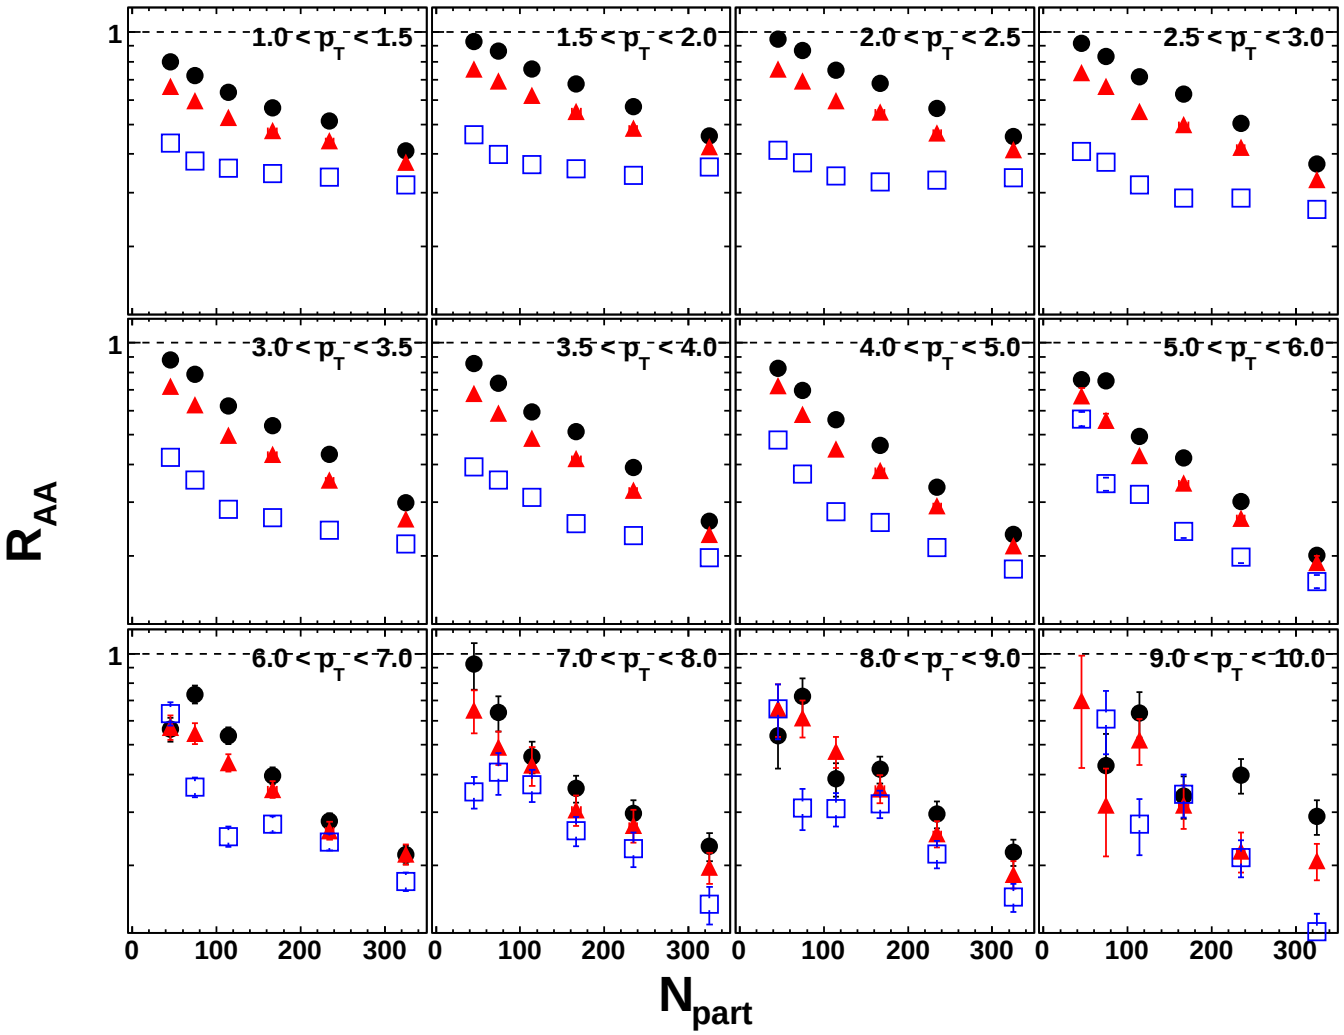

FIG. 18: (Color online) π^0 $R_{\rm AA}(N_{\rm part})$ in reaction-plane bins at fixed $p_{\rm T}$, with log scale on the y axis. Colors/data as in Fig. 17.

the in-plane path length will be sensitive to the degree of overlap and strongly influence the observed $R_{\rm AA}$. Thus it would lead to a small suppression in peripheral collisions while eventually converging on the same value as seen normal to the plane as the anisotropy vanishes in more central collisions. This effect is further borne out in the correlation observed between v_2 and the inclusive $R_{\rm AA}$. However, we have also argued that contamination from soft production could produce a similar behavior and we have no independent indication of how far in $p_{\rm T}$ soft contamination might extend. Nonetheless, under both interpretations we can conclude that the $R_{\rm AA}$ for pions produced along the normal to the reaction plane more directly reflects the physics of quenching. We also conclude that the correlation between $R_{\rm AA}$ and v_2 makes separate treatment of these quantities disadvantageous.

We have examined $R_{\rm AA}$ as function of the average path length of the parent parton through the overlap region in the collision, through the estimators $L_{\epsilon,hs}$, L_{ϵ}, $\rho L_{xy}/\rho_{\rm cent}$, and ρL_{xy}. Each of the first three quantities represents a progressively more sophisticated estimator for the distance traveled by the parton, with ρL_{xy} at the end providing a proxy for LPM energy loss. Comparison of the scaling with these three measures of lengths seems to suggest that the pion suppression at low- to moderate-$p_{\rm T}$ is mostly dependent upon simply the geometric length. The estimator that should in principle be the most realistic one, ρL_{xy}, exhibits good universality at the highest $p_{\rm T}$ values, suggesting that energy loss comparisons should be restricted to the $p_{\rm T}$ range $p_{\rm T} > 5$ GeV/c. The importance of simple geometry at low- to moderate-$p_{\rm T}$ is further supported when ρL_{xy} is normalized by the participant density at the center. This normalization effectively makes ρL_{xy} a length. These geometric descriptions offer a description of the suppression both at low and high $p_{\rm T}$ regions, clearly showing a transition between the ranges. The features seen in the $R_{\rm AA}$ as function of path length tie in consistently with the observations of a transition in the behavior of the measured v_2. These two observables, v_2 and $R_{\rm AA}(\Delta\phi)$, analyzed

(Dated: March 27, 2009)

Bose-Einstein correlations of charged kaons are used to probe Au+Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV and are compared to charged pion probes, which have a larger hadronic scattering cross section. Three dimensional Gaussian source radii are extracted, along with a one-dimensional kaon emission source function. The centrality dependences of the three Gaussian radii are well described by a single linear function of $N_{\rm part}^{1/3}$ with zero intercept. Imaging analysis shows a deviation from a Gaussian tail at $r \gtrsim 10$ fm, although the bulk emission at lower radius is well-described by a Gaussian. The presence of a non-Gaussian tail in the kaon source reaffirms that the particle emission region in a heavy ion collision is extended, and that similar measurements with pions are not solely due to the decay of long-lived resonances.

PACS numbers: 25.75.Dw

Experiments at the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory have revealed that collisions of Au ions at $\sqrt{s_{\rm NN}} = 200$ GeV produce a new form of matter which is opaque to jets and exhibits anisotropic flow consistent with perfect fluid hydrodynamics [1, 2]. Studies of the space-time evolution of the collisions are needed to elucidate the properties of the hot, dense, and strongly interacting matter, probe the time scale and degree of thermalization, and investigate the order of the deconfinement phase transition.

Two-particle interferometry, also known as HBT after the radio astronomers R. Hanbury Brown and R.Q. Twiss [3], is a powerful tool for measuring the space-time extent of particle-emitting sources. In elementary particle and nuclear physics, enhanced production of like-sign pions with small relative momenta was discovered experimentally and explained by the Bose-Einstein symmetrization of identical bosons [4]. Correlations are produced by the combination of quantum mechanical interference of identical particles and strong and/or electromagnetic final state interactions such as Coulomb repulsion for same-sign charged pairs. HBT radii refer to Gaussian measures of source sizes on the femtometer scale.

Although the traditional HBT analyses are constrained by the assumption of a Gaussian distribution of particle emission, recent detailed measurements of pion emission sources using an imaging technique show a non-Gaussian structure for the two-particle source region above ∼20 fm [5], suggesting the possibility that decays of long-lived resonances or a temporal component of the source contribute to the non-Gaussian tail [6]. While charged pions are strongly affected by rescattering among hadrons and decays of hadronic resonances, charged kaons have smaller rescattering cross sections than charged pions ($\sigma_{K-N} < \sigma_{\pi-N}$) and are less affected by resonance decays. Until recently, no full hydrodynamic calculation has accurately predicted particle spectra and HBT radii for pions, and none can simultaneously describe the momentum asymmetry measurements of flow. The measurement of the kaon source describe herein add an important new constraint to address this "HBT puzzle" [7, 8].

An angle-averaged one-dimensional Gaussian measurement of correlations of neutral kaons by STAR [9] suggests that the transverse mass dependence for neutral kaons and charged pions falls on one universal curve. In this paper, 3D Gaussian HBT correlations of like-sign kaons are presented in three transverse momentum bins for $0.3 < p_{\rm T} < 1.5$ GeV/c and three collision centrality bins. The resulting HBT radius parameters for kaons are compared to those of like-sign pion pairs [10]. In addition we present 1D emission source functions for charged kaons in relativistic heavy-ion collisions.

This analysis of 2004 data from the PHENIX detector [11] uses ∼ 600 million minimum bias events, which are triggered by the coincidence of the Beam-Beam Counters (BBC) and Zero-Degree Calorimeters (ZDC) with collision vertex $|z| < 30$ cm. A Monte Carlo Glauber model [12] is used to match the observed BBC and ZDC distributions and to bin the data according to the number of nucleons participating in the collisions, $N_{\rm part}$.

Charged kaons are tracked and identified using the drift chamber (DC), pad chambers (PC1,PC3) and PbSc Electromagnetic Calorimeters (EMCal) to cover pseudorapidity $|\eta| < 0.35$ and azimuthal angle $\Delta\phi = \pi/2$ ($\Delta\phi = \pi/4$) in one (and the other) central arm. A track model provides a 3-dimensional trajectory and momentum vector for charged particles based on DC and PC1 information with a momentum resolution of $\delta p/p \simeq 0.7\% \oplus 1.0\% \times p$ (GeV/c). Backgrounds are reduced by requiring 2 σ position match between track projections and EMCal hits, and 3 σ match for PC3. Kaons are separated from pions up to $p_{\rm T}$ ∼0.9 GeV/c using timing information from BBC and EMC. Particles at higher $p_{\rm T}$ that fall within 2 σ of the ideal mass-squared for kaons but $\geq 3\,\sigma$ away from the peak for pions or (anti-)protons are identified as kaons. The contamination level is ∼4% from pions, and ∼1% from protons at $p_{\rm T} \sim 1.5$ GeV/c.

The correlation function is experimentally measured as $C_2(\mathbf{q}) = A(\mathbf{q})/B(\mathbf{q})$ where $A(\mathbf{q})$ is the relative momentum ($\mathbf{q}$) distribution of actual pairs obtained by all possible combinations of pairs within the same events and $B(\mathbf{q})$ is the background pair distribution from mixed events. Two-track detection inefficiencies for charged kaons that traverse the DC and EMCal in close proximity have been carefully studied with Monte-Carlo detector simulation and the actual pair distribution is corrected by the MC efficiency factors. After pair selection cuts to remove track splitting and merging (see [10] for details), ∼15 million positive kaon pairs and 14 million negative kaon pairs remain.

To measure multi-dimension source sizes, $\mathbf{q}$ is decomposed into standard "side-out-long" axes [13]: for which $q_{\rm long}$ is parallel to the beam axis, $q_{\rm out}$ is parallel to the transverse momentum of the pair ($k_{\rm T} = (p_{1\rm T} + p_{2\rm T})/2$), and $q_{\rm side}$ is orthogonal to both $q_{\rm long}$ and $q_{\rm out}$. This analysis is performed in the Longitudinally Co-Moving System (LCMS) defined as $p_{1\rm Z} = -p_{2\rm Z}$. For the treatment of charged kaons emitted away from the central region (core), we adopt an effective core-halo Coulomb correction, proposed by Bowler and Sinyukov [14], in which the 3D Gaussian fit function is given by

$$C_2 = C_2^{core} + C_2^{halo} = [\lambda(1+G)]\,F_{\rm C} + [1-\lambda]\,, \qquad (1)$$

where the Coulomb correlation function $F_{\rm C}$ is iteratively evaluated from the Coulomb wave function of kaon pairs

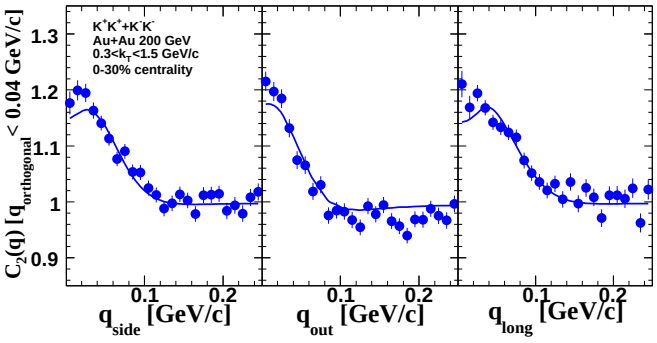

FIG. 1: (color online). 3D correlation function of charged kaon pairs measured for $0.3 < k_{\rm T} < 1.5$ GeV/c at $0-30\%$ centrality in Au+Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV. The curve is a 3D function is a Coulomb uncorrected fit with Eq. 1 and sliced over the lowest 40 MeV/c in the orthogonal directions.

assuming a spherical Gaussian source. The Gaussian correlation function in the side-out-long decomposition is determined by

$$G = \exp\left(-R^2_{\rm side}q^2_{\rm side} - R^2_{\rm out}q^2_{\rm out} - R^2_{\rm long}q^2_{\rm long}\right). \quad (2)$$

The systematic error estimate incorporates a contribution from the Coulomb interaction of the source halo using a prescription developed by Maj and Mrowczynski [15]. The fitted $R_{\rm side}$ and $R_{\rm long}$ are Gaussian measures of the spatial lengths of homogeneity, where particles of similar momenta are emitted [16], in the transverse and longitudinal directions at freeze-out. $R_{\rm out}$ contains a contribution from the duration of the particle emission in addition to the spatial length [17]. Note that an out-long cross-term vanishes in the expression for G for our $|\eta| < 0.35$ acceptance at midrapidity [18]. The fitted λ is empirically defined and includes contributions from misidentified particles $(1-f)^2$ along with components of the source that are not well resolved by the Gaussian fit.

Figure 1 shows the 3D correlation function of charged kaons without the Coulomb correction measured for $0.3 < k_{\rm T} < 1.5$ GeV/c at $0-30\%$ centrality in Au+Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV and the fit with Eq. (1). Separate fits to the $2K^+$ and $2K^-$ correlation functions were performed, yielding consistent results for all $k_{\rm T}$ and centrality bins.

Panels (a)-(e) in Fig. 2 show the HBT radius parameters of charged kaons for $0.3 < k_{\rm T} < 1.5$ GeV/c as functions of $N^{1/3}_{\rm part}$, which is proportional to the transverse radius of the initial collision volume. Similar to pions, kaon radii are well described by linear functions of $N^{1/3}_{\rm part}$. Because initial fits yielded slopes that were consistent for all radii and intercepts that were consistent with zero, the all three radii were fit to a single linear function with zero intercept: $R_i = p_1 * N^{1/3}_{\rm part}$, with $p_1 = 0.51 \pm 0.01$ and $\chi^2/{\rm ndf} = 14.6/8$. We note that similar fits to the pion radii yield non-zero intercepts. Although pions and

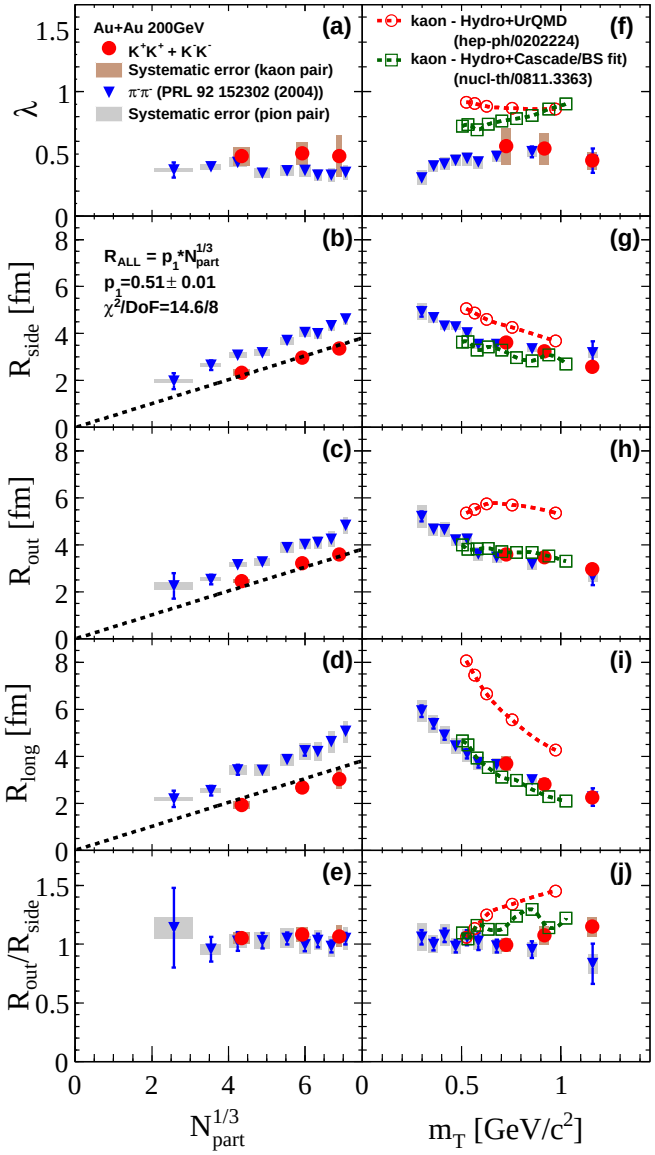

FIG. 2: (color online). 3D Gaussian HBT radius parameters extracted from Eq.(1) for charged kaon pairs as a function of (left) $N^{1/3}_{\rm part}$ measured for $0.3 < k_{\rm T} < 1.5$ GeV/c and (right) $m_{\rm T}$ measured for $0-30\%$ centrality in Au+Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV. In panels (b)-(d) the dashed line is a fit with $p_1 * N^{1/3}_{\rm part}$.

kaons are measured in a similar $k_{\rm T}$ range ($0.2 < k_{\rm T} < 2.0$ GeV/c for pions), the higher transverse mass ($m_{\rm T} = \sqrt{{k_{\rm T}}^2 + m^2}$) for kaons ($\langle m_{\rm T}\rangle \sim 0.89$ GeV/c^2) than for pions ($\langle m_{\rm T}\rangle \sim 0.47$ GeV/c^2) leads to smaller radii, as expected from $\langle m_{\rm T}\rangle$ scaling [16, 19, 20, 21].

Panels (f)-(j) in Fig. 2 show the $m_{\rm T}$ dependence of the radius parameters for kaons in 3 different $m_{\rm T}$ bins at $0-30\%$ centrality, compared with pions [10]. HBT radii are quite consistent at the same $m_{\rm T}$, clearly indicating that the radii follow $m_{\rm T}$ scaling. The $R_{\rm out}/R_{\rm side}$ ratio

for kaons is ∼1.0-1.2 which is consistent with the value for pions at low $m_{\rm T}$. Kaon HBT results from a 2D+1 hybrid, hydrodynamic + UrQMD calculation (open circles) [22] show slightly larger sidewards radii than the data, and the outwards and longitudinal components are too large by a factor of 2-3. A more recent 1D+1 hybrid calculation [23] for kaons (open squares), which assumes flat rapidity distribution and axial symmetry, compares more favorably, matching all radii to within systematic and statical errors. This calculation incorporates pre-equilibrium flow and a lattice-inspired equation of state, which are two features lacking in earlier calculations of HBT radii. Although promising, these theoretical results remain to be verified with full 3D+1 calculations that can also reproduce the elliptic flow.

Recent femtoscopic measurements [5, 6], which use an imaging technique [24] revealed that the emission source function of charged pions has a non-Gaussian tail which cannot be resolved with traditional Gaussian fitting techniques. In the imaging scheme, the correlation function is expressed by the Koonin-Pratt equation [25, 26]

$$C_2(\mathbf{q}) - 1 = \int d\mathbf{r} K(\mathbf{q},\mathbf{r}) S(\mathbf{r}), \qquad (3)$$

where the kernel $K(\mathbf{q},\mathbf{r})$ is the relative wave function as $|\Phi_{\mathbf{q}}^{(-)}(\mathbf{r})|^2 - 1$ that describes the propagation of pairs emitted with relative separation $\mathbf{r}$ and relative momentum $\mathbf{q}$ in the Pair Center-of-Mass System (PCMS). $S(\mathbf{r})$ is the emission source function of pairs.

The filled squares in Fig. 3 (a) show the 1D kaon correlation as a function of the invariant relative momentum of the pair ($q_{\rm inv} = \sqrt{-(p_1 - p_2)^2}/2$). The 1D source function $S(r)$ imaged from $C_2(q_{\rm inv})$ is shown by filled circles in Fig. 3 (b).

In this analysis, input parameters that govern the imaging procedure [24] were selected to minimize the χ^2 between the data and the restored $C_2(q_{\rm inv})$(χ^2/ndf ∼ 1), shown by open circles in Fig. 3 (a). The solid curve shows the traditional Gaussian source function, obtained by angle-averaging the 3D HBT radius parameters (λ, $R_{\rm side}$, $R_{\rm out}$, $R_{\rm long}$) in the PCMS frame, the same frame in which the imaging is performed.

The imaged $S(r)$ exhibits a non-Gaussian tail at $r \gtrsim 10$ fm. This excess corresponds to the deficit in the $q_{\rm inv} \lesssim 20$ MeV/c region of the angle-averaged Gaussian curve of Fig. 3 (a), and is also visible in the 3D Gaussian slices in Fig. 1. The $S(r)$ for pions in the same $k_{\rm T}$ range shows a similar trend. The deviation from a Gaussian in the shape of the $S(r)$ indicates that the particle emission region is extended, and a similar non-Gaussian tail in the pion source is not solely the result of long lived resonance decays such as the ω, although a less prominent contribution from the K^* is likely. The observation of a more substantial non-Gaussian tail for kaons than for pions is qualitatively consistent with a hadronic resonance

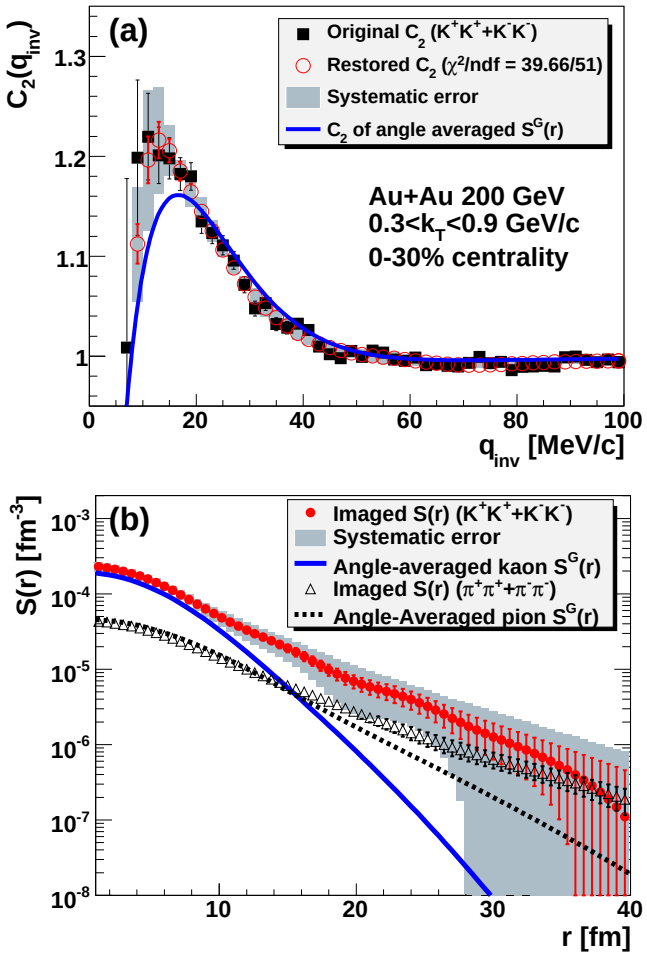

FIG. 3: (color online). (a) (filled squares) measured $C_2(q_{\rm inv})$. (open circles) restored $C_2(q_{\rm inv})$ from imaged $S(r)$, compared with (solid curve) angle-averaged Gaussian $C_2(q_{\rm inv})$ for charged kaon pairs measured for $0.3 < k_{\rm T} < 0.9$ GeV/c at $0-30\%$ central Au+Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV. (b) (filled circle) Imaged kaon $S(r)$ compared with (solid curve) angle-averaged Gaussian $S(r)$. Error bars are statistical only and boxes indicate the total systematic errors. (open triangle) $S(r)$ for charged pion pairs for the same $k_{\rm T}$ region. For the pion $S(r)$, error bars include both statistical and systematic errors.

cascade model with a time dependent density for an expanding source, in which the larger mean free path for kaons leads to an extended emission region [27, 28]. Detailed measurements with 3D HBT imaging of kaons, or 1D imaging of more species probing different hadronic cross sections will determine contributions from other kinetic effects to $S(r)$.

In summary, we have measured Bose-Einstein correlation functions of charged kaon pairs in Au+Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV. The 3D HBT radii $R_{\rm side}$ and $R_{\rm long}$ are consistent for pions and kaons at the same $N_{\rm part}$ and $m_{\rm T}$. The 1D emission source function for kaons extracted by imaging shows a non-Gaussian tail at distances greater

than 10 fm. This tail represents a direct measurement of the 1D length of homogeneity of the particle emission source and is not due primarily to resonance decays.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We acknowledge support from the Office of Nuclear Physics in DOE Office of Science and NSF (U.S.A.), MEXT and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), IN2P3/CNRS, and CEA (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE (India), ISF (Israel), KRF and KOSEF (Korea), MES, RAS, and FAAE (Russia), VR and KAW (Sweden), U.S. CRDF for the FSU, US-Hungarian NSF-OTKA-MTA, and US-Israel BSF.

(Received 20 March 2009; published 31 August 2009)

We report the observation at the Relativistic Heavy Ion Collider of suppression of back-to-back correlations in the direct photon+jet channel in Au + Au relative to $p + p$ collisions. Two-particle correlations of direct photon triggers with associated hadrons are obtained by statistical subtraction of the decay photon-hadron (γ-h) background. The initial momentum of the away-side parton is tightly constrained, because the parton-photon pair exactly balance in momentum at leading order in perturbative quantum chromodynamics, making such correlations a powerful probe of the in-medium parton energy loss. The away-side nuclear suppression factor, $I_{\rm AA}$, in central Au + Au collisions, is $0.32 \pm 0.12^{\rm stat} \pm 0.09^{\rm syst}$ for hadrons of $3 < p_T^h < 5$ in coincidence with photons of $5 < p_T^\gamma < 15$ GeV/c. The suppression is comparable to that observed for high-p_T single hadrons and dihadrons. The direct photon associated yields in $p + p$ collisions scale approximately with the momentum balance, $z_T \equiv p_T^h/p_T^\gamma$, as expected for a measurement of the away-side parton fragmentation function. We compare to Au + Au collisions for which the momentum balance dependence of the nuclear modification should be sensitive to the path-length dependence of parton energy loss.

I. INTRODUCTION

Experimental results from RHIC have established the formation of hot and dense matter of a fundamentally new nature in relativistic heavy-ion collisions at $\sqrt{s_{NN}} = 200$ GeV [1]. Energy loss in this dense nuclear matter by color-charged, hard ($E \gtrsim 2$ GeV) partons, and the jets into which they fragment, is generally accepted to be the mechanism responsible for the suppression of the high-p_T hadron yields observed in central $A + A$ collisions [2,3]. In the large multiplicity environment of heavy-ion collisions, two-particle correlations are often used to study jet modification and to infer properties of the medium. For example, high-p_T azimuthal dihadron correlations demonstrate that the degree of dijet away-side suppression depends on the p_T of the "trigger" and "associated" hadrons. At moderate $p_T (\gtrsim 3$ GeV/$c)$, the jet properties measured through two-particle correlations demonstrate novel features such as shape modifications that are thought to be a manifestation of the response of medium to the energy deposited by the attenuated parton [4].

Dihadron measurements of dijet pairs provide an ambiguous measurement of the energy loss of the away-side parton. The trigger hadron is a product of parton fragmentation and therefore it is not possible to determine, event by event, whether the near-side parton has itself lost energy. Given the steeply falling jet spectrum, the sample of hard scatterings is biased toward configurations in which the parton loses little energy. In particular, it is believed that hadron measurements are subject to a "surface bias" in which the hard scatterings sampled are likely to occur at the periphery of the overlap zone [5,6]. The away-side parton then is more likely to traverse a maximal path-length through the medium. For a sufficiently opaque medium, the attenuation of the parton may be nearly total, in which case the sensitivity to the average path-length is reduced [7]. Back-to-back, high-p_T hadron pairs may originate preferentially from configurations in which the outgoing parton trajectories are tangential to the surface of the overlap zone [8]. However, dihadron pairs may also originate from vertices deep in the collision zone if a parton has a finite probability to "punch-through" or pass through the medium without interaction [9]. Calculations of the relative importance of these two mechanisms depend both on the model of parton energy loss employed and the density profile of the medium [6,10,11].

Direct photon-jet pairs offer two major advantages in studying energy loss as compared to dijets because of the nature of the photon. First, in contrast to partons, photons do not carry color charge and hence do not interact strongly when traversing the medium [12]. The distribution of hard-scattering vertices sampled by direct photon-triggered correlations is thus unbiased by the trigger condition. Suppression of the opposite jet is averaged over all path lengths given by the distribution of hard-scattering vertices. Second, at the Born level, direct photon production in $p + p$ and $A + A$ collisions is dominated by the QCD Compton scattering process, $q + g \rightarrow q + \gamma$, and the photon momentum in the center-of-mass frame is exactly balanced by that of the recoil quark. Higher-order effects and other complications to this idealized picture, such as next-to-leading order (NLO) $2 \rightarrow 3$ bremsstrahlung and other "fragmentation" photons or soft gluon radiation, also do

*Deceased.
†PHENIX spokesperson: jacak@skipper.physics.sunysb.edu

need to be considered. Nonetheless, the level of suppression can then be related directly to the energy loss of a parton of known initial momentum. In this way, the average path length of the away-side parton may then be varied in a well-controlled manner by selecting events of various momentum differences between the γ-h pair.

For this reason, the γ+jet channel has long been considered the "golden channel" for studying parton energy loss [13,14]. Neglecting the above-mentioned complications, specifically effects like transverse momentum broadening (the k_T effect) and parton-to-photon fragmentation, back-to-back γ-h correlations in elementary collisions directly measure the fragmentation function of the recoil jet because $z \equiv p^h/p^{\rm jet} \approx p^h/p^\gamma$. In the standard picture of energy loss, partons are likely to lose some fraction of their energy in the medium but are likely to fragment outside the medium. Hence, the parton energy loss can be considered an effective modification to the fragmentation function. Such a picture may be tested using γ-h correlations in nuclear collisions. Complementary baseline measurements in $p+p$ collisions are used to test the theoretical description of correlations in vacuum and to constrain possible contributions from higher-order processes. Comprehensive reviews of direct photon phenomenology and data from elementary collisions may be found in Refs. [15–17].

II. DETECTOR DESCRIPTION AND PARTICLE IDENTIFICATION

The data were taken with the PHENIX detector [18] using approximately 950 million Au + Au minimum bias events from the 2004 data set and 471 million photon-triggered events from the 2005 and 2006 $p+p$ data sets corresponding to integrated luminosities of 3 (2005) and 10.7 (2006) pb^{-1}. The beam-beam counters (BBC) [19], which are used to trigger the minimum bias data, select 92% of the total inelastic cross section. In Au + Au the BBC and zero-degree calorimeters (ZDC) were used for offline minimum bias event selection and centrality determination. In $p+p$ collisions a high-energy photon trigger, defined by coincidence between the BBC and a high-energy electromagnetic calorimeter (EMCal) tower hit, was used. This EMCal based trigger [20] had an efficiency of >90% for events with photons and π^0 with energies in the range used in the analysis and within the detector's geometric acceptance.

The PHENIX central arms, each covering ± 0.35 units of pseudorapidity around midrapidity and 90° in azimuth, contain charged-particle tracking chambers and electromagnetic calorimeters [21]. The EMCal [22] consists of two types of detectors, six sectors of lead-scintillator (PbSc) sampling calorimeters and two of lead-glass (PbGl) Cerenkov calorimeters measuring EM energy with intrinsic resolution $\sigma_E/E = 8.1\%/\sqrt{E} \oplus 2.1\%$ and $5.9\%/\sqrt{E} \oplus 0.8\%$, respectively. The fine segmentation of the EMCal ($\Delta\eta \times \Delta\phi \sim 0.01 \times 0.01$ for PbSc and $\sim 0.008 \times 0.008$ for PbGl) allows for the reconstruction of π^0 and η mesons in the 2γ decay channel out to p_T of 20 GeV/c. The details of direct photon and π^0 - and η-meson detection and reconstruction within PHENIX have been described previously [12,23,24]. Photon candidates with very high purity (>98% for energies >5 GeV) are selected from EMCal clusters with the use of cluster shower shape and charged particle veto cuts. Two-photon π^0 and η candidates are selected from photon pairs with pair invariant mass in the appropriate π^0 or η mass range. Combinatorial 2γ background is reduced with cuts on energy asymmetry $\alpha_{12} = |E_1 - E_2|/(E_1 + E_2)$, described in detail below. Some fraction of π^0 with p_T starting at ≈13 GeV/c (in the PbSc detector) will appear as a single merged cluster, but with anomalous shower shape, and thus are removed from the analysis. The π^0 and η mesons in the p_T range from about 4 to 17 GeV/c and photons between 5 and 15 GeV/c are used in this analysis. For γp_T between 13 and 15 GeV/c there is a <2% contribution of merged π^0 cluster contamination; however, this together with all sources of nonphoton contamination are found to have a negligible impact on the two-particle correlation analysis of this report. Direct photons and their two-particle correlations are obtained by statistical subtraction of the estimated meson (mainly π^0) decay photon contribution from the inclusive photon and γ-h samples.

Charged hadrons are detected with the PHENIX tracking system [25] that employs a drift chamber in each arm spanning a radial distance of 2.0–2.4 m from the beam axis with a set of pixel pad chambers (PC1) directly behind them. The momentum resolution was determined to be $\delta p/p = 0.7\% \oplus 1.0\% p$, where p is measured in GeV/c. Secondary tracks from decays and conversions are suppressed by matching tracks to hits in a second pad chamber (PC3) at distance of ∼5.0 m. Track projections to the EMCal plane are used to veto photon candidates resulting from charged hadrons that shower in the EMCal.

III. METHOD

A. Two-particle correlations

Two-particle correlations are constructed by measuring the yield of particle pairs as a function of the measured azimuthal angle between photon or parent meson triggers and charged hadron partners. The correlation function, $C(\Delta\phi) \equiv N^{\rm pair}_{\rm real}(\Delta\phi)/N^{\rm pair}_{\rm mixed}(\Delta\phi)$, corrects for the limited acceptance of γ-h or meson-hadron pairs by dividing the distribution in real events $N^{\rm pair}_{\rm real}$ by the mixed event distribution $N^{\rm pair}_{\rm mixed}$. The correlation function is decomposed utilizing a two-source model of pair yields coming from two-particle jet correlations superimposed on a combinatorial background yield from an underlying event. The underlying event in Au + Au is known to have an azimuthal asymmetry of harmonic shape quantified in the elliptic flow parameter v_2 [26,27]. This flow represents a harmonic modulation of the $\Delta\phi$ distribution of this underlying event such that the flow-subtracted jet correlation signal is encoded in the jet pair ratio function, $JPR(\Delta\phi) \equiv C(\Delta\phi) - \xi(1 + 2\langle v_2^\gamma\rangle\langle v_2^h\rangle \cos 2\Delta\phi)$, using the notation of Ref. [4], where $\langle v_2\rangle$ is the average single-particle v_2.

Two methods of determining the background level ξ, known as zero-yield at minimum (ZYAM) and absolute normalization (ABS), respectively, were applied to the Au + Au data. Both methods are described in detail in previous PHENIX publications [4]; see also Refs. [4,28,29] (ABS) and [30]

(ZYAM). ZYAM assigns the level of zero jet yield and hence ξ to the minimum point of the correlation function $C(\Delta\phi)$. The ABS method uses the mean multiplicity of trigger-associated pairs in mixed events and a correction for finite centrality resolution to determine ξ. Where ZYAM statistical precision is reasonable, the direct γ-h extraction of the two methods agree to within much better than the total uncertainties, typically within $\leqslant$20%. The ABS method is chosen for the Au + Au results presented, as this method resulted in a more precise extraction of direct photon-jet pair yields at high trigger p_T where lack of statistics near $\Delta\phi = \pi/2$ severely impairs the ZYAM determination. In the comparatively low multiplicity $p+p$ collisions, the underlying event originates from different physical mechanisms than in Au + Au and is known not to be well described by event mixing. Instead the correlation functions are normalized by fitting to a double Gaussian + constant function, corresponding to the ZYAM method [4].

The results presented here are corrected for the associated charged hadron efficiency ϵ_h such that the quoted yields correspond to a detector with full azimuthal acceptance and $|\eta| < 0.35$ coverage. No correction is applied for the $\Delta\eta$ acceptance of pairs. Final results are presented in terms of the yield Y of jet pairs per trigger, $Y \equiv A \times JPR\,(\Delta\phi)/N_{\text{trigger}}$ with the constant $A = \int N^{\text{pair}}_{\text{mixed}}(\Delta\phi)/(2\pi\epsilon_h)$.

The magnitudes of elliptic flow were determined by measuring the distributions of inclusive photons, neutral pions, and charged hadrons as a function of the angle relative to the reaction plane, which was determined with the BBC's as described in Ref. [31]. The v_2 values measured for this analysis are consistent with previous PHENIX analyses [26,27,32].

At high-p_T ($\geqslant$6 GeV/c) the measured $\pi^0 v_2$ values used in the determination of the decay photon v_2 are fit to a constant function to reduce the effects of large statistical fluctuations. The p_T independence of v_2 of π^0's is motivated by recent preliminary data [33] and by the observed p_T independence of the R_{AA}, because parton energy loss is expected to be the dominant mechanism for azimuthal asymmetry generation at high-p_T [7]. It is also consistent with the findings of Ref. [32] that is direct measurement of $\pi^0 v_2$ for the same data set and is being published concurrently with this measurement. Because, as discussed in that publication, the high-p_T functional behavior for this data set cannot be well constrained, the level of uncertainty we assign to the constant fit assumption increases with p_T. It is further assumed that the v_2 for other mesons that contribute decay photons (e.g., η) are the same as that of the π^0 at high p_T. For the p_T range considered ($\gtrsim$4.5 GeV/c) this assumption is also well motivated under the same expectation of v_2 being due to jet quenching, because R_{AA} suppression is already measured to be the same for a variety of mesons (e.g., η itself [24]). Additionally, other high-p_T v_2 data measurements confirm the expectation [34] for other hadron species.

Table I lists the v_2 values for the inclusive and π^0 decay photons for all p_T ranges used, either the measurements, or for the highest p_T decay v_2 values from the constant fit value. For the fit values the fit errors are listed as statistical error, despite the inherent systematic correlation of the fit value across the p_T bins. The reduction of the statistical error for decay γ v_2 due to fit procedure is clear from comparison to statistical error on the inclusive γ v_2, for which no such fit procedure is used. The assumptions justifying the fit procedure do not apply to the inclusive photons because of their large fraction of direct photons. Direct photon v_2, if present, is not expected to be influenced by the same energy loss mechanisms. The decay photon v_2 is derived from the measured $\pi^0 v_2$ by the same $p_T^{\pi^0} \rightarrow p_T^{\text{decay}\,\gamma}$ mapping procedure applied to the yields, described below, though the difference between π^0 and decay v_2 values are negligible compared to the other uncertainties. Listed v_2 systematic uncertainties come only from reaction plane resolution propagated into each p_T bin [4,31]. This procedure has a component that depends again on the statistics in each bin and thus can fluctuate in relative size. The decay γ values are not corrected for π^0 combinatoric background that is discussed below along with the relevant associated systematic error for the estimated for the final jet yield results.

TABLE I. v_2 values used in the jet function extraction for inclusive and decay photons in Au + Au collisions.

B. Direct γ-hadron correlation subtraction

A direct photon is defined here to be any photon not from a decay process. Direct photons cannot be identified in Au + Au with reasonable purity on an event-by-event basis due to the large background of meson decay in the p_T range of the analysis and the inability to use isolation cuts in the high multiplicity Au + Au environment. Thus both direct γ and γ-h pairs must be determined from the already-mentioned statistical subtraction procedure, which is therefore consistently used in this report for both the $p + p$ and Au + Au.

Single direct photons have previously been measured in PHENIX for Au + Au [12] and $p + p$ [35]. In these analyses, the estimated yield of decay photons $N^{\gamma}_{\rm decay}$ is subtracted from a measured sample of inclusive photons $N^{\gamma}_{\rm inclusive}$ resulting in the direct photon yield. These measurements serve as an input to the current analysis, as they fix the fraction of the photon triggers that are expected to be direct. This fraction is quantified by the fraction $R_\gamma \equiv N^{\gamma}_{\rm inclusive}/N^{\gamma}_{\rm decay}$. The R_γ values used in this analysis are extracted from previous PHENIX measurements, [36,37] by interpolating to obtain the p_T binning used in this analysis. These interpolated values together with the error estimations are tabulated in Table II.

The per-trigger yield of inclusive γ-h pairs $Y_{\rm inclusive}$ is simply the weighted average of the contributions from decay and direct photon triggers,

$$Y_{\rm inclusive} = \frac{N^{\gamma}_{\rm direct} Y_{\rm direct} + N^{\gamma}_{\rm decay} Y_{\rm decay}}{N^{\gamma}_{\rm inclusive}}. \tag{1}$$

Having already determined R_γ, $Y_{\rm direct}$ may then be obtained by simple manipulation of the above terms. This results in a statistical subtraction that involves only per-trigger yields. Solving for $Y_{\rm direct}$ and rewriting in terms of R_γ we obtain the subtraction formula:

$$Y_{\rm direct} = \frac{R_\gamma Y_{\rm inclusive} - Y_{\rm decay}}{R_\gamma - 1}. \tag{2}$$

The direct γ or direct γ-h pair yields do not, by definition, exclude photons from jet fragmentation or medium induced photon production.

TABLE II. Extracted R_γ values used as input to direct γ-h per-trigger yield subtraction [Eq. (2)]. These values are interpolated from previous PHENIX measurements as described in the text.

C. Extraction of decay photon correlations

The decay photon associated yields are estimated from the measured π^0-h and η-h correlations through a calculation that determines the decay correlations statistically from a Monte Carlo (MC) based, pair-by-pair weighting procedure. In this procedure the decay γ-h pair yield $N^{\gamma\text{-}h}_{\rm decay}(p_T^\gamma)$ is constructed by a weighted integral over all π^0-h and η-h pairs. In what follows, we will first describe the procedure schematically, describing the ingredients and how they are obtained. We then give a more exact description and associated formula representing exactly how the weighting was performed in the measurement. Schematically the procedure may be expressed as a convolution of several factors according to the following relation, wherein for simplicity we only consider photons from π^0 decay, although the procedure is also applied to η-decay photons.

$$N^{\gamma\text{-}h}_{\rm decay}(p_T^\gamma) = \int \frac{\epsilon_\gamma(p_T^\gamma, p_T^\pi) \otimes \mathcal{P}(p_T^\gamma, p_T^\pi)}{\epsilon_\pi(p_T^\pi)} \otimes N^{\pi\text{-}h}(p_T^\pi), \tag{3}$$

where ϵ_π and ϵ_γ are the π^0 and single *decay* photon efficiencies, respectively, and $\mathcal{P}$ is the decay probability density, each of which is addressed in turn below.

First, because the starting point is the uncorrected raw meson-h pair yield $N^{\pi\text{-}h}$, a correction for the parent meson reconstruction efficiency, $\epsilon_\pi(p_T^\pi)$, is applied to the raw π^0's as a function of p_T to account for the π^0 daughter photons in the inclusive sample whose sisters lie outside the PHENIX acceptance or are otherwise undetected. Both efficiencies, ϵ_γ and ϵ_π, in Eq. (3) are also evaluated as a function of the position in the calorimeter along the beam direction; however, this dependence mostly cancels in the ratio $\epsilon_\gamma/\epsilon_\pi$ and therefore is suppressed for clarity. The value of $\epsilon_\pi(p_T^\pi)$ is determined by dividing the raw number of π^0's $N^\pi(p_T^\pi)$ obtained in the same data sample by our published π^0 invariant yields [2,24,38] assuming no pseudorapidity dependence over the narrow PHENIX acceptance. The top panel in Fig. 1 illustrates, for the example of central Au + Au events, the π^0 efficiency correction factor $1/\epsilon_\pi(p_T^\pi)$. The correction rises at small p_T due to a p_T-dependent pair energy asymmetry cut designed to reduce combinatorial 2γ pairs reconstructed as real π^0's. This cut, along with the effects of any remaining background, is described below. At large p_T the quantity $1/\epsilon_\pi(p_T^\pi)$ rises again due to losses from cluster merging.

Second, the effect of decay kinematics is evaluated by determining the probability density, $\mathcal{P}(p_T^\gamma, p_T^\pi)$, for the decay of a p_T-independent distribution of π^0's. $\mathcal{P}(p_T^\gamma, p_T^\pi)$ represents the relative probability of a π^0 of $p_T = p_T^\pi$, to decay into a photon of p_T^γ. For a perfect detector, this function is calculable analytically. A simple fast MC generator implements the

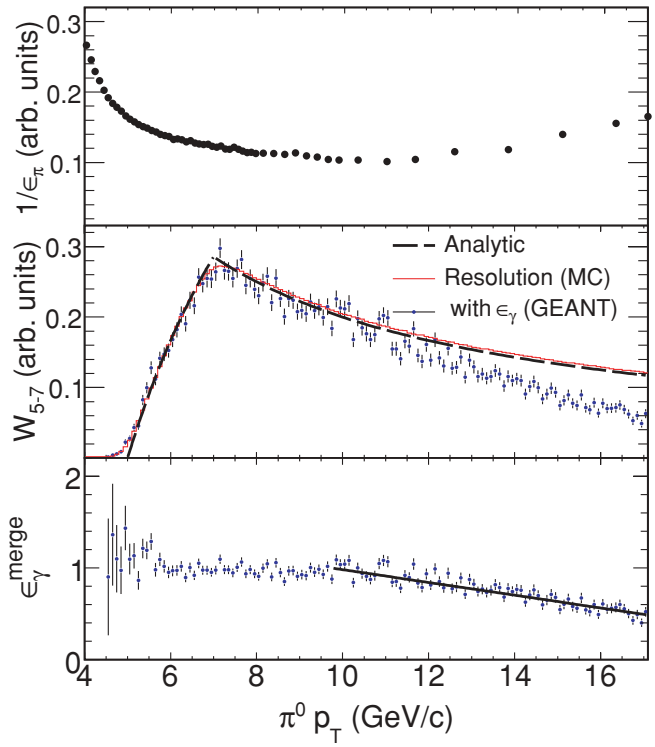

FIG. 1. (Color online) The weight factors used to obtain decay correlations from parent meson correlations. (Top) π^0 reconstruction efficiency correction, $1/\epsilon_\pi$, shown in arbitrary units. (Middle) Decay probability function, W_{ab}, also in arbitrary units, for 5–7 GeV/c decay photons from π^0 derived analytically (black line), using the detector acceptance and resolution smearing (red line) and including the single decay photon efficiency, ϵ_γ, from a GEANT simulation (blue points). (Bottom) $\epsilon_\gamma^{\text{merge}}$ obtained by taking ratio of the blue points to red curve in the previous panel.

PHENIX acceptance and uses Gaussian smearing functions to simulate detector resolution according to the known EMCal energy and position resolution. Occupancy effects give rise to an additional smearing of the π^0 and η invariant masses. This effect is included in the MC by tuning the resolution parameters to match the π^0 peak widths observed in data. False reconstruction of π^0's and η's from combinatorial matches are either subtracted or assigned to the systematic uncertainties as discussed below.

Finally, we wish to estimate the decay photon contribution to the measured raw inclusive photon sample that differs from the true decay photon distribution by the single decay photon efficiency, $\epsilon_\gamma(p_T^\pi)$. At intermediate p_T, $\epsilon_\gamma(p_T^\pi)$ depends only on the photon momentum and is included already implicitly by the fast MC simulation described above to produce $\mathcal{P}(p_T^\gamma, p_T^\pi)$. Thus, it is useful to think of them as a single factor $W(p_T^\gamma, p_T^\pi) \equiv \mathcal{P}(p_T^\gamma, p_T^\pi)\epsilon_\gamma(p_T^\gamma, p_T^\pi)$ At high p_T, however, an efficiency loss is incurred by photons from π^0's whose showers merge into a single cluster in the calorimeter and are rejected by the shower-shape cut. As a consequence, the fraction of photons that are direct is artificially enhanced in the sample of reconstructed photon clusters. The single decay photon efficiency depends on both the parent and daughter p_T and is evaluated in a GEANT simulation. In principle the convolution of both $\mathcal{P}(p_T^\gamma, p_T^\pi)$ and $\epsilon_\gamma(p_T^\gamma, p_T^\pi)$, $W(p_T^\gamma, p_T^\pi)$ could be extracted as one function from the GEANT simulation, but obtaining large-enough MC statistics necessary to properly parametrize the above-mentioned EMCal z position dependence of the $\epsilon_{\pi,\gamma}$ corrections is feasible only with the fast MC. Thus only the efficiency loss by cluster merging for photons $\epsilon_\gamma^{\text{merge}}$ is taken from the GEANT. The bottom panel of Fig. 1 shows $\epsilon_\gamma^{\text{merge}}(p_T^\pi)$ evaluated from the GEANT simulation.

Because we wish to construct per-trigger yields, the same procedure described in Eq. (3) can be applied to find the estimated single decay photon trigger yield from the measured single π^0's, i.e., replacing $N_{\text{decay}}^{\gamma\text{-}h}$ with $N_{\text{decay}}^{\gamma}$ and $N^{\pi\text{-}h}$ with N^π. The exact application of schematic Eq. (3) then takes the form of a sum over all π^0-h pairs and single π^0's found in the data. Each π^0 or π^0-h pair is given a weight that depends on $\pi^0 p_T$. Operationally we now split this weight into two parts: $\epsilon_\pi(p_T^\pi)$ discussed above and a factor $W_{ab}(p_T^\pi)$. The factor W_{ab} is simply the end result of the fast MC-GEANT combined calculation, the convolution of $\mathcal{P}$ and ϵ_γ, including $\epsilon_\gamma^{\text{merge}}$, averaged over a chosen decay photon bin of the range $a < p_T < b$. Thus in terms of the product $W(p_T^\gamma, p_T^\pi)$ then $W_{ab}(p_T^\pi)$ is given by

$$W_{ab}(p_T^\pi) = \int_a^b dp_T^\gamma W(p_T^\pi, p_T^\gamma). \tag{4}$$

The functions $W_{ab}(p_T^\pi)$ are defined for the four photon p_T bins used in the analysis, $[a,b] = [5,7]$, [7,9], [9,12], and [12,15] GeV/c. An example of $W_{ab}(p_T^\pi)$ for the 5- to 7-GeV/c bin is shown in Fig. 1. Procedurally, we construct W_{ab} as product of the fast MC curve shown in the middle panel and the linear fit discussed above to the bottom panel, $\epsilon_\gamma^{\text{merge}}(p_T^\pi)$. Although a decay of $p_T^\pi < a$, the lower limit of the decay p_T bin, is kinematically disallowed, W_{ab} is nonzero below this boundary when resolution effects are considered. For $p_T^\pi > b$, W_{ab} decreases as $\sim 1/p_T^\pi$, slowly enough that π^0's at values of p_T beyond the statistical reach of the data set contribute to the relevant decay photon p_T selections at a non-negligible rate. The π^0 sample is truncated at $p_T = 17$ GeV/c and extrapolated using power-law fits to the single and conditional π^0 spectra to estimate a correction. In the latter case, each associated hadron p_T range is fit independently. The truncation avoids the high-p_T region where cluster merging effects are dominant and the $1/\epsilon^\pi$ correction factor becomes large. Although the truncation corrections for the number of decay photons and decay γ-h pairs are non-negligible, they mostly cancel in the per-trigger yield and are therefore typically <1%, reaching a maximum value of 7% for only the $12 < p_T^\gamma < 15 \otimes 3 < p_T^h < 5$ GeV/c bin.

With the weight functions W_{ab} the entire set of π^0-hadron pairs and single π^0 candidates (within a given range of $\Delta\phi$, $\phi_1 < \Delta\phi < \phi_2$, defining each $\Delta\phi$ bin) are then summed over, once for each decay photon p_T bin, and the per-trigger yield is constructed for each of these decay p_T bins as

$$Y_{\text{decay}}\big|_{a<p_T^\gamma<b}^{\phi_1<\Delta\phi<\phi_2} = \frac{\sum_{i=1-N^{\pi\text{-}h}}^{\phi_1<\Delta\phi_{\pi\text{-}h}<\phi_2} W_{ab}\left(p_{Ti}^{\pi_i}\right)/\epsilon_\pi\left(p_T^{\pi_i}\right)}{\sum_{i=1-N^\pi} W_{ab}\left(p_{Ti}^{\pi_i}\right)/\epsilon_\pi\left(p_T^{\pi_i}\right)}. \tag{5}$$

In this form it is clear that the normalization of the functions $\epsilon_\pi(p_T^\pi)$ and $W_{ab}(p_T^\pi)$ cancel out completely in the per-trigger yield, and therefore only their shapes versus p_T^π are important. Hence in Fig. 1 the curves are shown with arbitrary units. Also, as Eq. (5) implies, the angular deviation between the direction of a decay photon and its parent meson is ignored. The $\Delta\phi$ opening angle of a decay photon and hadron pair is taken to be the same as the $\Delta\phi_{\pi\text{-}h}$ of the parent π^0-h pairs. This approximation is tested in the fast MC and found to be extremely accurate because the distribution of angular deviation between a leading decay photon in a 2γ decay and the parent mesons at these π^0 momenta have an rms around 0 of $\ll$0.01 radians, and the smallest $\Delta\phi$ bins considered in the analysis are typically $\sim$0.1 radians or larger.

D. π^0 and η reconstruction

In $p+p$ collisions $Y_{\rm decay}$ is estimated using both reconstructed π^0 and η mesons in invariant mass windows of 120–160 and 530–580 MeV/c^2, respectively. The total decay per-trigger yield is calculated from

$$Y_{\rm decay} = \left(1-\delta^\gamma_{h/\pi^0}\right)Y^{\pi^0}_{\rm decay} + \delta^\gamma_{h/\pi^0}Y^{\eta}_{\rm decay}, \qquad (6)$$

where δ^γ_{h/π^0} is the ratio of the total number of decay photons to the number of decay photons from π^0. Based on the measurements of η [24] and ω [39], which together with the π^0 account for >99% of decay photons, the value of δ^γ_{h/π^0} is determined to be 1.24 ± 0.05 in the high-p_T region covered by this analysis, independent of collision system and centrality. Note that the per-trigger yields for ω and other heavier meson triggers ($\omega, \eta', \phi, \ldots$) are not measured and are taken to be equivalent to $Y^\eta_{\rm decay}$ in Eq. (6). This assumption was studied in PYTHIA and found to influence $Y_{\rm decay}$ at the level of <2%. In Au + Au collisions correlations using η triggers are not directly measured but rather estimated from the $p+p$ measurement as discussed below.

Figure 2 shows the various components of the decay photon measurement in $p+p$. In $p+p$ collisions the rate of combinatorial background photon pairs is reduced by considering only photons of $p_T > 1$ GeV/c resulting in background levels of <10% for which no correction was applied. The effect of such remaining pairs on $Y^{\pi^0}_{\rm decay}$ was evaluated to be negligible (<2%) compared to the size of other uncertainties on the final $Y_{\rm direct}$ result using a detailed full PYTHIA test of the method that included π^0 reconstruction with combinatorial photon pairs. However, η reconstruction has a much smaller signal-to-background of 1.4–1.6, depending on the p_T selection, even in the low multiplicity $p+p$ environment. In this case, the per-trigger yield of the combinatorial photon pairs is estimated from photon pairs with invariant mass in "sideband" ranges of 400–460 and 640–700 MeV/c^2, beyond 3σ of the η peak. The sideband contribution $Y^{\rm sideband}_{\rm decay}$ is then subtracted using the signal-to-background ratio $f_{\rm bkg}$ evaluated from Gaussian + polynomial background fits to the invariant mass distributions according to $Y^{\rm signal}_{\rm decay} = Y^{\rm raw}_{\rm decay}/(1/f_{\rm bkg}+1) - Y^{\rm sideband}_{\rm decay}/f_{\rm bkg}$. The yield $Y^{\rm sideband}_{\rm decay}$ is generated from the full meson to decay photon weighting function procedure [Eq. (5)]. The subtraction procedure was also tested

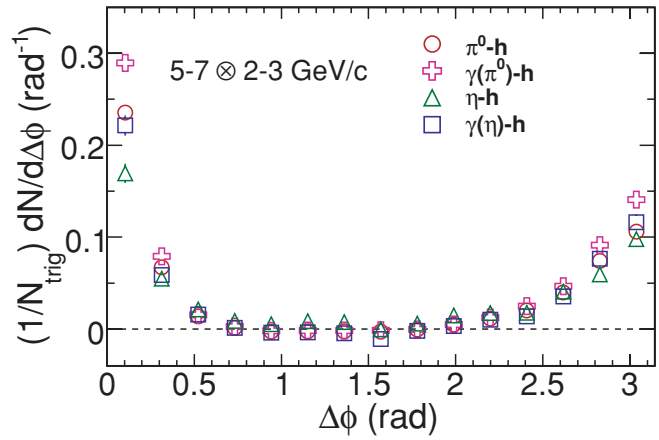

FIG. 2. (Color online) Examples of parent and daughter per-trigger yields for the π^0 and η in $p+p$ collisions for p_T selection $5 < p_T^\gamma < 7$ and $2 < p_T^h < 3$ GeV/c. These ZYAM correlation measurements, fully corrected for acceptance and efficiency (expcept the PHENIX rapidity acceptance), are used to determine the total decay photon per-trigger yield as described in the text.

in PYTHIA and the extracted and input per-trigger yields were found to agree to within 10%.

In Au + Au collisions the combinatorial rate for π^0 reconstruction is substantially larger. Correspondingly, a p_T-dependent cut on the pair energy asymmetry $\alpha_{12} = |E_1 - E_2|/(E_1+E_2)$ [23], visible in Fig. 1 with the smallest allowed asymmetry at the lowest $\pi^0 p_T$ values, is used to reduce this background. With such cuts the signal-to-background in central events varies from 5:1 at its lowest, increasing to about 15:1 for the highest p_T selection. The effect of the combinatorial background is studied through examination of a similar sideband subtraction analysis as in the $p+p\eta-h$ correlation extraction described, this time for π^0-h, using invariant mass ranges just outside the π^0 peak region. However, no clear trend beyond non-negligible statistical limitations is observed, so no correction for the background is applied. Instead the maximum size of the effect (typically $\simeq$7%) is included as source of systematic uncertainty on the decay yields and propagated to the final direct photon per-trigger yields.

In central Au + Au collisions the η meson cannot be reconstructed with sufficient purity to measure its correlations. Instead, a scaling argument is employed. Motivated by the similar high-p_T suppression pattern shown by η and π^0 in Au + Au [24] and corresponding near equality of the $p+p$ and Au + Au η/π^0 ratios, the ratio $Y_{\gamma(\eta)}/Y_{\gamma(\pi^0)}$ is measured in $p+p$ and applied as a correction to the Au + Au $Y_{\gamma(\pi^0)}$. This is justified by the assumption that the jet fragmentation is primarily occurring outside the medium. We do not attribute any additional uncertainty to this scaling beyond the 10% sideband systematic and statistical uncertainties of the η measurement in $p+p$. However, to give an idea of the possible impact of this assumption, the size of the total systematic uncertainty on $Y_{\rm decay}$ from all other sources would be equivalent to a variation of the Au + Au$Y_{\gamma(\eta)}$ by $\sim$50%. Given the similarity of the high-p_T suppression demonstrated

by all light quark bound states measured thus far, this would correspond to a rather large change.

IV. SYSTEMATIC UNCERTAINTIES

There are four main classes of systematic uncertainty in the Au + Au data: elliptic flow, normalization of the underlying event (ABS), R_γ, and the decay per-trigger yield estimate, only the latter two of which are present or non-negligible in the $p+p$ data. Table III lists the fractional contribution of each of these sources to the total systematic uncertainty on the direct photon per-trigger yields in the 20% most central Au + Au and $p+p$ data. In the central Au + Au data the uncertainty at low p_T^h is dominated by the v_2 and correlation function normalization (ABS method) estimation due to large multiplicity of hadrons. At higher p_T^h, but low trigger p_T, p_T^t, the decay error dominates due to the two-photon combinatorial background for π^0 reconstruction. Finally, at large p_T^h and p_T^t the backgrounds responsible for both of these sources of uncertainty decrease and the uncertainty on R_γ, which is relatively constant, dominates. In $p+p$ collisions the decay photon background forms a much larger fraction of the total photon sample. In this case, the decay uncertainty arises from the MC decay photon mapping procedure, the η sideband subtraction and the η/π^0 ratio in approximately equal parts. The yields associated with daughter photons are larger than for the meson parents because of feed-down from larger values of parent p_T, and hence, jet p_T.

The correction for single hadron efficiency $\epsilon_h(p_T^h)$ varies as a function of collision system and centrality. These corrections are obtained by finding the ratio of raw yields of hadrons obtained without the trigger condition in the same analysis (i.e., with the same cuts as in the analysis to the previous PHENIX published measurements of the corresponding charged hadron spectra) [40,41]. As in previous PHENIX two-particle correlation measurements [4,30], this procedure has inherent uncertainties assigned as a p_T-independent 10% uncertainty, on each system and/or centrality.

TABLE III. Fractional contribution to the total systematic uncertainty for each of the main sources of uncertainty in $p+p$ and 0–20% Au + Au collisions. Derived by propagating each uncertainty individually and finding fraction of the total (nonquadrature) sum. For the total systematic uncertainties (see Table IV), sources are added in quadrature as usual.

V. RESULTS

A. Direct γ-h per-trigger yields

Figure 3 shows examples of direct photon per-trigger yields in $p+p$ and central Au + Au collisions. Also shown are the per-trigger yields for inclusive and decay photon triggers that are the ingredients in the statistical subtraction method as expressed in Eq. (2). A clear away-side correlation is observed ($\Delta\phi \simeq \pi$) for direct photons triggers in $p+p$. In Au + Au collisions the away-side correlation is suppressed for both decay and direct photon triggers. The near-side direct photon associated yields are small relative to that of decay photons, an expected signature of prompt photon production [16].

The away-side yields, integrated over $|\Delta\phi - \pi| < \pi/5$ radians, are shown in Fig. 4 and Table IV for $p+p$ and Au + Au collisions. This range roughly corresponds to the "head region" as defined in Ref. [4] and is chosen primarily to minimize the influence of medium response that is thought to dominate the "shoulder" region further offset from $\Delta\phi = \pi$. Additionally, the acceptance and the signal itself are largest in this range so statistical precision is maximized. It should be noted that the width of the jet correlation is larger than this interval. We do not make a correction for this effect, because we are primarily concerned with the comparison of the yields from $p+p$ and Au + Au collisions. It should be noted, however, that in addition to parton energy loss, any broadening of azimuthal correlations, whether by hot or cold nuclear matter effects, will contribute to a suppression in the yield in the head region. Due to statistical and systematic fluctuations, the subtraction of the decay-photon hadron pairs

FIG. 3. from the inclusive γ-h sample can result in a negative yield. In this case 90% confidence-level upper limits are given. In the case that a positive yield is obtained, but the uncertainty is consistent with 0, the lower bound of the error bar is also replaced with an arrow. As noted in the figure caption, a 10% p_T-independent uncertainty due to the charged hadron efficiency corrections is not shown.

B. Suppression factor I_{AA}

Departure from the vacuum QCD processes is quantified by I_{AA}, the ratio of Au + Au to $p + p$ per-trigger yields:

$$I_{AA}\left(p_T^\gamma, p_T^h\right) = \frac{Y^{\text{Au+Au}}\left(p_T^\gamma, p_T^h\right)}{Y^{p+p}\left(p_T^\gamma, p_T^h\right)}. \quad (7)$$

Figure 5 shows the I_{AA} values for all direct photon and associated hadron bins for the most central 0–20% of collisions. The data points for which the subtraction resulted in a negative yield value (the 90% confidence level upper limits) are included with standard 1-σ uncertainties. For the p_T^γ range 5–12 GeV/c, a significant suppression is observed in the $3 < p_T^h < 5$ GeV/c bin in which the highest precision is obtained. At lower p_T^h, where the background subtraction is largest, the data do not have the statistical precision to determine the degree to which the yields are suppressed. I_{AA} for direct photon triggers is consistent to that of charged hadron triggers [4] as shown in the top left panel in which results with similar ranges of $p_{T,t}$ are compared.

Figure 6 shows the I_{AA} for the $p_T^h = 3$–5 GeV/c bin, integrated for all trigger p_T bins ($p_T^\gamma = 5$–15 GeV/c) and for three centrality bins, 0–20%, 20–40%, and 40–60%. For the most central bin, the suppression of the away-side direct photon per-trigger yield is clearly observed, $I_{AA} = 0.32 \pm 0.12^{\text{stat}} \pm 0.09^{\text{syst}}$. Within large uncertainties we see that the γ-jet I_{AA} in this p_T range, dominated by moderate to high values of z ($\equiv p^h/p^{\text{jet}}$), is consistent with the single-particle R_{AA} as a function of centrality, consistent with a scenario in which the geometry of suppression plays an important role as would be expected from a sample dominated by surface emission.

Figure 6 also compares I_{AA} from a measurement of high-p_T dihadron ($h^\pm - h^\pm$) correlations [4] to the γ-jet result for similar $p_{T,t}$ selections. The two results are remarkably similar in the most central bin. This may indicate that surface emission is dominant for both samples in this z region. However it should

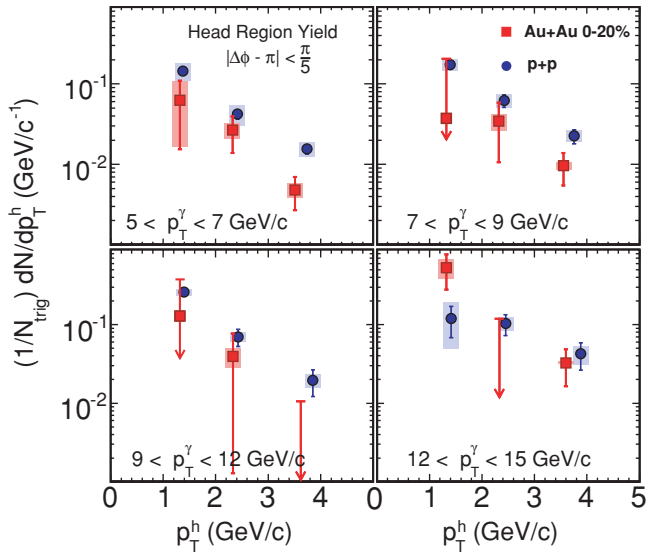

FIG. 4. (Color online) Direct γ-h per-trigger yields for the range $|\Delta\phi - \pi| < \pi/5$ radians vs. associated hadron p_T. Four different direct γp_T ranges (indicated on the figure) are shown in the most central 20% of Au + Au events and $p + p$ events. The upper limits are for 90% confidence levels. A p_T-independent uncertainty of 10% due to the charged hadron efficiency correction is suppressed from the plot.

be noted that the total uncertainties on either measurement are still quite large on a relative scale. Also, because our method does not remove the so-called "fragmentation prompt photon" or NLO direct photon contribution associated with dijet production, a small residual dijet contribution may be present; however, this contribution will be suppressed by R_{AA} relative to that of γ-jet and thus will not affect interpretations

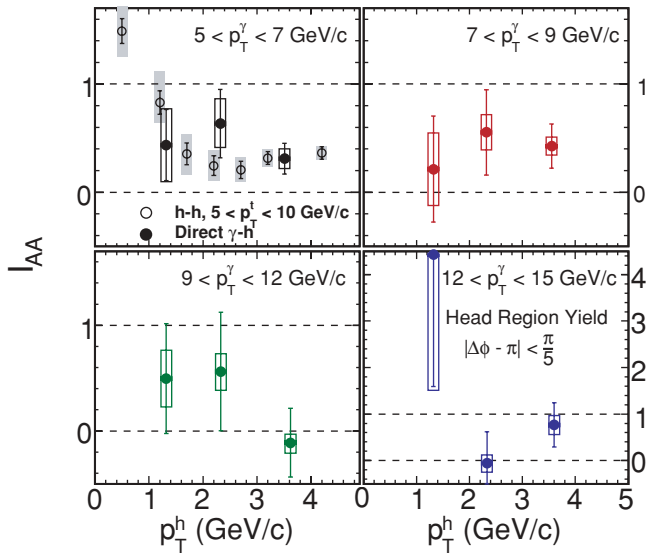

FIG. 5. (Color online) Ratio I_{AA} of the Au + Au to $p + p$ yields shown in Fig. 4. For comparison the first panel shows dihadron correlation data from Ref. [4]. An additional p_T-independent uncertainty of 14% due to the charged hadron efficiency corrections is not shown.

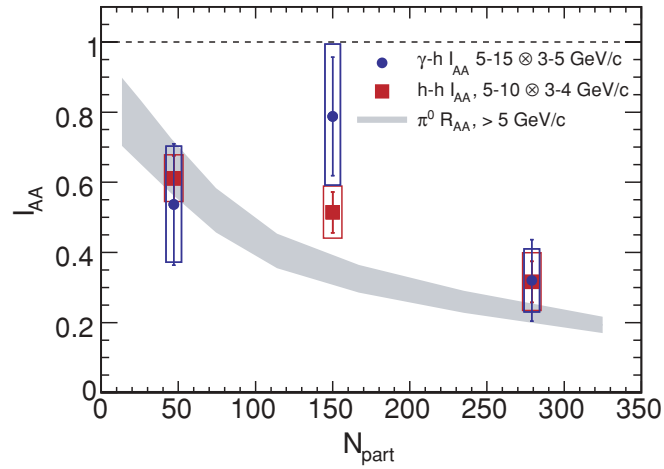

FIG. 6. (Color online) $I_{AA}(p_T^\gamma)$ integrated over the range $5 < p_T^\gamma < 15$ GeV/c for associated hadrons of $3 < p_T^h < 5$ GeV/c vs. centrality compared to single π^0 high-p_T R_{AA} (integrated over $p_T > 5$ GeV/c) [2]. An additional p_T-independent uncertainty of 14% due to the charged hadron efficiency corrections is not shown.

of the data presented here. As explained in the introduction, the dijet and γ-jet measurements should be subject to different geometrical effects. Disentangling such effects through precise comparisons of dihadron and γ-h suppression should be pursued with future measurements with improved statistics.

C. Towards the fragmentation function

Using the distribution of charged hadrons opposite direct γ triggers, parton energy loss may be studied directly as a departure from the (vacuum) fragmentation function. In distinction to π^0-h correlations, where the away-side distribution is sensitive only to the integral of the fragmentation function (the average multiplicity of the away-side jet) [42], the away-side distribution for direct γ-h correlations provides a measurement of the full fragmentation function of the jet from the away-side parton. To the extent that the transverse momentum of the away-side parton and the direct γ are equal and opposite, as in leading order pQCD, the fragmentation function of the jet from the away-parton should be given to a good approximation by the x_E distribution,

$$x_E = \frac{-\vec{p}_T^{\,t} \cdot \vec{p}_T^{\,h}}{\left|\vec{p}_T^{\,t}\right|^2} = \frac{-p_T^h \cos\Delta\phi}{p_T^t}, \tag{8}$$

where the transverse momentum of the trigger $p_T^t = p_T^\gamma$ in the case of γ-h correlations. The reasons why the scaling variable x_E is an approximation to, rather than an exact measure of, the fragmentation variable of the away-side jet with momentum z_a are (i) the away-side parton does not generally balance longitudinal momentum with the trigger γ, although it is restricted by the $\Delta\eta$ acceptance of the detector; (ii) the transverse momenta of the γ and away parton do not exactly balance. The transverse momentum imbalance was discovered at the CERN-ISR using x_E distributions

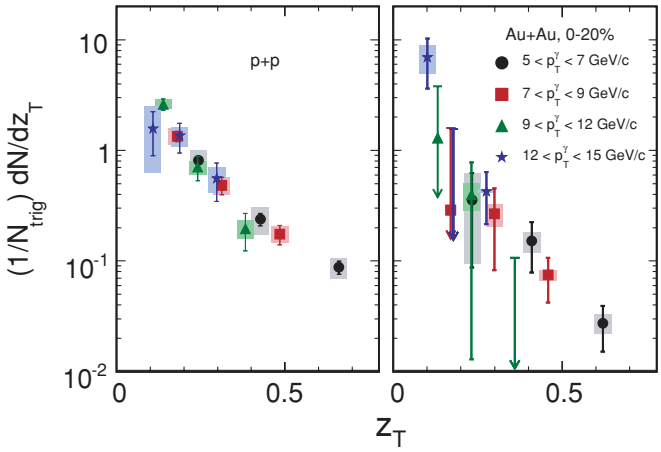

FIG. 7. (Color online) z_T distributions dN/dz_T from the direct photon associated yields in $p + p$ (left) and 0–20% Au + Au (right) collisions.

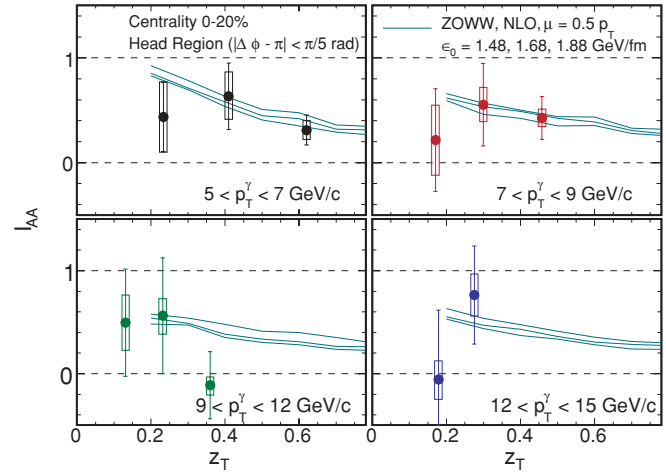

FIG. 8. (Color online) $I_{AA}(z_T)$ for the 20% most central Au + Au data compared to predictions from an energy loss calculation [50]. An additional p_T-independent uncertainty of 14% due to the charged hadron efficiency corrections is not shown.

[43] and originally attributed to an "intrinsic" transverse momentum k_T of each of the initial colliding partons [44], but now understood to be due to "resummation" of soft-gluon effects [45,46].

The validity of the approximation $x_E \approx z_a$ can be tested by observing identical x_E distributions for different values of trigger p_T^γ (x_E scaling), in which case one would accept the x_E distribution in γ-h correlations as the quark fragmentation function from the reaction $q + g \rightarrow q + \gamma$ without need of correction. We approximate x_E by z_T, the ratio of the mean associated p_T^h to mean trigger p_T for each p_T^γ bin.[1] The $\langle p_T^\gamma \rangle$ for the four trigger bins are 5.66, 7.75, 10.07, 13.07 GeV/c, close to the values obtained from a fit to the direct-γ invariant cross section of the form $p_T^{-6.5}$ [35].

Figure 7 shows the z_T distributions for $p + p$ and Au + Au collisions. The $p + p$ data [Fig. 7(a)] exhibit reasonable z_T scaling so that the measured distribution should represent the away-side jet fragmentation function. A fit of this data to a simple exponential (Ne^{-bz_T}) gives an acceptable $\chi^2/\mathrm{DOF} = 12.8/10$ with a value $b = 6.9 \pm 0.8$ that is consistent with the quark fragmentation function, parameterized [42] as a simple exponential with $b = 8.2$ for $0.2 < z < 1.0$, and inconsistent with the gluon fragmentation function value of $b = 11.4$. It should, however, be recalled that the data do not cover the full extent of the away peak, only $|\Delta\phi - \pi| < \pi/5$ radians and that possible variations of the widths of the peaks in both the $p + p$ data and the Au + Au data with p_T^γ and p_T^h have not been taken into account in the present analysis. Additionally a more detailed analysis, differential in trigger p_T, is necessary to study trigger p_T-dependent effects that can influence the fragmentation function fit values [42].

In central Au + Au collisions, the fragmentation function may be modified by the medium[2] so z_T scaling should not hold except in two special cases: (i) pure surface emission or punch-through where the away-side jets are not modified (the z_T distribution will be suppressed, but will have the same shape as in $p + p$ collisions); (ii) constant fractional energy loss of the away jet (the z_T scaling will be preserved in Au + Au collisions but with a steeper slope than in $p + p$ collisions). The Au + Au data [Fig. 7(b)] are consistent with z_T scaling with the same shape as the $p + p$ data, a value of $b = 5.6 \pm 2.2$ and excellent $\chi^2/\mathrm{DOF} = 10.1/10$ for the simple exponential fit. The point at lowest $z_T = 0.11$ for Au + Au is 1.6 standard deviations above the fit, suggesting that improved statistics will permit the observation of any nonsurface emission.

D. Model comparison

Several authors have recently reported predictions for γ-jet in heavy-ion collisions [47–50]. As a demonstration of how such calculations can be compared to the data, the I_{AA} values as a function of z_T are compared to energy loss predictions [50] in Fig. 8. The calculation uses effective fragmentation functions to parametrize the average energy loss of the leading parton by gluon radiation in terms of a parameter ε_0 that is expected to be proportional to the initial gluon density [51]. As in most energy loss calculations, the energy loss of subleading partons and possible medium response effects are neglected. We note that both of these may be important at low values of z. The data are well reproduced by the model over the range of values of ε_0 provided, 1.48–1.88 GeV/fm. This corresponds roughly to the range of ε_0 allowed by comparison to the PHENIX $\pi^0 R_{AA}$ data of $1.9^{+0.2}_{-0.5}$ [52].

[1]The reader is advised to carefully distinguish this variable $z_T = \langle p_T^h \rangle / \langle p_T^t \rangle$ from our previous notation used in Ref. [42] of $z_t = p_T^t / \hat{p}$, which is the fraction of jet momentum $\hat{p}$ contained in the trigger particle.

[2]See Equation 1 in Ref. [51].

It should be noted that the calculation rejects fragmentation photons with an isolation cut. Such a procedure has not yet been demonstrated in central Au + Au data, although doing so would help to eliminate beyond-leading-order effects.

VI. CONCLUSIONS

We have presented the first direct γ-h measurements in Au + Au and $p + p$ collisions at the Relativistic Heavy Ion Collider (RHIC). A significant suppression of $I_{\rm AA} = 0.32 \pm 0.12^{\rm stat} \pm 0.09^{\rm syst}$ for the away-side charged hadron yield in the range $3 < p_T^h < 5$ GeV/c is observed for direct photon triggers in Au + Au as compared to $p + p$. Furthermore, the level of suppression is found to be consistent with the single-particle suppression rate and the importance of energy-loss geometry, notably the expectation of surface emission in the kinematic range sampled. A possible indication that energy-loss geometry may also be important in dijet suppression is that γ-h suppression $I_{\rm AA}$ is also observed to be quite similar to that of dihadron suppression in central events; however, the current precision of the data does not exclude substantial differences. In the $p + p$ data z_T scaling is observed, suggesting that the measured z_T distribution (Fig. 7) is a statistically acceptable representation of the fragmentation function of the quark jet recoiling away from the direct photon. Improvement of the statistical and systematic precision of the measurements should allow further tests of vacuum fragmentation expectations in $p + p$ collisions and insights into details of the medium modification of jet fragmentation in Au + Au. Such studies have begun using subsequently collected larger data sets. The projected order of magnitude increase in RHIC luminosity over the next few years will enable true precision measurements.

ACKNOWLEDGMENTS

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions. We acknowledge support from the Office of Nuclear Physics in the Office of Science of the Department of Energy, the National Science Foundation, a sponsored research grant from Renaissance Technologies LLC, Abilene Christian University Research Council, Research Foundation of SUNY, and Dean of the College of Arts and Sciences, Vanderbilt University (USA), Ministry of Education, Culture, Sports, Science, and Technology and the Japan Society for the Promotion of Science (Japan), Conselho Nacional de Desenvolvimento Científico e Tecnológico and Fundação de Amparo à Pesquisa do Estado de São Paulo (Brazil), Natural Science Foundation of China (People's Republic of China), Ministry of Education, Youth and Sports (Czech Republic), Centre National de la Recherche Scientifique, Commissariat à l'Énergie Atomique, and Institut National de Physique Nucléaire et de Physique des Particules (France), Ministry of Industry, Science and Tekhnologies, Bundesministerium für Bildung und Forschung, Deutscher Akademischer Austausch Dienst, and Alexander von Humboldt Stiftung (Germany), Hungarian National Science Fund, OTKA (Hungary), Department of Atomic Energy (India), Israel Science Foundation (Israel), Korea Research Foundation and Korea Science and Engineering Foundation (Korea), Ministry of Education and Science, Russia Academy of Sciences, Federal Agency of Atomic Energy (Russia), VR and the Wallenberg Foundation (Sweden), the US Civilian Research and Development Foundation for the Independent States of the Former Soviet Union, the US-Hungarian Fulbright Foundation for Educational Exchange, and the US-Israel Binational Science Foundation.

ABSTRACT

We present the first measurement of photoproduction of J/ψ and of two-photon production of high-mass e^+e^- pairs in electromagnetic (or ultra-peripheral) nucleus–nucleus interactions, using Au + Au data at $\sqrt{s_{NN}} = 200$ GeV. The events are tagged with forward neutrons emitted following Coulomb excitation of one or both Au* nuclei. The event sample consists of 28 events with $m_{e^+e^-} > 2$ GeV/c^2 with zero like-sign background. The measured cross sections at midrapidity of $d\sigma/dy\,(J/\psi + Xn, y = 0) =$

1. Introduction

The idea to use the strong electromagnetic fields present in high-energy nucleus–nucleus collisions to study photoproduction at hadron colliders has attracted growing interest in recent years, see [1–3] for reviews. Electromagnetic interactions can be studied without background from hadronic processes in ultra-peripheral collisions (UPC) without nuclear overlap, i.e. impact parameters larger than the sum of the nuclear radii. This study focuses on the measurement of exclusively produced high-mass e^+e^- pairs at midrapidity in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV, $\text{Au} + \text{Au} \to \text{Au} + \text{Au} + e^+e^-$. The results have been obtained with the PHENIX detector [4] at the BNL Relativistic Heavy Ion Collider (RHIC).

The electromagnetic field of a relativistic particle can be represented by a spectrum of equivalent photons. This is the Weizsäcker–Williams method of virtual quanta [5,6]. The number of photons in the spectrum is proportional to Z^2, where Z is the charge number of the particle, and the equivalent two-photon luminosity is thus proportional to Z^4. The strong dependence on Z favours the use of heavy ions for studying two-photon and photonuclear processes. The virtualities of the equivalent photons when the field couples coherently to the entire nucleus are restricted by the nuclear form factor to $Q^2 = (\omega^2/(c\gamma)^2 + q_\perp^2) \lesssim (\hbar/R_A)^2$. Here, ω and $q_\perp$ are the photon energy and transverse momentum, respectively, R_A is the nuclear radius and γ the Lorentz factor of the beam. At RHIC energies, $\gamma = 108$ and the maximum photon energy in the center-of-mass system is of the order of $\omega_{\max} \sim 3$ GeV corresponding to maximum photon–nucleon and two-photon center-of-mass energies of $W_{\gamma N}^{\max} \sim 34$ GeV and $W_{\gamma\gamma}^{\max} \sim 6$ GeV.

The exclusive production of an e^+e^- pair can proceed either through a purely electromagnetic process (a two-photon interaction to leading order) or through coherent photonuclear production of a vector meson, which decays into an electron pair. Exclusive photoproduction of vector mesons is usually thought of as proceeding via Pomeron-exchange, the perturbative-QCD equivalent of which is the exchange of two gluons or a gluon ladder. The Feynman diagrams for the two leading order processes are shown in Fig. 1. The two-gluon picture is applicable to production of heavy vector mesons, such as the J/ψ, and to production of lighter mesons at high momentum transfers [7]. The J/ψ production cross section is consequently a good probe of the proton [8] and nuclear gluon distribution, $G_A(x, Q^2)$, as well as of vector-meson dynamics in nuclear matter [9,10]. For J/ψ-production, the coverage of the PHENIX central tracking arm, $-0.35 < \eta < 0.35$ corresponds to a range in the photon–nucleon center-of-mass energy between $21 < W_{\gamma N} < 30$ GeV, with a mean $\langle W_{\gamma N} \rangle = 24$ GeV. This corresponds to photon energies in the rest frame of the target nucleus of $240 < E_\gamma < 480$ GeV, with $\langle E_\gamma \rangle = 300$ GeV. Mid-rapidity photoproduction of J/ψ probes nuclear Bjorken-x values of $x = m_{J/\psi}^2/W_{\gamma A}^2 \approx 1.5 \times 10^{-2}$ [10], where the nuclear gluon density is partially depleted by "shadowing" effects [11] compared to the proton.

The strong fields associated with heavy ions at high energies lead to large probabilities for exchanging additional soft photons in the same event. Most of these photons have too low energy to produce particles, but they can excite the interacting nuclei. The dominating excitation is to a Giant-Dipole Resonance (GDR) with energies $\mathcal{O}(10$ MeV), which decays by emitting neutrons at very forward rapidities, providing a very useful means to trigger on UPCs with Zero-Degree Calorimeters (ZDC). The probability for having a Coulomb excitation leading to emission of neutrons in at least one direction in coincidence with coherent J/ψ production is $55\% \pm 6\%$ [12]. The probabilities for exchanging one or several photons factorise, i.e. the Coulomb tagging does not introduce any bias in the extraction of exclusive J/ψ photoproduction cross sections from these events [13]. The soft photons leading to moderate nuclear excitation are indicated to the right of the dashed line in Fig. 1. Incoherent (or quasi-elastic) vector-meson photoproduction can also proceed via the interaction of the exchanged photon with a *single* nucleon in the nucleus. In that case, J/ψ photoproduction is always accompanied by nuclear breakup and emission of nucleons in the forward direction [14].

Photoproduction of vector mesons has been studied with lepton beams first in the 60s [15,16] and more recently at the electron–proton collider HERA [17,18]. Measurements of photonuclear production of ρ mesons [19,20], as well as of two-photon production of *low-mass* e^+e^- pairs [21] in heavy ion interactions have been performed by the STAR Collaboration. The CDF Collaboration has studied two-photon production of e^+e^- pairs [22] and exclusive production of $\mu^+\mu^-$ pairs [23] in $p\bar{p}$ collisions at the Tevatron. The PHENIX analysis presented here is the first on heavy final states in ultra-peripheral nucleus–nucleus collisions. It supersedes a preliminary study presented earlier [24]. The cross section for J/ψ and e^+e^- photoproduction are compared with various theoretical calculations [10,14,25–27].

2. Experimental setup

The data presented here were collected with the PHENIX detector at RHIC during the 2004 high-luminosity Au + Au run at $\sqrt{s_{NN}} = 200$ GeV. The PHENIX detector [4], is a versatile detector designed to study the properties of strongly interacting matter at extreme temperatures and energy densities present in central heavy ion collisions. The current analysis demonstrates its capabilities to also study ultra-peripheral collisions, which have a very different event topology. The PHENIX central tracking system [28] consists of two arms, each covering $|\eta| < 0.35$ and $\Delta\phi = \pi/2$, equipped with multi-layer drift chambers (DC) followed by multi-wire proportional chambers (PC) with pixel-pad readout. The tracking arms also have Ring-Imaging-Čerenkov (RICH, with CO_2 gas radiator) detectors [29] and electromagnetic calorimeters (EMCal) [30] for electron and positron identification. The PHENIX EMCal consists of six sectors of lead-scintillator sandwich calorimeter (PbSc, 15552 individual towers with 5.54 cm × 5.54 cm × 37.5 cm,

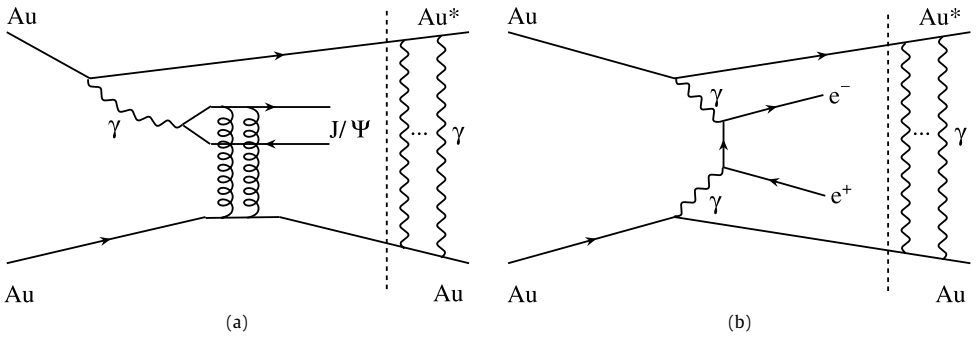

Fig. 1. Lowest order Feynman diagrams for exclusive photoproduction of (a) J/ψ and (b) dielectrons, in ultra-peripheral Au + Au collisions. The photons to the right of the dashed line are soft photons that may excite the nuclei but do not lead to particle production in the central rapidity region. Both diagrams contain at least one photon and occur when the nuclei are separated by impact parameters larger than the sum of the nuclear radii.

$18X_0$) and two sectors of lead-glass Čerenkov calorimeter (PbGl, 9216 modules with 4 cm × 4 cm × 40 cm, $14.4X_0$), at a radial distance of ∼ 5 m from the beam line.

The ultra-peripheral Au + Au events were tagged by neutron detection at small forward angles in the ZDC. The ZDCs [31,32] are hadronic calorimeters placed 18 m up- and down-stream of the interaction point that measure the energy of the neutrons coming from the Au* Coulomb dissociation with ∼ 20% energy resolution and cover $|\theta| < 2$ mrad, which is a very forward region.[3]

The events used in this analysis were collected with the UPC trigger set up for the first time in PHENIX during the 2004 run with the following characteristics:

(1) A veto on coincident signals in both Beam–Beam Counters (BBC, covering $3.0 < |\eta| < 3.9$ and full azimuth) selects exclusive-type events characterised by a large rapidity gap on either side of the central arm.
(2) The EMCal-Trigger (ERT) with a 2×2 tile threshold at 0.8 GeV. The trigger is set if the analog sum of the energy deposit in a 2×2 tile of calorimeter towers is above threshold (0.8 GeV).
(3) At least 30 GeV energy deposited in one or both of the ZDCs is required to select Au + Au events with forward neutron emission (Xn) from the (single or double) Au* decay.

The BBC trigger efficiency for hadronic Au + Au collisions is $92 \pm 3\%$ [33]. A veto on the BBC trigger has an inefficiency of 8%, which implies that the most peripheral nuclear reactions could be a potential background for our UPC measurement if they happen to have an electron pair in the final state. An extrapolation of the measured p–p dielectron rate [34] at $m_{\rm inv} > 2$ GeV/c^2 to the 8% most peripheral interactions – scaled by the corresponding number of nucleon–nucleon collisions (1.6) – results in a negligible contribution (only 0.4 e^+e^- pairs). On the other hand, the ERT trigger requirement (2) has an efficiency of 90 ± 10%, and the requirement (3) of minimum ZDC energy deposit(s) leaves about 55% of the coherent and about 100% of the incoherent J/psi events, as discussed above. All these trigger efficiencies and their uncertainties are used in the final determination of the production cross sections below.

The total number of events collected by the UPC trigger was 8.5 M, of which 6.7 M satisfied standard data quality assurance criteria. The useable event sample corresponds to an integrated luminosity $\mathcal{L}_{\rm int} = 141 \pm 12\ \mu{\rm b}^{-1}$ computed from the minimum bias triggered events.

[3] Much larger than the crossing angle of Au beams at the PHENIX interaction point (0.2 mrad).

3. Data analysis

Charged particle tracking in the PHENIX central arms is based on a combinatorial Hough transform in the track bend plane (perpendicular to the beam direction). The polar angle is determined from the position of the track in the PC outside the DC and the reconstructed position of the collision vertex [35]. For central collisions, the collision vertex is reconstructed from timing information from the BBC and/or ZDC. This does not work for UPC events, which, by definition, do not have BBC coincidences and often do not have ZDC coincidences. The event vertex was instead reconstructed from the position of the PC hits and EMCal clusters associated with the tracks in the event. This gave an event vertex resolution in the longitudinal direction of 1 cm. Track momenta are measured with a resolution $\delta p/p \approx 0.7\% \oplus 1.0\% p[{\rm GeV}/c]$ in minimum bias Au + Au nuclear collisions [36]. Only a negligible reduction in the resolution is expected in this analysis because of the different vertex resolution.

The following global cuts were applied to enhance the sample of genuine γ-induced events:

(1) A standard offline vertex cut $|vtx_z| < 30$ cm was required to select collisions well centered in the fiducial area of the central detectors and to avoid tracks close to the magnet poles.
(2) Only events with two charged particles were analyzed. This is a restrictive criterion imposed to cleanly select "exclusive" processes characterised by only two isolated particles (electrons) in the final state. It allows to suppress the contamination of non-UPC (mainly beam–gas and peripheral nuclear) reactions that fired the UPC trigger, whereas the signal loss is small (less than 5%).

Unlike the $J/\psi \to e^+e^-$ analyses in nuclear Au + Au reactions [36,37] which have to deal with large particle multiplicities, we did not need to apply very strict electron identification cuts in the clean UPC environment. Instead, the following RICH- and EMCal-based offline cuts were used:

(1) RICH multiplicity $n_0 \geqslant 2$ selects $e^\pm$ which fire 2 or more tubes around the track within the nominal ring radius.
(2) Candidate tracks with an associated EMCal cluster with dead or noisy towers within a 2 × 2 tile are excluded.
(3) At least one of the tracks in the pair is required to pass an EMCal cluster energy cut ($E_1 > 1$ GeV ∥ $E_2 > 1$ GeV) to select candidate $e^\pm$ in the plateau region above the turn-on curve of the ERT trigger (which has a 0.8 GeV threshold).

Beyond those global or single-track cuts, an additional "coherent" identification cut was applied by selecting only those e^+e^- candi-

dates detected in opposite arms. Such a cut aims at reducing the high-p_T pairs while improving the detection of the low-p_T pairs expected for $\gamma\gamma$, γA production. Nevertheless, after all the previous cuts were applied the influence of this selection is found to be small; there is only one event in which the e^+ and e^- are in the same arm and have $m_{e^+e^-} > 2$ GeV/c^2.

Finally, J/ψ were reconstructed by invariant mass analysis of the measured e^+e^- pairs. There was no remaining like-sign background after the aforementioned analysis cuts.

The cross sections were obtained after correcting the raw number of signal counts for the geometrical acceptance of our detector system, and the efficiency losses introduced by the previously described analysis cuts. Acceptance and efficiency corrections were obtained using the PHENIX GEANT3 [38] simulation package with input distributions from the STARLIGHT Monte Carlo (MC), based on the models presented in [12,25,39]. The measured $\gamma + p \to V + p$ cross sections from HERA and fixed target experiments with lepton beams are used as input to the models. STARLIGHT well reproduces the existing $d^3N/dy\,d\phi\,dp_T$ distribution of coherent ρ production in UPC Au + Au events measured at RHIC by STAR [19,20]. Helicity conservation is assumed in the model, and the angular distribution of the decay products ($J/\psi \to e^+e^-$) is given by $dN/d\cos(\theta) \propto 1 + \cos^2(\theta)$ in the J/ψ center-of-mass. The angular distribution is different from that for ρ production followed by the decay $\rho \to \pi^+\pi^-$, because of the different spin of the daughters, as well as from the angular distribution in two-photon interactions $\gamma + \gamma \to e^+e^-$. We generated 5×10^4 coherent J/ψ and 8×10^6 coherent high-mass e^+e^- pairs ($m_{e^+e^-} > 1$ GeV/c^2) in Au+Au collisions accompanied by forward neutron emission. The simulated events were passed through the same reconstruction programme as the real data.

Table 1
Coherent J/ψ and e^+e^- (continuum) acceptance and efficiency for $|y_{pair}| < 0.35$ as a function of invariant mass range. The last line shows the trigger efficiency.

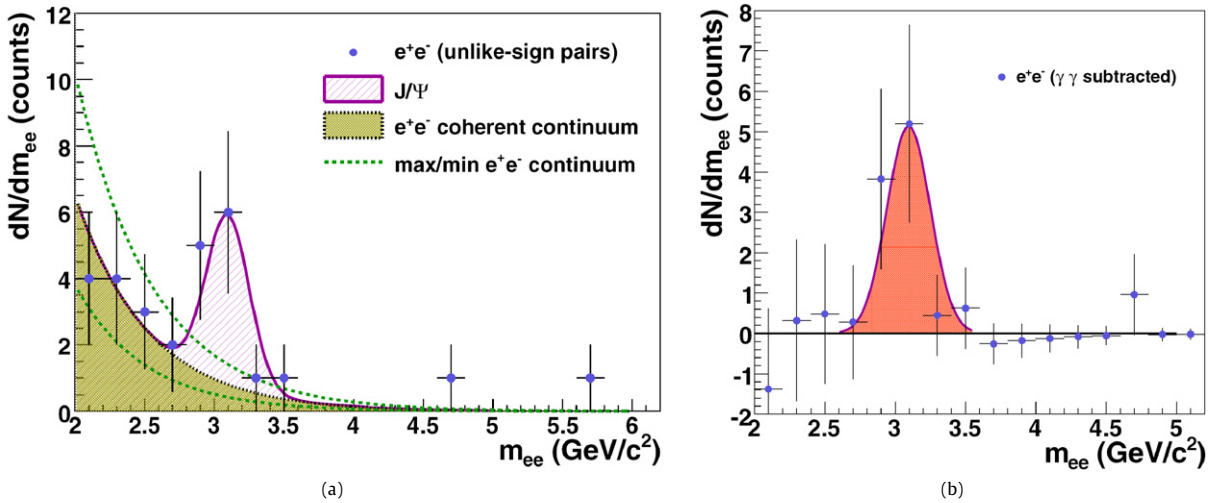
$m_{e^+e^-}$ [GeV/c^2]	$Acc \times \varepsilon$
J/ψ	$(2.49 \pm 0.25) \times 10^{-2}$
e^+e^- [2.0, 2.8]	$(2.24 \pm 0.22) \times 10^{-3}$
e^+e^- [2.0, 2.3]	$(2.16 \pm 0.22) \times 10^{-3}$
e^+e^- [2.3, 2.8]	$(2.33 \pm 0.23) \times 10^{-3}$
ϵ_{trigg}	0.9 ± 0.1

Table 1 summarises the J/ψ and dielectron acceptance and efficiency correction factors obtained from our simulation studies. For instance, for J/ψ photoproduction the correction is $1/(2.49 \pm 0.25)$%, of which the experimental acceptance to detect the decay electron pair is about 5% (for J/ψ produced at $|y| < 0.35$). In the $\gamma\gamma \to e^+e^-$ sample, most of the electrons/positrons are emitted at very forward angles. The fraction of events with $|y_{pair}| < 0.35$ and $2.0 < m_{e^+e^-} < 2.8$ GeV/c^2, where both the electron and positron are within $|\eta| < 0.35$ is 1.10%. The corresponding numbers for $2.0 < m_{e^+e^-} < 2.3$ GeV/c^2 and $2.3 < m_{e^+e^-} < 2.8$ GeV/c^2 are 1.11% and 1.08%, respectively. The acceptance and efficiency corrections have a systematic uncertainty of 10% resulting from the accuracy of the simulation to describe the detector, the electron identification parameters, and the event vertex position resolution.

4. Results and discussion

The measured e^+e^- invariant mass distribution for the sample is shown in Fig. 2(a). The amount of background can be estimated from the number of like-sign events (i.e. events where two electrons or two positrons are reconstructed). We find no like-sign pairs for $m_{e^\pm e^\pm} > 2$ GeV/c^2, compared with 28 events with an e^+e^- pair with $m_{e^+e^-} > 2$ GeV/c^2. The shape is consistent with the expected contribution from the two processes in Fig. 1: a continuum distribution corresponding to two-photon production of e^+e^- pairs and a contribution from $J/\psi \to e^+e^-$. Since the offline cuts ($E_1 > 1$ GeV $\parallel$ $E_2 > 1$ GeV) cause a sharp drop in the efficiency for $m_{e^+e^-} < 2$ GeV/c^2, we include only pairs with $m_{e^+e^-} \geqslant 2$ GeV/c^2 in the analysis.

The invariant mass distribution is fitted with a continuum (exponential) curve combined with a Gaussian function at the J/ψ peak, as shown by the solid curve in Fig. 2(a). Simulations based on events generated by the STARLIGHT MC (see last paragraphs of Section 3) processed through GEANT have shown that the shape of the measured continuum contribution is well described by an exponential function $dN/dm_{e^+e^-} = A \cdot e^{cm_{e^+e^-}}$. Those simulations allow us to fix the exponential slope parameter to $c = -1.9 \pm 0.1$ GeV^{-1} c^2. The combined data fit is done with three free parameters: the exponential normalisation (A), the J/ψ yield and the J/ψ peak width (the Gaussian peak position has been fixed at the known J/ψ mass of $m_{J/\psi} = 3.097$ GeV/c^2 [40]). Fig. 2(b) shows the resulting invariant mass distribution obtained by subtracting the fitted exponential curve of the dielectron continuum from the



(a) (b)

Fig. 2. Left: (a) Invariant mass distribution of e^+e^- pairs fitted to the combination of (shaded) a dielectron continuum [exponential distribution] and (hatched) a J/ψ [Gaussian] signal. The two additional dashed curves indicate the maximum and minimum continuum contributions considered in this analysis (see text). (b) J/ψ invariant mass distribution after subtracting the fitted dielectron continuum signal in (a).

total experimental e^+e^- pairs distribution. There is a clear J/ψ peak, the width of which ($\sigma_{J/\psi} \sim 155$ MeV/c^2) is consistent with the J/ψ width from our full MC.

The J/ψ and continuum yields and the corresponding statistical errors are calculated from the fit. The dashed curves in Fig. 2(a) show the maximum and minimum e^+e^- continuum contributions considered, including both the statistical and systematical uncertainties. The systematic uncertainties were determined varying the dielectron continuum subtraction method using a power-law form instead of an exponential function and by modifying the corresponding fitted slope parameters by $\pm 3\sigma$. The propagated uncertainty of the extracted yields was estimated to be one count in both cases. The total number of J/ψ's is: $N_{J/\psi} = 9.9 \pm 4.1(\text{stat}) \pm 1.0(\text{syst})$, and the number of e^+e^- continuum pairs for $m_{e^+e^-} \in [2.0, 2.8]$ GeV/c^2 is: $N_{e^+e^-} = 13.7 \pm 3.7(\text{stat}) \pm 1.0(\text{syst})$. Table 2 shows the obtained results per invariant mass range.

Table 2
$J/\psi \to e^+e^-$ and e^+e^- continuum yields obtained from the fit of the data to an exponential plus Gaussian function per invariant mass range. Systematic errors are obtained as described in the text.

$m_{e^+e^-}$ [GeV/c^2]	Yield
J/ψ	$N_{J/\psi} = 9.9 \pm 4.1(\text{stat}) \pm 1.0(\text{syst})$
e^+e^- [2.0, 2.8]	$N_{e^+e^-} = 13.7 \pm 3.7(\text{stat}) \pm 1.0(\text{syst})$
e^+e^- [2.0, 2.3]	$N_{e^+e^-} = 7.4 \pm 2.7(\text{stat}) \pm 1.0(\text{syst})$
e^+e^- [2.3, 2.8]	$N_{e^+e^-} = 6.2 \pm 2.5(\text{stat}) \pm 1.0(\text{syst})$

Fig. 3(a) shows a scatter plot of invariant mass $m_{e^+e^-}$ vs. pair p_T. From the plot, it is clear that most of the pairs outside the J/ψ peak originate in coherent processes with very low pair transverse momenta ($p_T \lesssim 100$ MeV/c), as expected for two-photon interactions. For events with $m_{e^+e^-}$ around the J/ψ mass, however, there are a few counts at larger p_T values which can be ascribed neither to the experimental p_T resolution nor to background events, since there are no like-sign pairs above 2 GeV/c^2. A purely coherent production – corresponding to events where the fields couple coherently to all nucleons and the nucleus remains in its ground state ($\gamma + A \to V + A$) – would yield $p_T \lesssim 200$ MeV/c after reconstruction. On the other hand, incoherent production ($\gamma + A \to V + X$) – dominated by the quasi-elastic vector meson production off one nucleon inside the nucleus, $\gamma + N \to V + N$ – results in much larger p_T for the photoproduced J/ψ [14]. The cross sections for coherent and incoherent J/ψ photoproduction in UPCs at RHIC are expected to be of the same order [14]. We discuss below whether our data confirm such a prediction.

The transverse momentum distribution of the events with $m_{e^+e^-} > 2$ GeV/c^2 is shown in Fig. 3(b). For clarity, only points below $p_T < 1$ GeV/c are drawn. The p_T is here the magnitude of the vector sum of the $\vec{p_T}$ of the electron and positron. One sees a

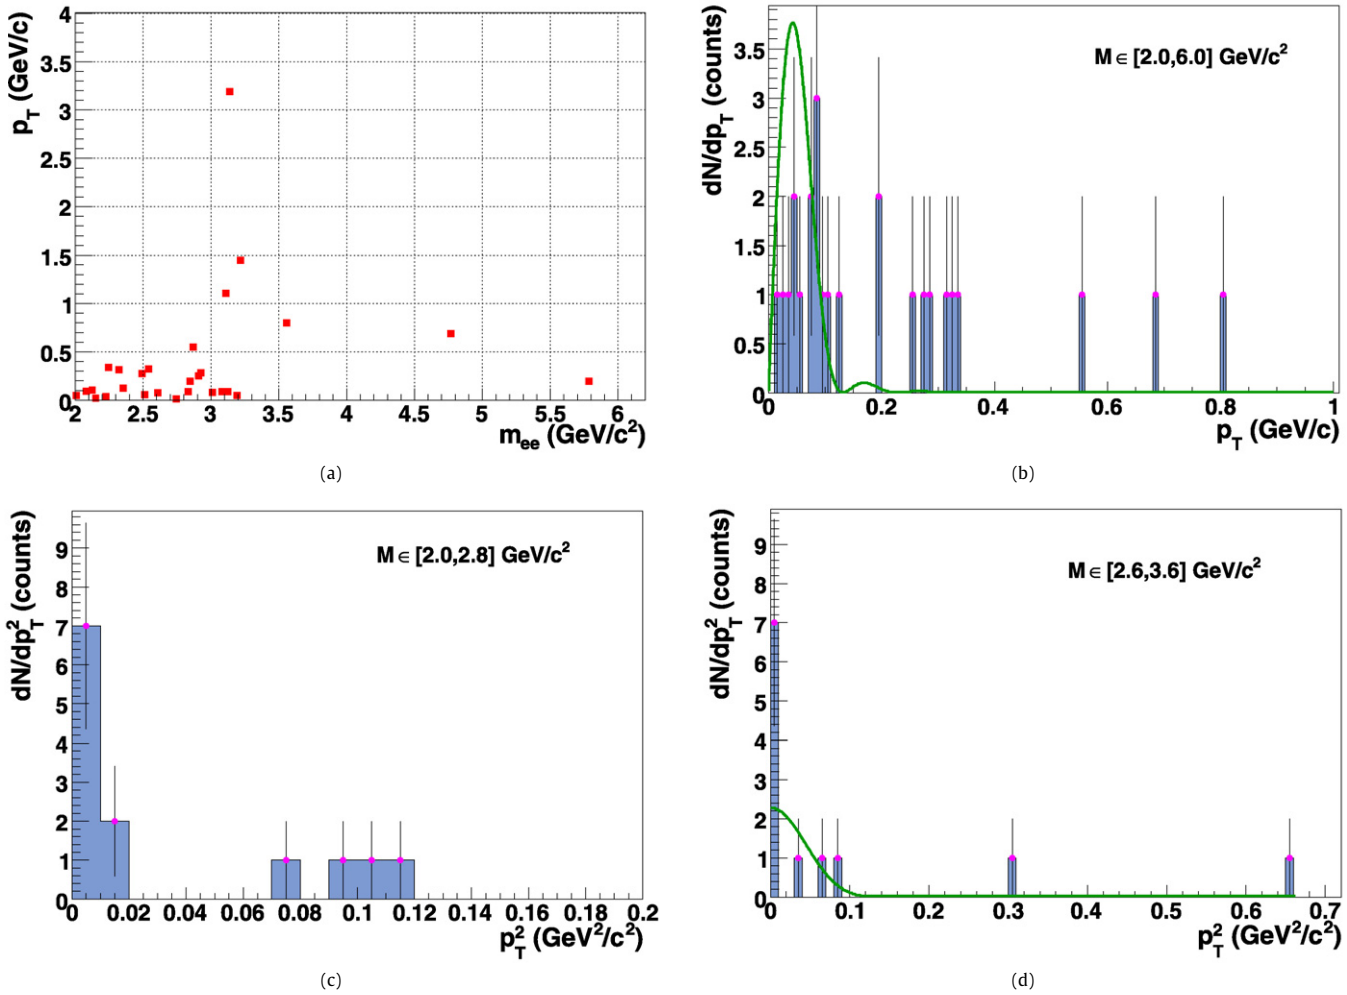


Fig. 3. Top: (a) Scatter plot of $e^+e^- m_{e^+e^-}$ vs. pair p_T. (b) dN/dp_T distribution of the pairs with $m_{e^+e^-} \in [2.0, 6.0]$ GeV/c^2 compared to the Au nuclear form factor, Eq. (1), and for simplicity showing only points with $p_T < 1$ GeV/c. Bottom: dN/dp_T^2 distributions of pairs with (c) $m_{e^+e^-} \in [2.0, 2.8]$ GeV/c^2 and (d) $m_{e^+e^-} \in [2.6, 3.6]$ GeV/c^2 compared to the expected Au nuclear form factor, also for clarity only points with $p_T^2 < 0.7$ GeV^2/c^2 are drawn. Note the difference in scale on the x-axis in the four plots.

Table 3
Measured J/ψ and e^+e^- continuum photoproduction cross sections at midrapidity in ultra-peripheral Au + Au collisions (accompanied with forward neutron emission) at $\sqrt{s_{NN}} = 200$ GeV. The rightmost column in the lower part shows the STARLIGHT predictions [39].

J/ψ	$d\sigma/dy\|_{y=0}$ [μb] $76 \pm 31(\text{stat}) \pm 15(\text{syst})$	
$m_{e^+e^-}$ [GeV/c^2]	$d^2\sigma/dm_{e^+e^-}\,dy\|_{y=0}$ [μb/(GeV/c^2)] data	STARLIGHT
e^+e^- continuum [2.0, 2.8]	$86 \pm 23(\text{stat}) \pm 16(\text{syst})$	90
e^+e^- continuum [2.0, 2.3]	$129 \pm 47(\text{stat}) \pm 28(\text{syst})$	138
e^+e^- continuum [2.3, 2.8]	$60 \pm 24(\text{stat}) \pm 14(\text{syst})$	61

clear enhancement of events with very low transverse momenta, consistent with coherent production. The squared form-factor of a gold nucleus,

$$\left|F_{\text{Au}}\left(p_{\text{T}}^2\right)\right|^2 = \left|3\frac{\sin(Rp_{\text{T}}) - Rp_{\text{T}}\cos(Rp_{\text{T}})}{(Rp_{\text{T}})^3(1+(ap_{\text{T}})^2)}\right|^2, \tag{1}$$

is shown for comparison. Here, $R = 6.7$ fm is the gold radius, and $a = 0.7$ fm represents the diffuseness of the nuclear surface [41]. The magnitude of the form-factor is a free parameter fitted to reproduce the spectra. Fig. 3 also presents the corresponding distribution expressed in terms of the squared momentum transfer from the target nucleus, $p_{\text{T}}^2 \approx -t$, for events with $m_{e^+e^-}$ corresponding to the dielectron continuum $m_{e^+e^-} \in [2.0, 2.8]$ GeV/c^2 (Fig. 3(c) and below the J/ψ-peak, $m_{e^+e^-} \in [2.6, 3.6]$ GeV/c^2 (Fig. 3(d)). The 4 events with $p_T^2 \approx 0.1$ GeV/c^2 in Fig. 3(c) have transverse momenta slightly above what one would expect for two-photon production. They could thus be due to some other, incoherent production process for dielectron pairs. The simulations of the experimental resolution show, however, that a spread in p_T of that magnitude can also be caused by the experimental resolution. We therefore include also these events in the calculation of the continuum cross section.

The extracted yields of J/ψ and e^+e^- are used to calculate the final cross section for photoproduction at midrapidity in ultra-peripheral Au + Au collisions accompanied by forward neutron emission. For dielectrons at midrapidity (y is the rapidity of the pair) the double differential cross section is:

$$\begin{aligned}\frac{d^2\sigma_{e^+e^-+Xn}}{dy\,dm_{e^+e^-}} &= \frac{N_{e^+e^-}}{Acc\cdot\varepsilon\cdot\varepsilon_{\text{trigg}}\cdot\mathcal{L}_{\text{int}}}\cdot\frac{1}{\Delta y}\cdot\frac{1}{\Delta m_{e^+e^-}} \\ &= 86 \pm 23(\text{stat}) \pm 16(\text{syst})\ \mu\text{b}/\left(\text{GeV}/c^2\right) \\ &\quad \text{for } m_{e^+e^-} \in [2.0, 2.8]\ \text{GeV}/c^2 \text{ and } |y| < 0.35. \end{aligned} \tag{2}$$

For J/ψ at midrapidity ($|y| < 0.35$) the differential cross section is:

$$\begin{aligned}\frac{d\sigma_{J/\psi+Xn}}{dy} &= \frac{1}{\text{BR}}\cdot\frac{N_{J/\psi}}{Acc\cdot\varepsilon\cdot\varepsilon_{\text{trigg}}\cdot\mathcal{L}_{\text{int}}}\cdot\frac{1}{\Delta y} \\ &= 76 \pm 31(\text{stat}) \pm 15(\text{syst})\ \mu\text{b}. \end{aligned} \tag{3}$$

The correction factors (and corresponding uncertainties) are quoted in Table 1 as described in previous sections, and BR = 5.94% is the known J/ψ dielectron branching ratio [40]. Table 3 summarises the measured cross sections per invariant mass interval.

The measured dielectron cross sections at midrapidity are in very good agreement with the STARLIGHT predictions for coherent dielectron photoproduction (rightmost column of Table 3) [39]. Exclusive dilepton production in STARLIGHT is calculated combining the two equivalent (Weizsäcker–Williams) photon fluxes from each ion with the Breit–Wheeler formula for $\gamma\gamma \to l^+l^-$. The agreement between STARLIGHT and other leading order calculations [42] is good as long as the pair invariant mass is not too low. A recent calculation has found that higher order terms suppress the e^+e^- cross section by 29% in the invariant mass range $140 < m_{e^+e^-} < 165$ MeV/c^2 [43]. A reduction of the same magnitude in the invariant mass range considered here, $2.0 < m_{e^+e^-} < 2.8$ GeV/c^2, would still be in agreement with our measurement.

The final $J/\psi + Xn$ cross section is compared to the theoretical predictions computed in references [12,14,25,27,39,44] in Fig. 4. The rapidity distributions for the coherent production of Strikman et al. [14] and Ivanov et al. [27] have been scaled down according to [12] to account for the reduction of the yield expected when requiring coincident forward neutron emission (Xn). The scaling has been applied as a function of rapidity with the integrated cross section being 55% of the original one.

The upper limit of the band covered by the Strikman et al. predictions corresponds to calculations in the impulse approximation (no shadowing), and the lower limit corresponds to calculations using the eikonal (Glauber) model with $\sigma(J/\Psi + N) = 3$ mb. The bands for the calculations of Ivanov et al. corresponds to two different parameterisations of the dipole cross section [27]. The predictions by [14] and [27] for the coherent and incoherent photoproduction cross sections are drawn separately in Fig. 4(a) and summed up in Fig. 4(b). STARLIGHT [12,25,39] and Gonçalves–Machado [44] calculations only evaluate the coherent contribution.

As mentioned above, the measured pair p_{T} distributions suggest coherent J/ψ photoproduction ($\gamma + A \to J/\psi + X$) and a possible additional incoherent ($\gamma + N \to J/\psi + X$) contribution at higher p_{T}. To give an indicative estimate of the size of the incoherent contribution, we can assume that it corresponds to the counts in the J/ψ mass window with $p_{\text{T}}^2 > 0.1(0.05)$ GeV$^2/c^2$. This corresponds to about 4(6) counts, which amounts to a contribution of about 40(60)% of the total J/ψ production, compatible with the theoretical calculations [14]. The limited data statistics prevents us from separating in a more quantitative way the two components. Note that although the acceptance correction for the J/ψ was calculated using a Monte Carlo which includes only the coherent component, the obtained correction is also a reasonable approximation for the incoherent component, provided that quasi-elastic scattering on a single nucleon, $\gamma + N \to V + N$, gives the main contribution. The polarisation of the vector meson will then be the same as for coherent production, and the reduction in acceptance because of the different p_{T} range will be of the order of ~ 10–20%. If the incoherent contribution to the total J/ψ photoproduction was 40%, the coherent J/ψ cross section would become ~ 46 μb.

Despite these uncertainties, the final J/ψ cross section is in good agreement, within the (still large) statistical errors, with the theoretical values computed in [12,14,25,27,39,44] as shown in Fig. 4. The current uncertainties unfortunately preclude any more detailed conclusion at this point regarding the two crucial ingredients of the models (nuclear gluon shadowing and J/ψ nuclear absorption cross section). The statistical uncertainties can be improved with significantly higher Au + Au luminosities and a concurrent measurement of the J/ψ in the dimuon decay channel in the more forward acceptances covered by the PHENIX muon spectrometers.

Finally, one can attempt to compare the obtained photonuclear J/ψ cross sections to those from e–p collisions at HERA by dividing the measured differential cross section ($d\sigma/dy$) with the (theoretical) equivalent photon spectrum ($dN_\gamma/d\omega$). At midrapidity: $\sigma_{\gamma A\to J/\psi A} = (d\sigma_{AA\to J/\psi AA}/dy)/(2\,dN_\gamma/d\omega)$, with $2\,dN_\gamma/d\omega = 6.7$ (10.5) for the coherent (incoherent) spectrum at a photon–nucleon center-of-mass energy of $\langle W_{\gamma p}\rangle = 24$ GeV [12]. Assuming, for the sake of simplicity, a 50%–50% contribution from coherent and in-

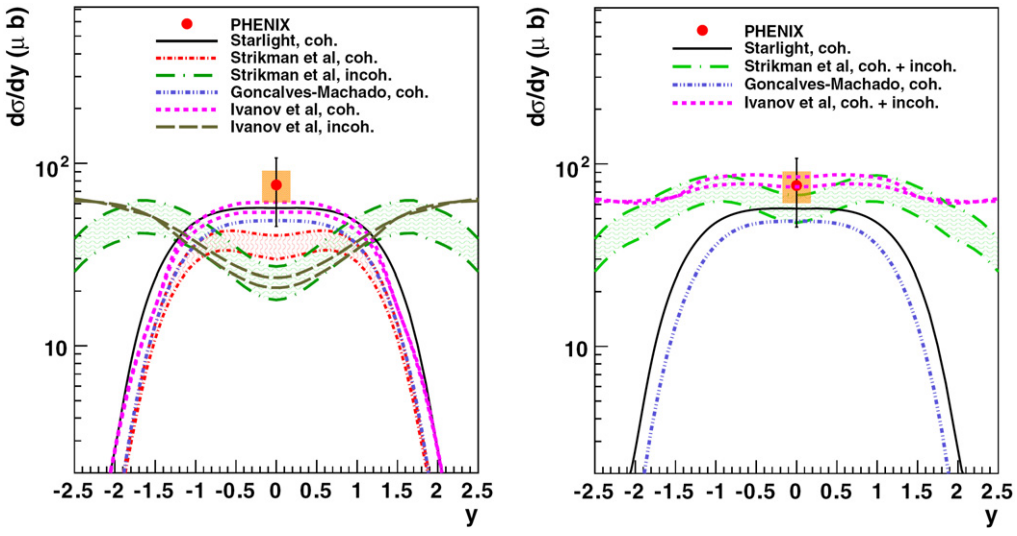

Fig. 4. Measured cross section of $J/\psi + Xn$ production at midrapidity in UPC Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The error bars (boxes) show the statistical (systematical) uncertainties. When available, the theoretical calculations for the coherent and incoherent components are shown separately in (a), and summed up in (b). The theoretical calculations (a) in order from top to bottom near $y = 0$: (short dashed lines) coherent Ivanov et al. [27], (solid line) coherent STARLIGHT [12,25,39], (dashed-double-dotted line) Goncalves–Machado [44], (shaded between short dashed-dotted lines) coherent Strikman et al. [14], (shaded between long dashed-dotted dashed lines) incoherent Strikman et al. [14], and (long dashed lines) coherent Ivanov et al. [27]. And (b) in order from top to bottom near $y = 0$: (short dashed lines) Ivanov et al. [27], (shaded between long dashed-dotted solid lines) Strikman et al. [14], (solid line) STARLIGHT [12,25,39], and (dashed–double-dotted line) Goncalves–Machado [44].

coherent interactions in our total ultra-peripheral J/ψ sample, the extracted photonuclear cross sections are: $\sigma(\gamma + \mathrm{Au} \to J/\psi + \mathrm{Au}) = 5.7 \pm 2.3(\mathrm{stat}) \pm 1.2(\mathrm{syst})$ μb, and $\sigma(\gamma + \mathrm{Au} \to J/\psi + X) = 3.6 \pm 1.4(\mathrm{stat}) \pm 0.7(\mathrm{syst})$ μb, respectively. A fit to the results from the H1 and ZEUS Collaborations [17,18] over their measured energy range gives $\sigma(\gamma + p \to J/\psi + p) = 30.5 \pm 2.7$ nb at $W_{\gamma p} = 24$ GeV. Therefore, the ratios $\sigma(\gamma + \mathrm{Au} \to J/\psi)/\sigma(\gamma + p \to J/\psi) = 186 \pm 88$, 118 ± 54 for the coherent and incoherent components (statistical and systematic errors assumed independent and added in quadrature) are consistent with a scaling of the photonuclear cross section with the number of nucleons in gold ($A = 179$): $\sigma(\gamma + \mathrm{Au} \to J/\psi) = A^{\alpha}\, \sigma(\gamma + p \to J/\psi)$ with $\alpha_{\mathrm{coh}} = 1.01 \pm 0.07$, and $\alpha_{\mathrm{incoh}} = 0.92 \pm 0.08$, respectively.[4]

5. Summary and conclusions

We have presented the first exclusive photoproduction of $J/\psi \to e^+e^-$ and high-mass e^+e^- pairs ever measured in nucleus–nucleus (as well as hadron–hadron) interactions. The measurement has been carried out by the PHENIX experiment in ultra-peripheral Au + Au interactions at $\sqrt{s_{NN}} = 200$ GeV tagged by forward (ZDC) neutron detection from the (single or double) Au* dissociation. Clear signals of J/ψ and high mass dielectron continuum have been found in the data. We have observed 28 e^+e^- pairs in $m_{e^+e^-} \in [2.0, 6.0]$ GeV/c^2 with zero like-sign background. Their p_{T} spectrum is peaked at low $p_{\mathrm{T}} \approx 90$ MeV/c as expected for coherent photoproduction with a realistic Au nuclear form factor.

The measured number of continuum e^+e^- events in the PHENIX acceptance for $m_{e^+e^-} \in [2.0, 2.8]$ GeV/c^2 is: $N(e^+e^-) = 13.7 \pm 3.7(\mathrm{stat}) \pm 1.0(\mathrm{syst})$. After correcting for acceptance and efficiency losses and normalising by the measured luminosity, we obtain a cross section of $d^2\sigma/dm_{e^+e^-}\, dy\, (e^+e^- + Xn)|_{y=0} = 86 \pm 23(\mathrm{stat}) \pm 16(\mathrm{syst})$ μb/(GeV/c^2), which is in good agreement with theoretical expectations for coherent exclusive dielectron production in photon–photon interactions.

The measured invariant mass distribution has a clear peak at the J/ψ mass with an experimental width in good agreement with a full GEANT-based simulation for UPC production and reconstruction in the PHENIX detector. The measured number of J/ψ mesons in the PHENIX acceptance is: $N(J/\psi) = 9.9 \pm 4.1(\mathrm{stat}) \pm 1.0(\mathrm{syst})$. The higher p_{T} distribution suggests an additional incoherent contribution to J/ψ photoproduction in accordance with predictions [14], but statistical limitations prevent a more quantitative estimate. After correcting for acceptance and efficiency losses and normalising by the measured luminosity, the total J/ψ photoproduction cross section is $d\sigma/dy\, (J/\psi + Xn)|_{y=0} = 76 \pm 31(\mathrm{stat}) \pm 15(\mathrm{syst})$ μb, which is consistent (within uncertainties) with theoretical expectations. The low background in the present data sample shows that future higher luminosity runs with reduced experimental uncertainties of the measured cross sections will provide more quantitative information on the nuclear gluon distribution and J/ψ absorption in cold nuclear matter at RHIC energies.

Acknowledgements

[4] Note, for comparison, that repeating the same exercise for the photoproduced ρ in the STAR UPC measurement [20], $\sigma(\gamma + \mathrm{Au} \to \rho + \mathrm{Au}) = 530 \pm 19(\mathrm{stat}) \pm 57(\mathrm{syst})$ μb for $\langle W_{\gamma N} \rangle \sim 12.5$ GeV, and taking the experimentally-derived value $\sigma(\gamma + p \to \rho + p) = 9.88$ μb from [25], yields $\alpha_{\mathrm{coh}} = 0.75 \pm 0.02$ closer to the $A^{2/3}$-scaling expected for soft particle production.

(Received 6 October 2008; published 1 July 2009)

The double helicity asymmetry in neutral pion production for $p_T = 1$ to 12 GeV/c was measured with the PHENIX experiment to access the gluon-spin contribution, ΔG, to the proton spin. Measured asymmetries are consistent with zero, and at a theory scale of $\mu^2 = 4$ GeV^2 a next to leading order QCD analysis gives $\Delta G^{[0.02,0.3]} = 0.2$, with a constraint of $-0.7 < \Delta G^{[0.02,0.3]} < 0.5$ at $\Delta\chi^2 = 9$ ($\sim 3\sigma$) for the sampled gluon momentum fraction (x) range, 0.02 to 0.3. The results are obtained using predictions for the measured asymmetries generated from four representative fits to polarized deep inelastic scattering data. We also consider the dependence of the ΔG constraint on the choice of the theoretical scale, a dominant uncertainty in these predictions.

DOI: 10.1103/PhysRevLett.103.012003 PACS numbers: 13.88.+e, 13.85.Ni, 21.10.Hw, 25.40.Ep

The originally surprising observations [1–3] that the quark spin contribution to the proton spin is only $\sim 25\%$ indicate that the majority of the proton spin on average comes from the gluon-spin contribution, ΔG, and/or from gluon and quark orbital angular momentum. High energy polarized $p + p$ collisions at the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory access ΔG through spin-dependent gluon-gluon (gg) and quark-gluon (qg) scattering.

This Letter presents results from the 2006 RHIC run on ΔG from measurements by the PHENIX experiment of the double-helicity asymmetry ($A_{\rm LL}$) in inclusive midrapidity π^0 production. ΔG can be extracted from $A_{\rm LL}^{\pi^0}$ using next-to-leading order (NLO) perturbative quantum chromodynamics (pQCD) [4], which successfully describes unpolarized cross sections measured at RHIC for many inclusive processes [5–7], including midrapidity π^0 production [8], at $\sqrt{s} = 200$ GeV. These $A_{\rm LL}^{\pi^0}$ data represent a factor of 2 improvement in the statistical uncertainty compared to previous results [8–10]. The data significantly constrain ΔG, as presented in a recent global fit (DSSV) [11] of both RHIC and polarized deep inelastic scattering (pDIS) data, which used a preliminary version of these results. We further present the impact of experimental systematic and two theoretical uncertainties on our determination of ΔG.

We define $\Delta G^{[a,b]}(\mu^2) \equiv \int_a^b dx \Delta g(x, \mu^2)$, with $\Delta g(x, \mu^2)$, the polarized gluon distribution, a function of x, the gluon momentum fraction, and μ^2, the factorization scale. Thus $\Delta G^{[0,1]} \equiv \Delta G$. Figure 1(a) shows the best fit (BF) $\Delta g(x)$ from four NLO pDIS fits (in the $\overline{\rm MS}$ scheme): GRSV-std [12], BB ("ISET-4") [13], LSS [14], and GS-C [15] which assumes a node, or sign change, in $\Delta g(x)$. As the pDIS data have limited sensitivity to ΔG, there remains large uncertainty. Table I lists $\Delta G^{[a,b]}$ for two x ranges.

We define $A_{\rm LL}^{\pi^0} = (\sigma_{++} - \sigma_{+-})/(\sigma_{++} + \sigma_{+-})$, with σ_{++} (σ_{+-}) the beam helicity dependent differential cross sections for inclusive π^0 production from collisions of longitudinally polarized protons with the same (opposite) helicity. The asymmetry is measured using

$$A_{\rm LL}^{\pi^0} = \frac{1}{\langle P_B P_Y \rangle} \frac{N_{++} - R N_{+-}}{N_{++} + R N_{+-}}, \qquad R = \frac{L_{++}}{L_{+-}} \quad (1)$$

where P_B and P_Y are the polarizations of the two RHIC beams, called "blue" and "yellow," and R, the relative luminosity, is the ratio of integrated luminosities (L) for the same and opposite helicity collisions. Here we take N to be the π^0 yield in a transverse momentum (p_T) bin.

Each π^0 p_T bin is sensitive to a broad range in gluon x. Figure 1(b) shows the π^0 yield as a function of gluon x for

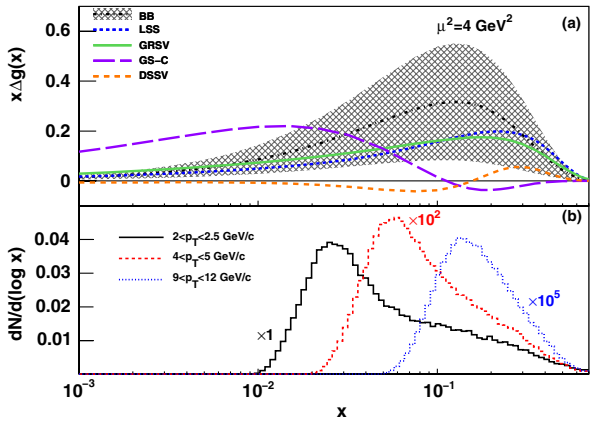

FIG. 1 (color online). (a) The polarized gluon distribution as a function of x for five fits to polarized data. The hatched band is pDIS uncertainty (BB). (b) π^0 yield as a function of gluon x in three π^0 p_T bins from an NLO pQCD simulation.

TABLE I. $\Delta G^{[a,b]}$ at $\mu^2 = 4$ GeV^2 for each group's best fit and the χ^2 when comparing the expected A_{LL} in Fig. 3(a) with the data (8 degrees of freedom). Also shown are the minimum χ^2 and corresponding $\Delta G^{[0.02,0.3]}$ found in Fig. 3(b).

	Published best fit			From Fig. 3(b)	
Group	$\Delta G^{[0,1]}$	$\Delta G^{[0.02,0.3]}$	χ^2	$\Delta G^{[0.02,0.3]}$	χ^2
GS-C	0.95	0.18	8.3	0.1	8.5
DSSV	−0.05	−0.03	7.5	···	···
LSS	0.60	0.37	22.4	0.2	7.0
GRSV	0.67	0.38	14.8	0.2	7.1
BB	0.93	0.67	69.0	0.2	7.2

three $A_{LL}^{\pi^0}$ p_T bins from a NLO pQCD simulation [4,16]. They are peaked at $x_T/0.7$ [17], with $x_T \equiv p_T/(\sqrt{s}/2)$. The x ranges overlap, with the data covering primarily the range $0.02 < x < 0.3$, and so we probe $\Delta G^{[0.02,0.3]}$.

The highly segmented PHENIX electromagnetic calorimeter (EMCal) [18] is used to detect $\pi^0 \to \gamma\gamma$ decays. The EMCal covers a pseudorapidity range of $|\eta| < 0.35$ and azimuthal angle range of $\Delta\phi = \pi$, with segmentation $\Delta\eta \times \Delta\phi = 0.01 \times 0.01$. We required for each of the two decay photons an energy deposition pattern consistent with an electromagnetic shower, no charged track pointing to the location of the deposited energy, and standard quality assurance requirements [9]. Events were obtained from an EMCal based high p_T photon trigger [19] in coincidence with a minimum bias trigger [8] (also used to obtain the relative luminosity). The EMCal based trigger efficiency for π^0 was 5% at $p_T \approx 1$ GeV/c and plateaued at 90% for $p_T > 3.5$ GeV/c. The minimum bias trigger was defined as the coincidence of signals from forward and backward beam-beam counters (BBC) with full azimuthal coverage located at pseudorapidities $\pm(3.0$–$3.9)$ [20]. The analyzed data sample corresponded to an integrated luminosity of 6.5 pb^{-1}.

Each collider ring of RHIC was filled with up to 111 out of a possible 120 bunches, spaced 106 ns apart, with bunch helicities set such that all four beam helicity combinations occurred in sequences of four bunch crossings. The pattern of helicity combinations for each RHIC fill (typically 8 hrs) was cycled between four possibilities to reduce systematic uncertainties that could be correlated to the bunch structure in RHIC [8]. Events were tagged with the bunch crossing number to obtain the beam helicities for the event. The luminosity weighted beam polarization product was $\langle P_B P_Y \rangle = 0.322 \pm 0.027$ (8.3%), with single beam polarizations of 0.560 and 0.575. Small nonzero transverse single spin asymmetries in very forward neutron production [8,21] were measured for each beam. The fill-by-fill ratio of this asymmetry to the beam polarization was constant within statistical uncertainties, confirming the polarization direction stability at PHENIX and the spin sign identification of the recorded collisions. The polarization vector was found to be 99% aligned with the beam (momentum) axis.

As in our previous analyses [8,9], the relative luminosity ratio R was obtained from crossing-by-crossing collected minimum bias (BBC) trigger counts, which measure about half of the $p + p$ inelastic cross section [19]. The uncertainty on R was derived from the comparison with a second trigger based on the zero degree calorimeters [22], which count very forward, energetic neutrals, and so is sensitive to different physics processes with a different angular acceptance than the BBC. It contributed a p_T independent systematic uncertainty to A_{LL} of 7×10^{-4}.

Equation (1) is used to determine, on a fill-by-fill basis, A_{LL} for the yield in the π^0 mass peak (112–162 MeV/c^2) for each p_T bin. The asymmetries were averaged over fills and corrected for the asymmetry in the background contribution (determined from two 50 MeV/c^2 wide sidebands on either side of the π^0 peak) [9], which was consistent with zero.

Figure 2(a) shows the measured $A_{LL}^{\pi^0}$ in comparison with our published data from the 2005 RHIC run [8]. The results are found to be statistically consistent with a 13% confidence level. The inset shows an expanded view of the low p_T region, as well as the relative luminosity uncertainty. Besides this and the scale uncertainty from polarization, other systematic uncertainties that can be found by using a bunch polarization sign randomization technique [9] appear negligible. In addition, the results were robust against variation of the π^0 identification criteria. The parity-violating single helicity asymmetry A_L was measured for each beam, and was consistent with zero within statistical uncertainty for all p_T bins.

Also shown in Fig. 2(a) are NLO pQCD predictions (assuming $\mu = p_T$) of $A_{LL}^{\pi^0}$ [4] based on fits of pDIS data by GRSV with three values for ΔG at the *input* scale of $\mu^2 = 0.4$ GeV^2: (1) "std," their best fit value with $\Delta G = 0.24$, (2) $\Delta G = 0$, and (3) $\Delta G = -1.05$. The results are most consistent with GRSV $\Delta G = 0$. CTEQ6 unpolarized parton distribution functions [23] and DSS fragmentation functions [24] were used in all calculations. Using alternative parton distribution functions [25] or fragmentation functions [26] did not lead to significant differences in the A_{LL} expectations.

A_{LL} expectations were calculated [4] based on refits to the pDIS data with a range of inputs for $\Delta G^{[0,1]}$ at

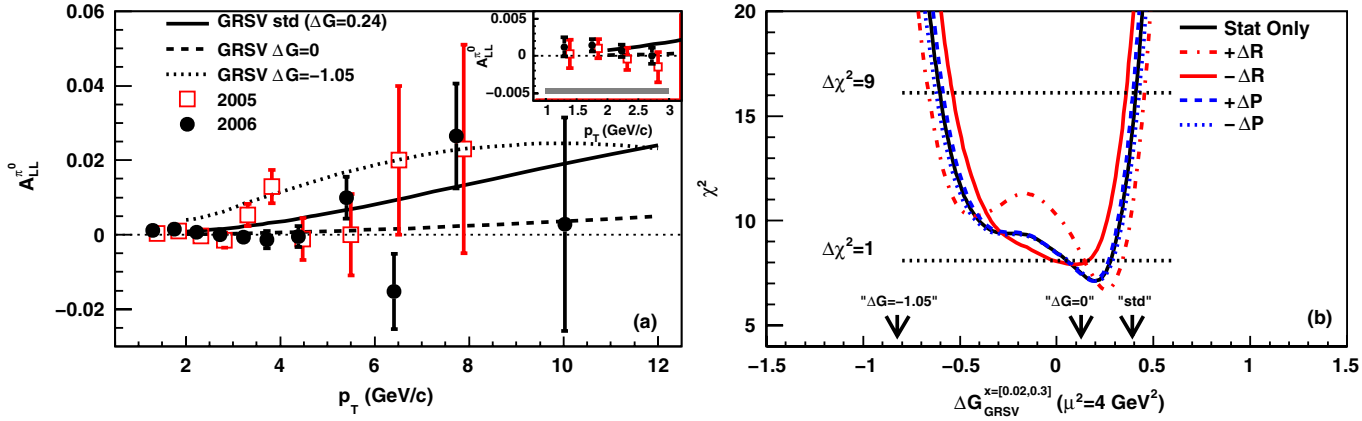

FIG. 2 (color online). (a) Asymmetry in π^0 production as a function of p_T. The error bars are statistical uncertainties. An 8.3% scale uncertainty due to the uncertainty in beam polarization is not shown. The p_T independent uncertainty of 7×10^{-4} due to relative luminosity is shown only in the inset as a shaded bar. For comparison, we also show our 2005 result. NLO pQCD expectations based on several inputs for ΔG in the GRSV parametrization are plotted. (b) The χ^2 profile as a function of $\Delta G^{[0.02,0.3]}_{\mathrm{GRSV}}$ using the combined 2005 and 2006 data considering only statistical uncertainty, or also varying by $\pm 1\sigma$ the two primary experimental systematic uncertainties, from beam polarizations ($\pm\Delta P$) and relative luminosity ($\pm\Delta R$).

$\mu^2 = 0.4$ GeV^2 in the GRSV parametrization. Similar to our previous analysis [8], χ^2 values were calculated using our combined 2005 and 2006 data for these expectations. In Fig. 2(b), these values are plotted as a function of $\Delta G^{[0.02,0.3]}$ evolved to $\mu^2 = 4$ GeV^2. We previously estimated the nonperturbative contribution to be small for $p_T > 2$ GeV$/c$ [8], and so use this as a minimum cutoff in this analysis. The solid curve shows the result considering only statistical uncertainties.

The quadratic ΔG contribution from gg interactions in $p + p$ collisions leads to two minima in Fig. 2(b), while the linear ΔG contribution from qg interactions breaks the symmetry in these minima [4,8]. The χ^2 profile is thus not parabolic, and so we show $\Delta\chi^2 \equiv \chi^2 - \chi^2_{\mathrm{min}} = 1$ and 9 corresponding to "1σ" and "3σ" uncertainties.

The effects of the two largest experimental systematic uncertainties, due to polarization and relative luminosity, are shown in Fig. 2(b). The polarization uncertainty is insignificant when extracting ΔG. However, the uncertainty on relative luminosity, though small, cannot be neglected. Accounting for statistical uncertainty, we find $\Delta G^{[0.02,0.3]}_{\mathrm{GRSV}} = 0.2 \pm 0.1$ (1σ) and $0.2^{+0.2}_{-0.8}$ (3σ) with an additional experimental systematic uncertainty of ± 0.1.

Figure 3(a) shows A_{LL} expectations [4,16] based on the parametrizations discussed above, along with the pDIS uncertainty on $\Delta g(x)$ in BB propagated to A_{LL}. The χ^2 values for comparing each curve with the data are given in Table I. The three fit results without a node in $\Delta g(x)$—LSS, GRSV and BB—have large values of $\Delta G^{[0.02,0.3]}$ which lead to relatively large asymmetries that lie mostly above the data, though they are consistent within the large uncertainty from pDIS. For GS-C and DSSV, which have a node in $\Delta g(x)$ near the center of the sampled x region, a cancellation between the positive and negative contribution in the wide x distribution in each p_T bin leads to a small value of $\Delta G^{[0.02,0.3]}$ and thus small A_{LL}.

To investigate if there is any consistent constraint on $\Delta G^{[0.02,0.3]}$, independent of the parametrization choice, the χ^2 profiles in Fig. 3(b) were calculated based on the pDIS fit results in Fig. 1(a) (excluding DSSV). New polarized gluon distributions were produced using $\Delta g(x) = \lambda \Delta g_{\mathrm{BF}}(x)$ at the input scale, with $\Delta g_{\mathrm{BF}}(x)$ the *best fit* result. For each parametrization, a family of A_{LL} curves were generated by varying λ, i.e., varying $\Delta G^{[0,1]}$ while fixing both the quark helicity distributions and the shape of $\Delta g(x)$ to the best fit values. This approach differs from that of Fig. 2(b), where both the quark helicity distributions and

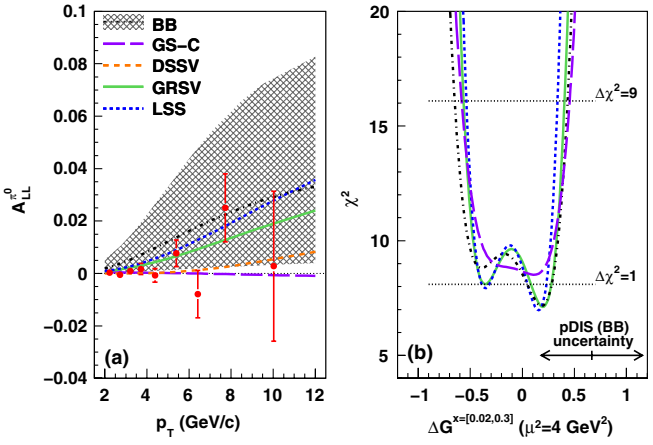

FIG. 3 (color online). (a) π^0 asymmetry expectations for different $\Delta g(x)$ in Fig. 1(b). The hatched band is the pDIS uncertainty (BB). Combined 2005 and 2006 data are also plotted (statistical errors only). (b) The χ^2 profile as a function of $\Delta G^{[0.02,0.3]}$ for the same parametrizations. Arrows indicate uncertainty on the BB best fit. $\Delta\chi^2$ values are shown for GRSV.

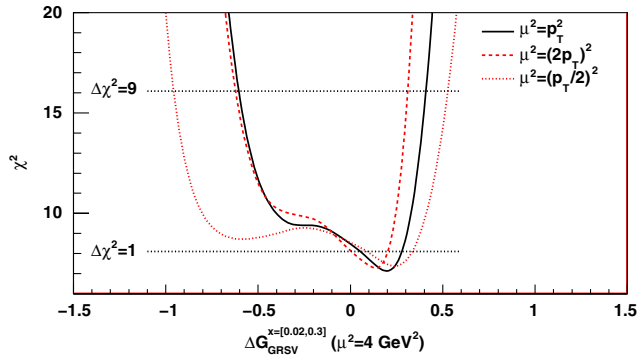

FIG. 4 (color online). χ^2 profile as a function of $\Delta G_{\mathrm{GRSV}}^{[0.02,0.3]}$ when the theoretical scale is set to $\mu = p_T$, $p_T/2$, and $2p_T$.

the shape of $\Delta g(x)$ were also varied. While this results in different GRSV χ^2 profiles, the $\Delta\chi^2 = 1$ and 9 constraints are consistent. The $\Delta G^{[0.02,0.3]}$ values at the χ^2 minimum for each parametrization are between 0.1 and 0.2, and are listed in Table I. At $\Delta\chi^2 = 9$, the profiles of all parametrizations are consistent with $-0.7 < \Delta G^{[0.02,0.3]} < 0.5$, indicating that the data are primarily sensitive to the size of $\Delta G^{[0.02,0.3]}$, while remaining largely insensitive to the shape of $\Delta g(x)$.

The cross section for π^0 production has been presented [8] and compared with NLO pQCD expectations with the theoretical scales (factorization, fragmentation, and renormalization) in the calculation all set equal to $\mu = kp_T$ with $k = 1$. The calculation agreed with the results within the sizable theoretical uncertainties in the choice of scale, which were estimated by varying k up and down by a factor of 2. As we rely on NLO pQCD to extract $\Delta G^{[0.02,0.3]}$ from the measured $A_{\mathrm{LL}}^{\pi^0}$, we must consider the effect of this uncertainty. Figure 4 shows the change in the $\Delta G_{\mathrm{GRSV}}^{[0.02,0.3]}$ constraint when varying k in the A_{LL} calculation in the GRSV parametrization. This variation leads to an additional uncertainty of $\pm 0.1(^{+0.1}_{-0.4})$ at $\Delta\chi^2 = 1$ ($\Delta\chi^2 = 9$). Thus, including these theoretical uncertainties, we find $\Delta G_{\mathrm{GRSV}}^{[0.02,0.3]} = 0.2 \pm 0.1(\mathrm{stat}) \pm 0.1(\mathrm{syst})^{+0.0}_{-0.4} \times (\mathrm{shape}) \pm 0.1(\mathrm{scale})$.

We have presented results for $A_{\mathrm{LL}}^{\pi^0}$ from 2006 which are consistent with zero. We extract $\Delta G^{[0.02,0.3]}$ after combining with the 2005 results [8]. Using four parametrizations of $\Delta g(x)$, we find a shape independent constraint of $-0.7 < \Delta G^{[0.02,0.3]} < 0.5$ at $\Delta\chi^2 = 9$ ($\sim 3\sigma$). The theoretical scale induced uncertainty is small for positive values of $\Delta G_{\mathrm{GRSV}}^{[0.02,0.3]}$, but is sizable for negative values. Future measurements will be required to measure $\Delta g(x)$ for $x < 0.02$ where large uncertainty remains [11] and which may still contribute a significant amount of the proton spin. The quark spin contribution was well constrained by pDIS and our results begin to significantly constrain the gluon-spin contribution.

We thank the staff of the Collider-Accelerator and Physics departments at BNL for their vital contributions, and Marco Stratmann and Werner Vogelsang for communications. (Received 6 October 2008; published 22 January 2009)

The PHENIX experiment presents results from the RHIC 2006 run with polarized $p + p$ collisions at $\sqrt{s} = 62.4$ GeV, for inclusive π^0 production at midrapidity. Unpolarized cross section results are measured for transverse momenta $p_T = 0.5$ to 7 GeV/c. Next-to-leading order perturbative quantum chromodynamics calculations are compared with the data, and while the calculations are consistent with the measurements, next-to-leading logarithmic corrections improve the agreement. Double helicity asymmetries A_{LL} are presented for $p_T = 1$ to 4 GeV/c and probe the higher range of Bjorken x of the gluon (x_g) with better statistical precision than our previous measurements at $\sqrt{s} = 200$ GeV. These measurements are sensitive to the gluon polarization in the proton for $0.06 < x_g < 0.4$.

I. INTRODUCTION

Spin is a property of particles as fundamental as charge and mass. The spin of the proton was first determined in the 1920s, yet we still do not have a detailed understanding of what inside the proton makes up the spin of the proton. Polarized lepton-nucleon deep-inelastic scattering (DIS) experiments have revealed that only ~25% of the proton spin can be attributed to the spins of the quarks and antiquarks [1,2] indicating that the proton spin must be largely carried by the spin of the gluons and/or orbital angular momentum of quarks and gluons. Polarized proton-proton collisions at the Relativistic Heavy-Ion Collider (RHIC) provide a laboratory to study the gluon-spin contribution to the proton spin structure, ΔG, with strongly interacting probes via measurements of double helicity asymmetries (A_{LL}) [3].

The A_{LL} of π^0's is defined as

$$A_{LL}^{\pi^0} = \frac{\sigma_{++} - \sigma_{+-}}{\sigma_{++} + \sigma_{+-}}, \tag{1}$$

where $\sigma_{++}(\sigma_{+-})$ represents the π^0 production cross section in polarized $p + p$ collisions with the same (opposite) helicities. In leading order (LO) perturbative Quantum Chromodynamics (pQCD), π^0 production is the sum of all possible subprocesses $ab \to cX$, where a,b represent the initial partons in the protons, c is the final state parton which fragments into a π^0, and X is the unobserved parton. Then A_{LL} is calculated as

$$A_{LL}^{\pi^0} = \frac{\Sigma_{a,b,c} \Delta f_a \Delta f_b \hat{\sigma}^{[ab\to cX]} \hat{a}_{LL}^{[ab\to cX]} D_c^{\pi^0}}{\Sigma_{a,b,c} f_a f_b \hat{\sigma}^{[ab\to cX]} D_c^{\pi^0}}, \tag{2}$$

where $f_{a,b}$ represent unpolarized parton distribution functions (PDFs) of parton a, b and $\Delta f_{a,b}$ represent polarized PDFs, $D_c^{\pi^0}$ is a fragmentation function (FF) of parton c to π^0, $\hat{\sigma}^{[ab\to cX]}$ and $\hat{a}_{LL}^{[ab\to cX]}$ denote, respectively, the cross section and A_{LL} of the subprocess $ab \to cX$. The sum is performed for all possible partons (quarks and gluons). The Bjorken-x dependence of the PDFs, the kinematical dependence of the FFs, and the integral over all possible kinematics are omitted in the equation. The partonic quantities $\hat{\sigma}$ and $\hat{a}_{LL}$ can be calculated in pQCD. Since π^0 production is dominated by gluon-gluon and quark-gluon scattering in the measured p_T range ($p_T < 4$ GeV/c), A_{LL} is directly sensitive to the polarized gluon distribution function in the proton.

Cross-section measurements at RHIC have established the validity of using a next-to-leading order (NLO) pQCD description at $\sqrt{s} = 200$ GeV for inclusive midrapidity π^0 [4,5] and forward π^0 production [6], and for midrapidity jet [7] and direct photon production [8]. However, at lower center of mass energy, NLO pQCD calculations have been less successful in describing the data [9]. The inclusion of "threshold resummation" at next-to-leading logarithmic accuracy (NLL) [10] improves the agreement between theory and data at fixed-target energies. While taking into account threshold logarithms at the fixed-target kinematic region is essential, they may also need to be accounted for at $\sqrt{s} = 62.4$ GeV, but will provide a smaller effect [11].

A precise measurement of the inclusive π^0 production cross section at $\sqrt{s} = 62.4$ GeV is important for the heavy-ion program at RHIC. A new state of dense matter is formed in Au + Au collisions at 200 GeV and parton energy loss in the produced dense medium results in high p_T leading hadron suppression. Measurements of high p_T data at lower energies are of great importance in identifying the energy range at which the suppression sets in. However, they require solid measurements of the cross section in $p + p$ collisions as a baseline for medium effects. At the ISR, inclusive neutral and charged pion

cross sections were measured several times at $\sqrt{s} \sim 62$ GeV [12,13], but they have large uncertainties and have a large variation [14]. Having both heavy-ion and baseline $p + p$ measurements with the same experiment is advantageous as it leads to a reduction of the systematic uncertainties and, thus, to a more precise relative comparison of the data.

In this paper, we present results on inclusive neutral pion production at midrapidity from proton-proton collisions at $\sqrt{s} = 62.4$ GeV from data collected during the RHIC 2006 run. A sample of events from longitudinally polarized $p + p$ collisions (about 2/3 of the total data sample) was used for double helicity asymmetry measurements. The other events from the 2006 data sample were from transversely polarized $p + p$ collisions and, along with the longitudinally polarized data, were used for the unpolarized cross section measurements, by averaging over the different initial spin states.

The structure of this paper is as follows. The PHENIX subsystems used in this analysis are briefly introduced in Sec. II. The unpolarized π^0 cross section analysis and the results are discussed in Sec. III. The π^0 A_{LL} analysis and the results follow in Sec. IV, and a summary is given in Sec. V.

II. EXPERIMENT

The PHENIX experiment at RHIC measured π^0's via $\pi^0 \rightarrow \gamma\gamma$ decays using a highly segmented ($\Delta\eta \times \Delta\phi \sim 0.01 \times 0.01$) electromagnetic calorimeter (EMCal) [15], covering a pseudorapidity range of $|\eta| < 0.35$ and azimuthal angle range of $\Delta\phi = \pi$. The EMCal comprises two calorimeter types: 6 sectors of lead scintillator sampling calorimeter (PbSc) and 2 sectors of a lead glass Cherenkov calorimeter (PbGl). Each of the EMCal towers was calibrated by the two-photon invariant mass from π^0 decays and cross checked against the energy deposited by the minimum ionizing particles in the EMCal, and the correlation between the measured momenta of electron and positron tracks and the associated energy deposited in the EMCal. The uncertainty on the absolute energy scale was 1.2%.

The π^0 data in this analysis were collected using two different triggers. One is a beam-beam counter (BBC) trigger which was defined by the coincidence of signals in two BBCs located at pseudorapidities $\pm(3.0$–$3.9)$ with full azimuthal coverage [16]. The time difference between the two BBCs was used to determine the collision vertex along the beam axis, which in this analysis was required to be within 30 cm from the center of the PHENIX interaction region (IR). The other trigger is an EMCal-based high p_T photon trigger, in which threshold discrimination corresponding to a deposited energy of 0.8 GeV was applied independently to sums of analog signals from 2×2 groupings of adjacent EMCal towers [4]. This trigger had limited efficiency for π^0 detection at low p_T (e.g. 50% in 1.0–1.5 GeV/c p_T bin) and close to 100% efficiency at $p_T > 3$ GeV/c.

Beam-beam counters along with zero degree calorimeters (ZDC) [17], which detect neutral particles near the beam axis ($\theta < 2.5$ mrad), were utilized to determine the integrated luminosity for the analyzed data sample needed for the absolute normalization of the measured cross sections. Trigger counts defined with the BBCs and ZDCs were also used for the precise measurements of the relative luminosity between bunches with different spin configuration, and the spin dependence of very forward neutron production [5,18,19], detected by the ZDCs, served for monitoring the orientation of the beam polarization in the PHENIX interaction region (IR) through the run. These are necessary components of the spin asymmetry measurements.

III. THE $pp \rightarrow \pi^0 X$ CROSS SECTION

The unpolarized cross section analysis technique was very similar to our analyses of $\sqrt{s} = 200$ GeV data [4,5] and is briefly discussed in Sec. III A. Cross-section measurements require an absolute determination of luminosity which is described in Sec. III B. The π^0 cross section results are presented and discussed in Sec. III C.

A. π^0 analysis

The π^0 yield in each p_T bin was determined from the two-photon invariant mass spectra. The background contribution under the π^0 peak in the two-photon invariant mass distribution varied from 75% in the lowest 0.5–0.75 GeV/c p_T bin to less than 4% for $p_T > 3$ GeV/c.

One of the main corrections applied to the measured π^0 spectrum is the BBC trigger bias f_{π^0}, which is defined as the fraction of high p_T π^0 events in the midrapidity spectrometer acceptance which fire the BBC trigger. This fraction was determined from the ratio of the number of reconstructed π^0 in the high p_T photon triggered sample with and without the BBC trigger requirement. As shown in Fig. 1, f_{π^0} was about 40% up to $p_T \sim 3$ GeV/c and then monotonically dropped down to 25% at $p_T \sim 7$ GeV/c. The drop can be explained by the fact that most of the energy is used for the production of high-energy jets which contain the measured high p_T π^0 and there is not enough energy left to produce particles in the BBC acceptance $3.0 \leq |\eta| \leq 3.9$, which was optimized for $\sqrt{s} = 200$ GeV (where such a drop was not observed [4]) and was not moved for the present $\sqrt{s} = 62.4$ GeV measurements.

The main contributors to the systematic uncertainties of the measured π^0 spectrum are given in Table I. The ''Energy scale'' uncertainty includes uncertainties due to EMCal energy absolute calibration and nonlinearity. The ''Yield extraction'' uncertainty comes from the background subtraction. The ''Yield correction'' uncertainty comes from the correction for the geometric acceptance,

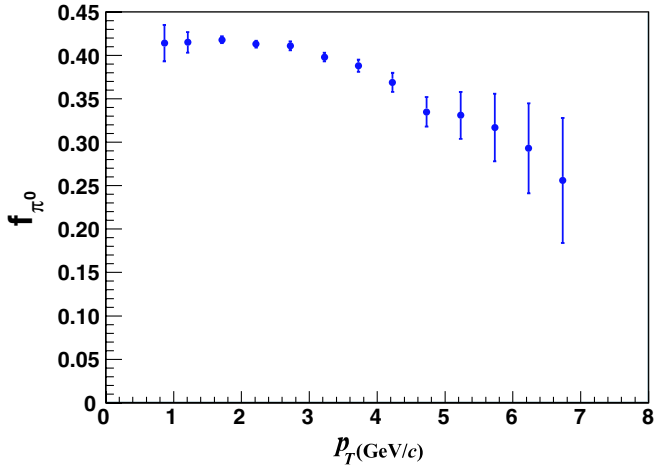

FIG. 1 (color online). The fraction of the inclusive π^0 yield which satisfied the BBC trigger condition.

TABLE I. Main systematic uncertainties in % of the π^0 spectrum from the PbSc for two representative p_T bins (the PbGl uncertainties are similar).

$\langle p_T \rangle$ (GeV/c)	1.2	6.7
Energy scale	3.9	13.1
Yield extraction	3.9	2.0
Yield correction	6.4	6.0

trigger efficiency, reconstruction efficiencies, detector response, and photon conversion. The normalization uncertainty is not included and is discussed in Sec. III B.

The data sets from the two EMCal subsystems, PbSc and PbGl, were analyzed separately and combined for the final results. Results from the two subsystems were consistent within uncertainties. The systematic uncertainty of the combined result is reduced as the major systematic uncertainties in the two EMCal subsystems are not correlated. For final π^0 cross section results, BBC-triggered events were used for $p_T < 3$ GeV/c and high p_T photon triggered events in coincidence with the BBC trigger were used for $p_T > 3$ GeV/c.

B. Vernier scan analysis

The measured π^0 cross section was normalized to the integrated luminosity for the analyzed data sample (L) which was determined from the number of BBC-triggered events using an absolute calibration of the BBC trigger cross section $\sigma_{\rm BBC}$. The value of $\sigma_{\rm BBC}$ is obtained via the van der Meer or Vernier scan technique [20]. This is a crucial part of the absolute cross section analysis and is therefore discussed in detail in this section.

In a scan, the transverse widths of the beam overlap σ_x and σ_y were measured by sweeping one beam across the other in small steps while monitoring the BBC trigger rate. Then the instantaneous machine luminosity of each bunch crossing $L_{\rm machine}$ is computed as

$$L_{\rm machine} = \frac{f_{\rm rev}}{2\pi\sigma_x\sigma_y} \cdot N_B \cdot N_Y, \tag{3}$$

where N_B and N_Y are the bunch intensities of the two beams ($\sim 10^{11}$/bunch), $f_{\rm rev}$ is the revolution frequency (78 kHz). The BBC trigger cross section $\sigma_{\rm BBC}$ is the ratio of the BBC trigger rate when the beams were overlapping maximally ($R_{\rm max}$) to the effective luminosity $L_{\rm eff}$:

$$\sigma_{\rm BBC} = R_{\rm max}/L_{\rm eff}, \tag{4}$$

where

$$L_{\rm eff} = L_{\rm machine} \cdot \epsilon_{\rm vertex}, \tag{5}$$

and $\epsilon_{\rm vertex}$ is the fraction of the number of collisions in the PHENIX interaction region (IR) within the BBC trigger vertex cut (usually $|z| < 30$ cm).

$L_{\rm machine}$ was corrected for the z dependence of the transverse beam sizes caused by the beam focusing in the IR (hourglass effect) and for the beam crossing angle. The value of $\epsilon_{\rm vertex}$ was extracted from the z-vertex distribution of events measured by the BBCs and was corrected for the dependence of the BBC trigger efficiency on the collision vertex position z along the beam axis. These corrections are discussed in more detail below.

In $p + p$ collisions at $\sqrt{s} = 62.4$ GeV, the BBC trigger efficiency vs z shape was estimated from the comparison with a ''detector unbiased'' z-vertex distribution obtained from the convolution of colliding bunch intensity profiles along the z-axis as measured by Wall Current Monitors (WCMs) [21]. The correction factor of 0.83 ± 0.08 for $\epsilon_{\rm vertex}$ in Eq. (5) was obtained, resulting in $\epsilon_{\rm vertex} = 0.37 \pm 10\%$. This approach is confirmed in $p + p$ collisions at $\sqrt{s} = 200$ GeV where the ZDCs have enough efficiency to measure the z vertex distribution. The efficiency of the ZDCs (located at $z = \pm 18$ m) does not depend on collision vertex position in the PHENIX IR, which was distributed with a sigma of 0.5–0.7 m around $z = 0$. The vertex distribution obtained with the WCMs is well reproduced by the measurement with the ZDCs at $\sqrt{s} = 200$ GeV [Fig. 2(a)].

Beam focusing in the IR causes bunch transverse sizes to vary away from the nominal collision point ($z = 0$) as $\sigma^2(z) = \sigma^2(z = 0) \times (1 + z^2/\beta^{*2})$, where β^* is the value of the betatron amplitude function at the interaction point. This is the so-called hourglass effect. The product $\sigma_x\sigma_y$ in Eq. (3) should be replaced by an effective $\langle \sigma_x \cdot \sigma_y \rangle$, which differs from what was measured in a scan (mainly due to the vertex cut implemented in BBC trigger). The correction due to this effect for Vernier scan data at $\sqrt{s} = 62.4$ GeV with a betatron amplitude function at the collision point of $\beta^* = 3$ m was simulated with WCM data and calculated to be 0.93 ± 0.02. The applicability of our calculational technique is illustrated in Fig. 2 with the high statistics Vernier scan data at $\sqrt{s} = 200$ GeV.

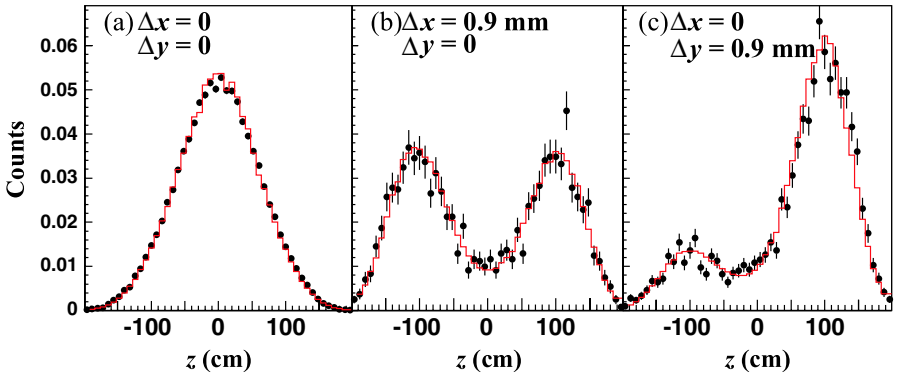

FIG. 2 (color online). Collision z-vertex distribution in the PHENIX IR measured by ZDCs in a Vernier scan at $\sqrt{s} = 200$ GeV (points) and calculations from convolution of colliding bunch intensity profiles along z-axis and including the hourglass effect for $\beta^* = 1$ m, for bunches with typical length of 1 m and transverse size of 0.3 mm (histograms); (a) beams are head-on; (b) one beam is 0.9 mm displaced relative to the other beam in the horizontal direction (illustrates the hourglass effect) and (c) one beam is 0.9 mm displaced relative to the other beam in the vertical direction. The calculations include the bunch crossing angle with a vertical projection of 0.15 mrad.

Figures 2(b) and 2(c) shows the sensitivity of our data for the transversely displaced beams to the hourglass effect and to the crossing angle between the colliding beams, compared with a head-on vertex distribution in Fig. 2(a). The two peaks in Figs. 2(b) and 2(c) caused by the hourglass effect, show an overlap of the diverging colliding beams at large $|z|$ in a particular displaced beam setting from a Vernier scan. The obvious asymmetry in the two peaks in Fig. 2(c) is a result of the nonzero crossing angle between colliding bunches. In all Vernier scan measurements the crossing angle was found to be less than 0.2 mrad, which translates to a negligible correction for L_{machine} at $\sqrt{s} = 62.4$ GeV, with a typical bunch length of $\sim$1 m and bunch transverse size of 1 mm.

After all the corrections discussed above were applied, our BBC trigger cross section in $p + p$ collisions at $\sqrt{s} = 62.4$ GeV was found to be $\sigma_{\text{BBC}} = 13.7$ mb with a systematic uncertainty of ± 1.5 mb ($\pm$ 11%), i.e. $\sim$40% of the world-average value of the inelastic $p + p$ scattering cross section at $\sqrt{s} = 62.4$ GeV[14]. Major contributors to the systematic uncertainty are 4% from the uncertainty in the normalization of bunch intensity measurements and in the calibration of the beam position measurements in the Vernier scan, 10% from the BBC trigger efficiency correction of ϵ_{vertex}, and 2% from the hourglass correction.

C. π^0 cross section results and discussion

Figure 3 presents the inclusive midrapidity π^0 invariant production cross section at $\sqrt{s} = 62.4$ GeV versus p_T, from $p_T = 0.5$ GeV/c to $p_T = 7$ GeV [22]. An overall normalization uncertainty of 11% due to the uncertainty in absolute normalization of the luminosity is not shown. The analyzed data sample with 0.76×10^9 BBC triggers corresponded to about 55 nb^{-1} integrated luminosity. The measurements fall within the large spread of ISR data [12–14].

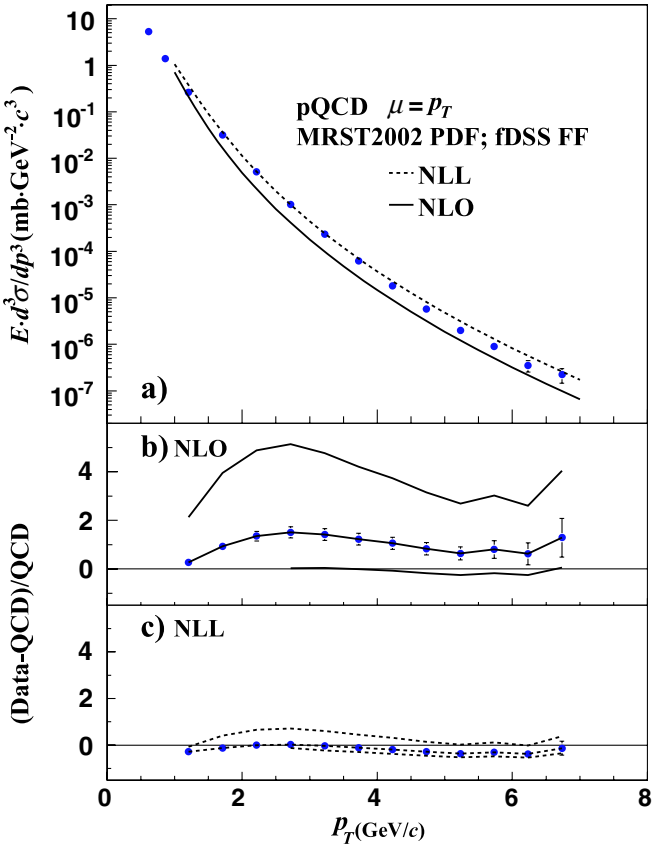

FIG. 3 (color online). (a) The neutral pion production cross section at $\sqrt{s} = 62.4$ GeV as a function of p_T (circles) and the results of NLO (solid) and NLL (dashed) pQCD calculations for the theory scale $\mu = p_T$. (b) The relative difference between the data and NLO pQCD calculations for the three theory scales $\mu = p_T/2$ (upper line), p_T (middle line) and $2p_T$ (lower line); experimental uncertainties (excluding the 11% normalization uncertainty) are shown for the $\mu = p_T$ curve. (c) The same as b) but for NLL pQCD calculations.

The data are compared to NLO and NLL pQCD calculations at a theory scale $\mu = p_T$, where μ represents equal factorization, renormalization, and fragmentation scales [11]. The NLL corrections extend the NLO calculations to include the resummation of extra ''threshold'' logarithmic terms which appear in the perturbative expansion at not very high energies because the initial partons have just enough energy to produce the high p_T parton that fragments into a final pion. The MRST2002 parton distribution functions [23] and the fDSS set of fragmentation functions [24], which are extracted in NLO, are used in both NLO and NLL calculations. We have previously seen that the data are well described by NLO pQCD with a scale of $\mu = p_T$ at $\sqrt{s} = 200$ GeV [4,5]. In contrast, NLO calculations with the same scale underestimate the π^0 cross section at $\sqrt{s} = 62.4$ GeV. At the same time, it is known that NLO calculations are not always successful at describing low-energy fixed-target data [9], while NLL calculations have been successful [10]. The NLL calculations have a smaller scale dependence and describe our data well with $\mu = p_T$; however, as noted in [11], subleading perturbative corrections to the NLL calculation may be significant. The results may indicate that $\sqrt{s} = 62.4$ GeV is at an intermediate energy region where calculations that include threshold logarithm effects may describe the data more accurately. Consequently, we show comparisons below to both NLO and NLL at a scale of $\mu = p_T$.

General principles of hard scattering, including the principle of factorization of the reaction into parton distribution functions for the protons, fragmentation functions for the scattered partons and a short-distance parton-parton hard-scattering cross section, predicted a general x_T-scaling form for the invariant cross section of inclusive particle production near midrapidity [25]:

$$E\frac{d^3\sigma}{dp^3} = \frac{1}{p_T^n}F(x_T) = \frac{1}{\sqrt{s}^n}G(x_T) \tag{6}$$

where $x_T = 2p_T/\sqrt{s}$, and $F(x_T)$ and $G(x_T)$ are universal functions. The parameter n relates to the form of the force-law between constituents. For example for QED or Vector Gluon exchange, $n = 4$ [26]. Because of higher order effects, the running of the coupling constant $\alpha(Q^2)$, the evolution of the parton distribution functions and fragmentation functions, and the initial-state transverse momentum k_T, n is not a constant but is a function of x_T and $\sqrt{s}$: $n(x_T, \sqrt{s})$ [27].

Figure 4(a) shows the inclusive π^0 cross section scaled by $\sqrt{s}^n$ for $\sqrt{s} = 62.4$ GeV and 200 GeV data [5] as a function of x_T, with the parameter $n = 6.38$, which is a weighted average of $n(x_T)$ for $x_T > 0.07$ (corresponding to $p_T > 2$ GeV/c at $\sqrt{s} = 62.4$ GeV). The parameter $n(x_T)$ was calculated as $\ln(\sigma_{62.4}(x_T)/\sigma_{200}(x_T))/\ln(200/62.4)$ for each x_T of $\sqrt{s} = 62.4$ GeV data; $\sigma_{62.4}$ and σ_{200} are invariant differential cross sections at $\sqrt{s} = 62.4$ GeV and $\sqrt{s} = 200$ GeV, respectively. Cross-section values for the corresponding x_T at $\sqrt{s} = 200$ GeV were obtained from parametrization of the measured cross section at $\sqrt{s} = 200$ GeV: $T(p_T)\frac{A}{(1+p_T/p_0)^m} + (1 - T(p_T))\frac{B}{p_T^k}$, $T(p_T) = \frac{1}{1+\exp((p_T-t)/w)}$, where $t = 4.5$ GeV/c, $w = 0.084$ GeV/c, $A = 253.8$ mb $\cdot$ GeV$^{-2} \cdot c^3$, $p_0 = 1.488$ GeV/c, $m = 10.82$, $B = 14.7$ mb $\cdot$ GeV$^{-2+k} \cdot c^{3-k}$, and $k = 8.11$. All $\sqrt{s} = 200$ GeV data points agree with the parametrization curve within uncertainties. The parametrization is shown as the solid curve in Fig. 4(a).

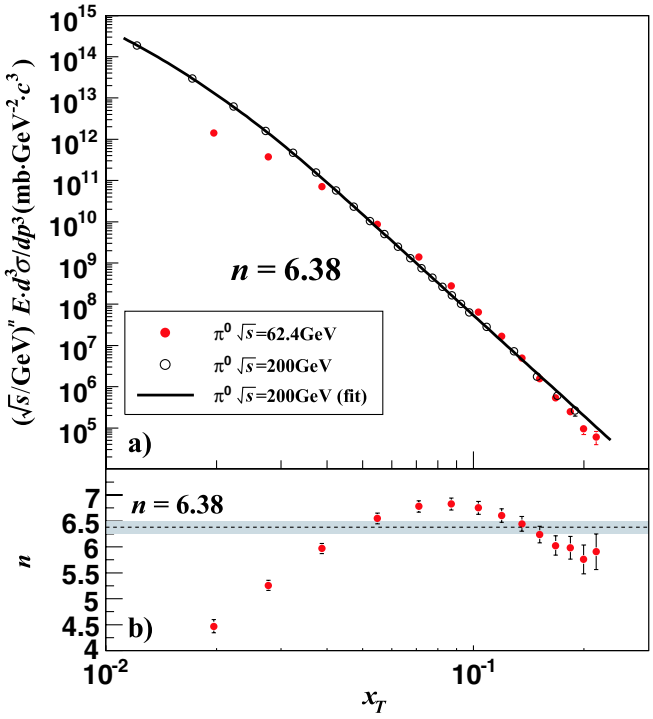

FIG. 4 (color online). (a) The neutral pion production cross section at $\sqrt{s} = 62.4$ GeV and $\sqrt{s} = 200$ GeV as a function of x_T, scaled by $(\sqrt{s}/\text{GeV})^n$ with $n = 6.38$; the solid line is a parametrization of $\sqrt{s} = 200$ GeV data. (b) The parameter n in (6) obtained from the ratio of invariant cross section at $\sqrt{s} = 62.4$ GeV and $\sqrt{s} = 200$ GeV, at each x_T of $\sqrt{s} = 62.4$ GeV data; error bars show the statistical and systematic uncertainties of the $\sqrt{s} = 62.4$ GeV and $\sqrt{s} = 200$ GeV data. The shaded band reflects the 11% $\oplus$ 9.7% normalization uncertainty in the $\sqrt{s} = 62.4$ and 200 GeV cross section measurements, correspondingly.

At low x_T, where soft physics dominates particle production, $n(x_T)$ is supposed to increase with x_T due to the similar exponential shapes of the soft part of the invariant cross section versus p_T at different $\sqrt{s}$ ($\sim e^{-6p_T}$) [26]. In the hard-scattering region $n(x_T)$ is expected to decrease with increasing x_T, due to stronger scale breaking at lower p_T. Such behavior of $n(x_T)$ is demonstrated by our data in Fig. 4(b). A similar drop in the parameter n at $x_T \gtrsim 0.1$ was observed at ISR energies [12]. Figure 4(b) also shows the possible transition from soft- to hard-scattering regions

in π^0 production at $p_T \sim 2$ GeV/c. A similar conclusion was derived from the shape of the π^0 spectrum at $\sqrt{s} = 200$ GeV in [5]. This can serve as a basis for applying the pQCD formalism to the double helicity asymmetry data with $p_T > 2$ GeV/c in order to allow access to ΔG.

IV. INCLUSIVE π^0 DOUBLE HELICITY ASYMMETRY

A. π^0 A_{LL} analysis

For the 2006 run, each of the two independent RHIC collider rings were filled with up to 111 bunches in a 120 bunch pattern, with one of four, fill-by-fill alternating predetermined patterns of polarization sign for the bunches. Bunch polarization signs in each pattern were set in such a way that all four colliding bunch spin combinations occurred in sequences of four bunch crossings. That greatly reduced the systematic effects in spin asymmetry measurements due to variation of detector response versus time and due to possible correlation of detector performance with RHIC bunch structure.

To collect data from collisions of longitudinally polarized protons, the polarization orientation of the beams was rotated from vertical, the stable spin direction in RHIC, to longitudinal at the PHENIX IR and then back to vertical after the IR by spin rotators [28]. PHENIX local polarimeters measured the residual transverse component of the beam polarizations, using the spin dependence of very forward neutron production [5,18,19] observed by the ZDC, and by that means monitored the orientation of the beam polarization in the PHENIX IR throughout the run.

The magnitudes of the beam polarizations at RHIC are measured using fast carbon target polarimeters [29], normalized to absolute polarization measurements by a separate polarized atomic hydrogen jet polarimeter [30]. The luminosity-weighted beam polarizations over 11 RHIC fills used in the A_{LL} analysis were $\langle P \rangle = 0.48$ for both beams, with 0.035 and 0.045 systematic uncertainty for the two RHIC beams, respectively. For the longitudinal polarization run period, the residual transverse polarizations of the beams were $\langle P_T/P \rangle^B = 0.11 \pm 0.15$ and $\langle P_T/P \rangle^Y = 0.11 \pm 0.12$ for ''Blue'' and ''Yellow'' RHIC beams, respectively. The average transverse component of the product was $\langle P_T^B \cdot P_T^Y \rangle / \langle P^B \cdot P^Y \rangle \leq \langle P_T/P \rangle^B \cdot \langle P_T/P \rangle^Y = 0.012 \pm 0.021$; the average of the polarization product over the run was $\langle P^B \cdot P^Y \rangle = 0.23$, with a systematic uncertainty of $\pm 14\%$.

Experimentally, the double helicity asymmetry for π^0 production is determined as

$$A_{LL}^{\pi^0} = \frac{1}{|P^B \cdot P^Y|} \cdot \frac{N_{++} - R \cdot N_{+-}}{N_{++} + R \cdot N_{+-}}; R = \frac{L_{++}}{L_{+-}}, \qquad (7)$$

where N_{++} and N_{+-} are the number of π^0's and R is the relative luminosity between bunches with the same and opposite helicities. The analysis technique for the π^0 A_{LL} measurements is similar to our analyses of $\sqrt{s} = 200$ GeV data [5,18,31].

Double helicity asymmetry results were obtained from longitudinally polarized $p + p$ collisions corresponding to ~ 40 nb^{-1} integrated luminosity. Because of the limited BBC trigger efficiency for high p_T π^0 events, high p_T photon triggered events without the BBC trigger condition requirement were used for the π^0 asymmetry analysis. This led to a slightly increased background in the π^0 reconstruction and additional systematic uncertainty in the measurements of the relative luminosity between bunches with different helicity states.

The background asymmetry under the π^0 peak in the two-photon mass distribution A_{LL}^{BG} was estimated from the counts outside the π^0 peak, from a 177–217 MeV/c^2 range in the two-photon mass distribution. Unlike our $\sqrt{s} = 200$ GeV data analyses, a lower mass range was not used for A_{LL}^{BG} estimations due to cosmic background from noncollision events. This background contribution in the mass ranges of π^0 peak and higher mass was negligible ($< 1\%$), and A_{LL}^{BG} was consistent with zero in all p_T bins.

Similar to our previous analyses, crossing-by-crossing accumulated number of BBC triggers were used for the measurements of the relative luminosity between bunches with different spin configuration. The uncertainty on the relative luminosity measurements δR was derived from the comparison between BBC trigger events and other trigger events, selecting different physics processes in different kinematic ranges. In the $\sqrt{s} = 200$ GeV data analysis the comparison was done to triggers defined by the coincidence of signals from the two ZDCs [5,18,31]. Because of the limited efficiency of the ZDC at $\sqrt{s} = 62.4$ GeV, the comparison in this analysis was performed with the number of events which fired simultaneously either of the two BBCs and either of the two ZDCs. Only 20% of the event statistics in this sample is contributed by BBC-triggered events, so this sample can be considered as essentially independent from the BBC event sample. From this comparison the upper limit of δR was estimated to be 0.6×10^{-3}, which for the average beam polarizations of 0.48 translates to $\delta A_{LL} = 1.4 \times 10^{-3}$, the p_T independent uncertainty of the π^0 double helicity asymmetry results. Single beam background $<0.35\%$, as determined by the trigger counts of noncolliding bunches and pileup probability of $\lesssim 0.002\%$, had negligible impact on the relative luminosity measurements.

A transverse double spin asymmetry A_{TT}, the transverse equivalent to Eqs. (1) and (7), can contribute to A_{LL} through the residual transverse component of the product of the beam polarizations discussed above. Similar to [5], A_{TT} was obtained from the sample with transverse polarization. The maximal possible A_{TT} effect on A_{LL} was determined by $\pm \delta A_{TT}$ from the measured A_{TT}, which was $< 0.15 \cdot \delta A_{LL}$ in all p_T bins.

B. π^0 A_{LL} results and discussion

Figure 5 presents the measured double helicity asymmetry in π^0 production versus p_T [22]. A scale uncertainty of 14% in $A_{LL}^{\pi^0}$ due to the uncertainty in beam polarizations is not shown. The other systematic uncertainties are negligible, as discussed above, and checked using a technique to randomize the sign of bunch polarization and by varying the π^0 identification criteria [18].

Figure 5 also shows a set of A_{LL} curves from pQCD calculations that incorporates different scenarios for gluon polarization within the GRSV parametrization of the polarized parton distribution functions [32]. GRSV-std corresponds to the best fit to inclusive DIS data. The other three scenarios in Fig. 5 (GRSV-max, $\Delta G = 0$, and $\Delta G = -G$) are based on the best fit, but use the functions $\Delta G(x_g) = G(x_g)$, 0, $-G(x_g)$ at the initial scale for parton evolution ($Q^2 = 0.4$ GeV^2), where $G(x_g)$ is the unpolarized gluon distribution, and $\Delta G(x_g)$ is the difference between the distribution of gluons with the same and opposite helicity to the parent proton. In Fig. 5, we compare our asymmetry data with both NLO and NLL calculations. The NLL calculations indicate that we have a reduced sensitivity to positive ΔG, but the effect is far less pronounced than at Fermilab fixed-target energies [11]. Similar to our $\sqrt{s} = 200$ GeV results [5,18], our $\sqrt{s} = 62.4$ GeV A_{LL} data do not support a large gluon polarization scenario, such as GRSV-max.

Figure 6 presents the measured A_{LL} versus x_T in π^0 production overlaid with the results at $\sqrt{s} = 200$ GeV [5]. Clear statistical improvement can be seen at higher x_T. For the measured p_T range 2–4 GeV/c, the range of x_g in each bin is broad and spans the range $x_g = 0.06 - 0.4$, as calculated by NLO pQCD [33]. Thus our data set extends our x_g reach of sensitivity to ΔG and also overlaps previous measurements, providing measurements with the same x_g but at a different Q^2 scale.

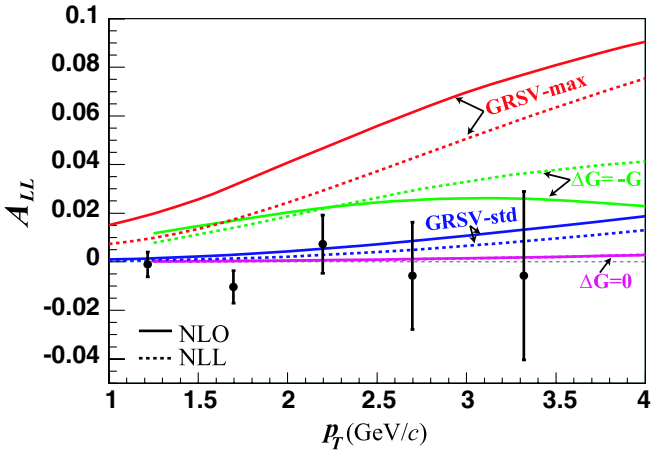

FIG. 5 (color online). The double helicity asymmetry for neutral pion production at $\sqrt{s} = 62.4$ GeV as a function of p_T(GeV/c). Error bars are statistical uncertainties, with the 14% overall polarization uncertainty not shown; other experimental systematic uncertainties are negligible. Four GRSV theoretical calculations based on NLO pQCD (solid curves) and on NLL pQCD (dashed curves) are also shown for comparison with the data (see text for details). Note that the $\Delta G = 0$ curves for NLO and NLL overlap.

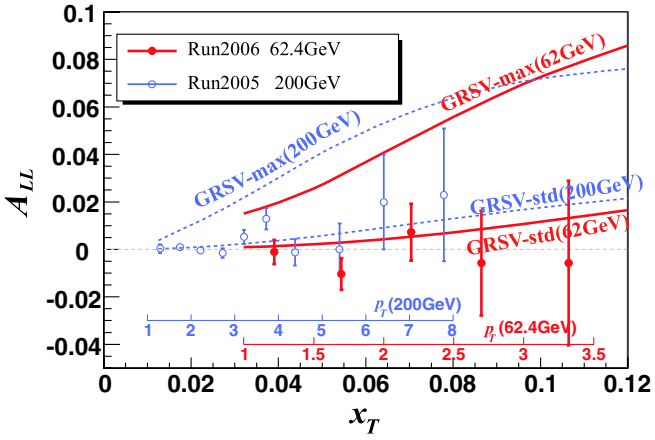

FIG. 6 (color online). The double helicity asymmetry for neutral pion production at $\sqrt{s} = 62.4$ GeV and 200 GeV as a function of x_T. Error bars are statistical uncertainties, with the 14% (9.4%) overall polarization uncertainty for $\sqrt{s} = 62.4$ GeV (200 GeV) data not shown. Two GRSV theoretical calculations based on NLO pQCD are also shown for comparison with the data (see text for details.)

V. SUMMARY

To summarize, we have presented the unpolarized cross section and double helicity asymmetries for π^0 production at midrapidity, for proton-proton collisions at $\sqrt{s} = 62.4$ GeV. The accuracy of the cross section measurements, which fall within the large spread of ISR data, relies on direct π^0 two-photon decay reconstruction, precise calibration of the photon energy measurements, careful study of the trigger performance and accurate control of the integrated luminosity of the analyzed data sample. The results serve as a precise baseline for heavy-ion measurements. Comparisons to NLO and NLL theoretical calculations indicate that including the effects of threshold logarithms may be necessary to more accurately describe the cross section at $\sqrt{s} = 62.4$ GeV. The A_{LL} results extend the sensitivity to the polarized gluon distribution in the proton to higher x_g compared to the previous measurements at $\sqrt{s} = 200$ GeV. A preliminary version of these double helicity asymmetry results was already used in a recent global fit of both RHIC and polarized DIS data to constrain ΔG [34].

ACKNOWLEDGMENTS

We thank the RHIC Polarimeter Group and the staff of the Collider-Accelerator and Physics Departments at

Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions. We thank W. Vogelsang and M. Stratmann for providing the pQCD calculations and for informative discussions. (Received 11 May 2008; published 7 October 2008)

A comprehensive survey of event-by-event fluctuations of charged hadron multiplicity in relativistic heavy ions is presented. The survey covers Au+Au collisions at $\sqrt{s_{NN}} = 62.4$ and 200 GeV, and Cu+Cu collisions at $\sqrt{s_{NN}} = 22.5$, 62.4, and 200 GeV. Fluctuations are measured as a function of collision centrality, transverse momentum range, and charge sign. After correcting for nondynamical fluctuations due to fluctuations in the collision geometry within a centrality bin, the remaining dynamical fluctuations expressed as the variance normalized by the mean tend to decrease with increasing centrality. The dynamical fluctuations are consistent with or below the expectation from a superposition of participant nucleon-nucleon collisions based upon $p+p$ data, indicating that this dataset does not exhibit evidence of critical behavior in terms of the compressibility of the system. A comparison of the data with a model where hadrons are independently emitted from a number of hadron clusters suggests that the mean number of hadrons per cluster is small in heavy ion collisions.

DOI: 10.1103/PhysRevC.78.044902 PACS number(s): 25.75.Gz, 25.75.Nq, 21.65.Qr, 25.75.Ag

I. INTRODUCTION

Recent work with lattice gauge theory simulations has attempted to map out the phase diagram of quantum chromodynamics (QCD) in temperature and baryo-chemical potential (μ_B) using finite values of the up and down quark masses. The results of these studies indicate that the QCD phase diagram may contain a first-order transition line between the hadron gas phase and the strongly coupled quark-gluon plasma (sQGP) phase that terminates at a critical point [1]. This property is analogous to that observed in the phase diagram for many common liquids and other substances, including water. However, different model predictions and lattice calculations yield widely varying estimates of the location of the critical point on the QCD phase diagram [2]. Direct experimental observation of critical phenomena in heavy ion collisions would confirm the existence of the critical point, narrow down its location on the QCD phase diagram, and provide an important constraint for the QCD models.

The estimated value of energy densities achieved in heavy ion collisions at the BNL Relativistic Heavy Ion Collider (RHIC) exceeds the threshold for a phase transition from normal hadronic matter to partonic matter. Recent experimental evidence indicates that properties of the matter being produced include strong collective flow and large opacity to scattered quarks and gluons—the matter appears to behave much like a perfect fluid [3]. While measurements suggest the produced matter has properties that differ from normal nuclear matter, unambiguous evidence of the nature and location of any phase transition from normal nuclear matter has been elusive thus far. Described here is a search for direct evidence of a phase transition by measuring the fluctuations of the event-by-event multiplicities of produced charge particles in a variety of collision systems.

To illustrate how the measurement of charged particle multiplicity fluctuations can be sensitive to the presence of a phase transition, the isothermal compressibility of the system can be considered [4]. The isothermal compressibility is defined as

$$k_T = -1/V\,(\delta V/\delta P)_T\,, \tag{1}$$

where V is the volume, T is the temperature, and P is the pressure of the system. To relate the compressibility to measurements of multiplicity fluctuations, we assume that relativistic nucleus-nucleus collisions can be described as a thermal system in the grand canonical ensemble (GCE) [5]. The GCE can be applied to the case of measurements near midrapidity, since energy and conserved quantum numbers in this region can be exchanged with the rest of the system, which serves as a heat bath [6]. Detailed studies of multiplicity fluctuations in the canonical and microcanonical ensembles with the application of conservation laws can be found elsewhere [7,8]. In the GCE, the isothermal compressibility is directly related to the variance of the particle multiplicity as follows:

$$\langle (N - \langle N\rangle)^2\rangle = \mathrm{var}(N) = \frac{k_B T \langle N\rangle^2}{V} k_T, \tag{2}$$

where N is the particle multiplicity, $\langle N\rangle = \mu_N$ is the mean multiplicity, and k_B is the Boltzmann constant [9]. Here, multiplicity fluctuation measurements are presented in terms of the scaled variance, ω_N:

$$\omega_N = \frac{\mathrm{var}(N)}{\mu_N} = k_B T \frac{\mu_N}{V} k_T. \tag{3}$$

In a continuous, or second-order, phase transition, the compressibility diverges to an infinite value at the critical point.

†PHENIX spokesperson: jacak@skipper.physics.sunysb.edu

Near the critical point, this divergence is described by a power law in the variable $\epsilon = (T - T_C)/T_C$, where T_C is the critical temperature. Hence, the relationship between multiplicity fluctuations and the compressibility can be exploited to search for a clear signature of critical behavior by looking for the expected power law scaling of the compressibility,

$$k_T \propto \left(\frac{T - T_C}{T_C}\right)^{-\gamma} \propto \epsilon^{-\gamma}, \tag{4}$$

where γ is the critical exponent for isothermal compressibility [9]. If the QCD phase diagram contains a critical point, systems with a low value of baryo-chemical potential (μ_B) could pass through the cross-over region and undergo a continuous phase transition [2]. Recent estimates [10,11] of the behavior of the quark number susceptibility χ_q, which is proportional to the value of the isothermal compressibility of the system, predict that its value will increase by at least an order of magnitude close to the QCD critical point. Given that the scaled variance is proportional to k_T, measurements of charged particle multiplicity are expected to be a sensitive probe for critical behavior. In addition, within a scenario where droplets of QGP are formed during a first-order phase transition, the scaled variance of the multiplicity could increase by a factor of 10–100 [12].

Experimentally, a search for critical behavior is facilitated by the rich and varied dataset provided by RHIC. It is expected that the trajectory of the colliding system in the QCD phase diagram can be modified by varying the colliding energy [2]. If the system approaches close enough to the critical line for a long enough time period, then critical phenomena could be readily apparent through the measurement of multiplicity fluctuations [13]. It may also be possible to determine the critical exponents of the system. Nature tends to group materials into universality classes whereby all materials in the same universality class share identical values for their set of critical exponents. Although beyond the scope of this analysis, observation of critical behavior in heavy ion collisions and the subsequent measurement of the critical exponents could determine the universality class in which QCD is grouped, providing essential constraints for the models.

Charged particle multiplicity fluctuations have been measured in elementary collisions over a large range of collision energies [14–20]. Initial measurements of multiplicity fluctuations in minimum-bias O+Cu collisions at $\sqrt{s_{NN}} = 4.86$ GeV were made by BNL Experiment E802 [21], minimum-bias O+Au collisions at $\sqrt{s_{NN}} = 17.3$ GeV by CERN Experiment WA80 [22], and minimum-bias S+S, O+Au, and S+Au collisions at $\sqrt{s_{NN}} = 17.3$ GeV by CERN Experiment NA35 [23]. Recently, larger datasets have enabled the measurement of the centrality dependence of multiplicity fluctuations in Pb+Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV by CERN Experiment WA98 [24] and in Pb+Pb, C+C, and Si+Si collisions at $\sqrt{s_{NN}} = 17.3$ GeV by CERN Experiment NA49 [25]. The PHENIX Experiment at RHIC has performed an analysis of density correlations in longitudinal space with a differential analysis of charged particle multiplicity fluctuations in 200 GeV Au+Au collisions over the entire transverse momentum range [26]. Thus far, the fluctuation measurements in heavy ion collisions do not indicate significant signs of a phase transition. However, the full range of collision energies and species accessible by RHIC are yet to be explored.

Presented here is a comprehensive survey of multiplicity fluctuations of charged hadrons measured by the PHENIX Experiment at RHIC. The survey will cover the following collision systems: $\sqrt{s_{NN}} = 200$ GeV Au+Au, 62.4 GeV Au+Au, 200 GeV Cu+Cu, 62.4 GeV Cu+Cu, and 22.5 GeV Cu+Cu with comparisons to $\sqrt{s} = 200$ GeV $p+p$ collisions, which serve as a baseline measurement. The Au+Au data were taken during RHIC Run-4 (2004), the Cu+Cu data were taken during RHIC Run-5 (2005), and the $p+p$ data were taken during RHIC Run-3 (2003). Multiplicity fluctuations for each collision system with the exception of $p+p$ will also be presented as a function of centrality to help select the system volume. Multiplicity fluctuations will also be presented as a function of transverse momentum range and charge sign.

This paper is organized as follows: Sec. II will discuss the experimental apparatus and details; Sec. III will discuss the methods applied for the measurement of multiplicity fluctuations and the removal of nondynamical fluctuations due to fluctuations of the collision geometry within a centrality bin; Sec. IV will present the results and compare them to those of other models. Sec. V will present a discussion and summary of the results.

II. EXPERIMENTAL SETUP

The PHENIX detector consists of two central spectrometer arms designed for charged particle tracking, designated east and west, and two muon spectrometers designed for muon tracking and identification, designated north and south. The muon spectrometers are not used in this analysis. A comprehensive description of the PHENIX detector is documented elsewhere [27]. The analysis described here utilizes the central spectrometer arms, which consist of a set of tracking detectors [28], particle identification detectors [29], and an electromagnetic calorimeter [30]. The central spectrometer arms cover a rapidity range of $|\eta| < 0.35$, and each arm subtends 90° in azimuth. A detailed description of the algorithms and performance of the central arm track reconstruction and momentum reconstruction can be found in Ref. [31].

There are two detectors that are used for triggering, centrality determination, and event vertex determination. The beam-beam counters (BBCs) consist of 64 individual quartz Cherenkov counters that cover the full azimuthal angle in the pseudorapidity range $3.0 < |\eta| < 3.9$. The zero degree calorimeters (ZDCs) cover the pseudorapidity range $|\eta| > 6$ and measure the energy of spectator neutrons with an energy resolution of approximately 20%. More details about these detectors can be found in Ref. [32]. The collision vertex position is determined using timing information from the BBCs with an r.m.s. resolution for central Au+Au events of 6 mm along the beam axis. The collision vertex is required to be reconstructed within ± 30 cm from the center of the spectrometer. The BBCs also provide a minimum-bias (MB) event trigger.

Because of the large dynamic range in $\sqrt{s_{NN}}$ covered by this analysis, it is necessary to implement algorithms that are dependent on the collision energy for the determination of the centrality of each event. In Au+Au collisions at $\sqrt{s_{NN}} =$ 200 GeV, the centrality of the collision is determined by using correlations of the total energy deposited in the ZDCs with the total charge deposited in the BBCs as described in Ref. [33]. However, in 200 GeV Cu+Cu, 62.4 GeV Cu+Cu, and 62.4 GeV Au+Au collisions, the resolving power of the ZDCs is insufficient to significantly contribute to the centrality definition. Therefore, only the total charge deposited in the BBCs is used to determine centrality in these collision systems, as described in Ref. [33]. Using the 200 GeV Au+Au data, it has been verified that application of the BBC-ZDC correlation for the centrality definition as opposed to the BBC-only definition shows no significant differences in the values of the charged hadron fluctuation quantities presented here as a function of centrality.

The location of the BBCs are fixed for every collision energy. At the lowest collision energy ($\sqrt{s_{NN}} = 22.5$ GeV), it becomes kinematically possible for spectator nucleons to fall within the acceptance of the BBC. This results in a BBC response in its total charge sum that is no longer linear with the number of participating nucleons ($N_{\rm part}$). In this case, it becomes necessary to define the centrality using the total charged particle multiplicity in pad chamber 1 (PC1) [28]. PC1 is chosen because of its fine segmentation, high tracking efficiency, and relative proximity to the event vertex. Details on this procedure are also described in Ref. [33]. For all collision species and energies, the distribution of the number of participants was determined using a Monte Carlo simulation based upon the Glauber model [33,34].

The number of minimum-bias events analyzed for each dataset are 25.6×10^6 events for 200 GeV Au+Au, 24.9×10^6 events for 62.4 GeV Au+Au, 15.0×10^6 events for 200 GeV Cu+Cu, 12.2×10^6 events for 62.4 GeV Cu+Cu, 5.5×10^6 events for 22.5 GeV Cu+Cu, and 2.7×10^6 events for 200 GeV $p+p$. Only a fraction of the complete 200 GeV Au+Au, Cu+Cu, and $p+p$ datasets are analyzed, but this fraction is more than sufficient for this analysis.

The charged particle multiplicity is determined on an event-by-event basis by counting the number of unambiguous reconstructed tracks in the drift chamber originating from the collision vertex that have corresponding hits in PC1 and PC3. Track selection includes cuts on reconstructed tracks in the drift chamber to reduce double-counted ghost tracks to a negligible level. To minimize background originating from the magnets, reconstructed tracks are required to lie within ± 75 cm from the center of the drift chamber along the beam axis. This requirement reduces the pseudorapidity range of reconstructed tracks to $|\eta| < 0.26$. The ring imaging Cherenkov detector (RICH) is utilized to reduce background from electrons resulting from photon conversions.

Although the central arm spectrometer covers a total azimuthal range of π radians, detector and tracking inefficiencies reduce the effective average azimuthal active area to 2.1 radians for the 200 Gev Au+Au and 200 GeV $p+p$ datasets, and 2.0 radians for the other datasets. Fluctuation quantities are quoted for these acceptances separately for each dataset. The differences in acceptance between datasets, which are due to variations in the detector over the three-year period in which the data were collected, result in less than a 1% variation in the fluctuation quantities quoted here.

III. DATA ANALYSIS

Multiplicity fluctuations of charged particles, designated $\omega_{\rm ch}$, can be generally defined [35] as

$$\omega_{\rm ch} = \frac{\langle N_{\rm ch}^2 \rangle - \langle N_{\rm ch} \rangle^2}{\langle N_{\rm ch} \rangle} = \frac{\sigma_{\rm ch}^2}{\mu_{\rm ch}}, \tag{5}$$

where $N_{\rm ch}$ is the charged particle multiplicity. Simply stated, the fluctuations can be quoted as the variance of the multiplicity ($\sigma_{\rm ch}^2$) normalized by the mean ($\mu_{\rm ch} = \langle N_{\rm ch} \rangle$). This is also referred to as the scaled variance [25]. If the multiplicity distribution is Poissonian, the scaled variance is 1.0.

It has been well established that charged particle multiplicity distributions in elementary nucleon-nucleon collisions can be described by the negative binomial distribution (NBD) [17–19]. The NBD also describes well the multiplicity distributions in heavy ion collisions [21,23]. The NBD of an integer n is defined as

$$P(n) = \frac{\Gamma(n + k_{\rm NBD})}{\Gamma(n+1)\Gamma(k_{\rm NBD})} \frac{(\mu_{\rm ch}/k_{\rm NBD})^n}{(1 + \mu_{\rm ch}/k_{\rm NBD})^{n+k_{\rm NBD}}}, \tag{6}$$

where $P(n)$ is normalized to 1.0 over the range $0 \leqslant n \leqslant \infty$, $\mu_{\rm ch} = \langle N_{\rm ch} \rangle = \langle n \rangle$, and $k_{\rm NBD}$ is an additional parameter. The NBD reduces to a Poisson distribution in the limit $k_{\rm NBD} \to \infty$. The NBD variance and mean is related to $k_{\rm NBD}$ as follows:

$$\frac{\sigma_{\rm ch}^2}{\mu_{\rm ch}^2} = \frac{\omega_{\rm ch}}{\mu_{\rm ch}} = \frac{1}{\mu_{\rm ch}} + \frac{1}{k_{\rm NBD}}. \tag{7}$$

Hence, the scaled variance is given by

$$\omega_{\rm ch} = 1 + \frac{\mu_{\rm ch}}{k_{\rm NBD}}. \tag{8}$$

A useful property of the negative binomial distribution concerns its behavior when a population that follows the NBD is subdivided randomly by repeated independent trials with a constant probability onto smaller subsets. This results in a binomial decomposition of the original population into subsets that also follow the NBD with the same value of $k_{\rm NBD}$ [21]. This property can be applied to estimate the behavior of multiplicity fluctuations as a function of acceptance, assuming that there are no significant correlations present over the acceptance range being examined. Starting with an original NBD sample with mean $\mu_{\rm ch}$ and scaled variance $\omega_{\rm ch}$, a sample in a fractional acceptance with mean $\mu_{\rm acc}$ is also described by an NBD distribution. An acceptance fraction can be defined as $f_{\rm acc} = \mu_{\rm acc}/\mu_{\rm ch}$. The scaled variance of the subsample from Eq. (8) is thus

$$\omega_{\rm acc} = 1 + (\mu_{\rm acc}/k_{\rm NBD}) = 1 + (f_{\rm acc}\mu_{\rm ch}/k_{\rm NBD}). \tag{9}$$

Since $k_{\rm NBD}$ is identical for the two samples, $\mu_{\rm ch}/k_{\rm NBD} = \omega_{\rm ch} - 1$ can be substituted, yielding the following relation between

TABLE I. Tabulation of the charged hadron multiplicity data and corrections for $0.2 < p_T < 2.0$ GeV/c. The errors quoted for $\mu_{\rm ch}$ and $\sigma_{\rm ch}$ represent their time-dependent systematic error. The errors quoted for $\omega_{\rm ch,dyn}$ and $1/k_{\rm NBD,dyn}$ represent their total systematic error. For each dataset, the first three columns give the species, collision energy, and geometric correction factor $f_{\rm geo}$, respectively.

the scaled variances of the original and fractional acceptance samples:

$$\omega_{\rm acc} = 1 + f_{\rm acc}(\omega_{\rm ch} - 1). \quad (10)$$

Thus, the measured scaled variance will decrease as the acceptance is decreased, while $k_{\rm NBD}$ remains constant, if there are no additional correlations present over the given acceptance range.

Figures 1 and 2 show the uncorrected, or raw, multiplicity distributions in the p_T range $0.2 < p_T < 2.0$ GeV for all centralities from each collision system overlaid with fits to negative binomial distributions (dashed lines). For presentation purposes, the data have been normalized on the horizontal axis by the mean of the distribution and scaled on the vertical axis by the successive amounts stated in the legend. The NBD fits describe the data distributions very well for all collision systems, centralities, and p_T ranges. Hence, the mean and variance of the multiplicity distributions presented here are all extracted from NBD fits. The results of each fit for $0.2 < p_T < 2.0$ GeV are compiled in Table I. The mean and standard deviation of each fit for $0.2 < p_T < 2.0$ GeV are plotted in Fig. 3.

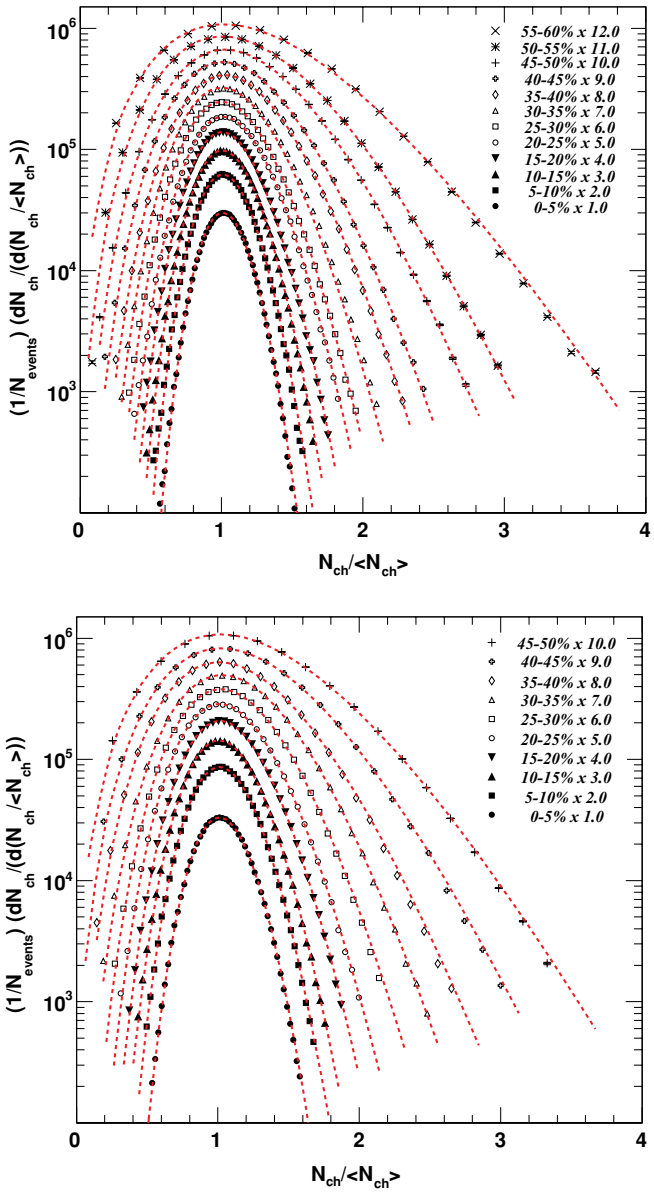

FIG. 1. (Color online) Uncorrected multiplicity distributions of charged hadrons with $0.2 < p_T < 2.0$ GeV/c for 200 (upper) and 62.4 (lower) GeV Au+Au collisions. The dashed lines are fits to the NBD. The data are normalized to the mean and scaled by the amounts in the legend.

Each dataset was taken over spans of several days to several weeks, all spanning three separate RHIC running periods. During these periods, changes in the total acceptance and efficiency of the central arm spectrometers cause the fluctuation measurements to vary, thus introducing an additional systematic error to the results. This systematic error was minimized by requiring that the dataset is stable in quantities that are sensitive to detector variations, including the mean charged particle multiplicity, mean collision vertex position, and mean centrality. A time-dependent systematic error is applied independently to each point by calculating the standard deviation of the scaled variance calculated from subsets of the entire dataset, with each subset containing about 1×10^6

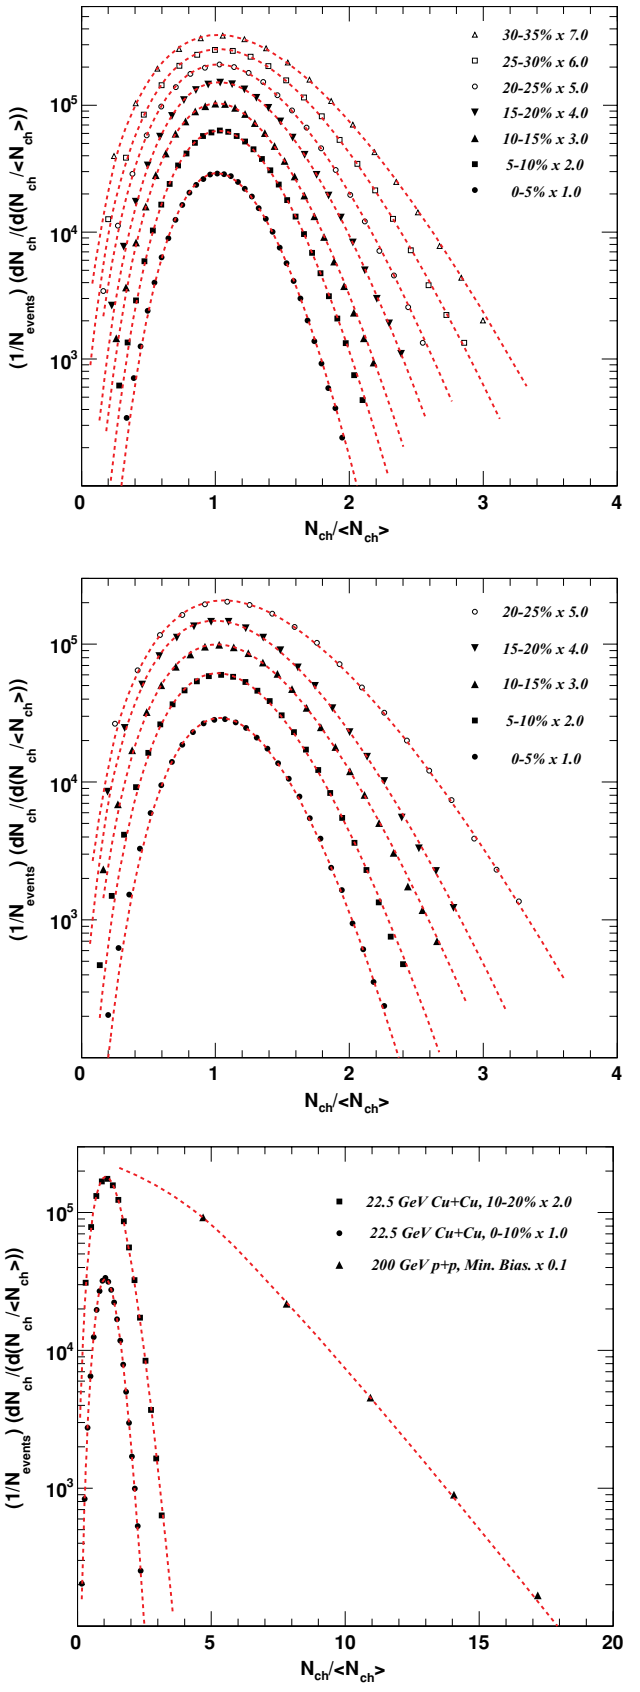

FIG. 2. (Color online) Same as Fig. 1, but for 200 (upper), 62.4 (middle), and 22.5 (lower) GeV Cu+Cu and 200 GeV $p+p$ (lower) collisions.

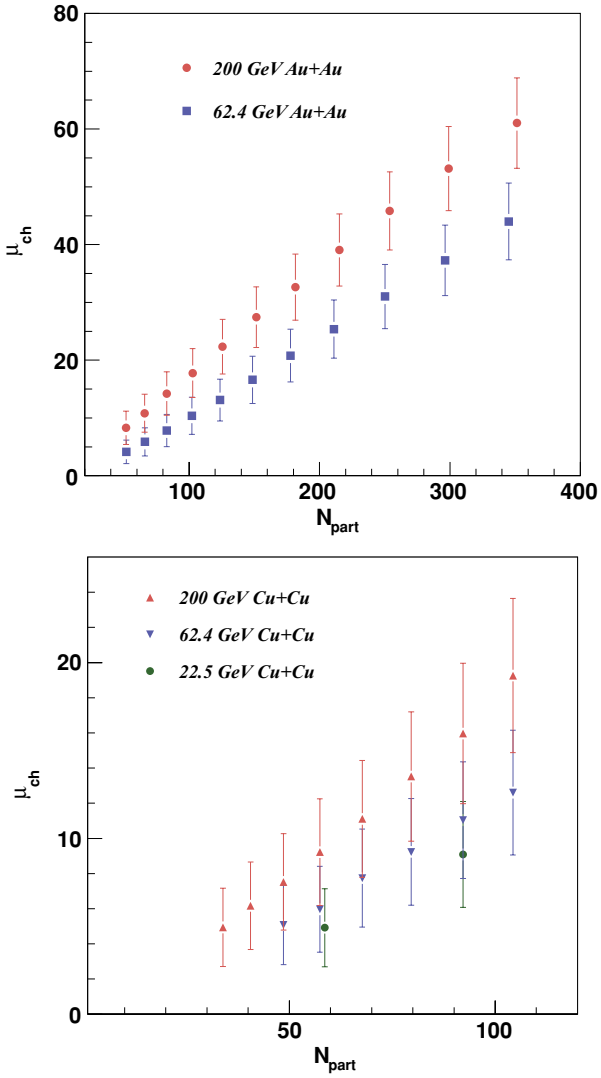

FIG. 3. (Color online) Mean from the NBD fit as a function of N_{part} for Au+Au (upper) and Cu+Cu (lower) collisions over the range $0.2 < p_T < 2.0\,\text{GeV}/c$. The mean shown is within the PHENIX central arm spectrometer acceptance. The error bars represent the standard deviation of the distribution.

events. These systematic errors are applied to all subsequent results.

The tracking efficiency of the PHENIX central arm spectrometer is dependent on centrality, especially in the most central 200 GeV Au+Au collisions [36]. With the assumption that tracking inefficiencies randomly affect the multiplicity distribution on an event-by-event basis, the effect of inefficiencies on the scaled variance can be estimated using Eq. (10), where f_{acc} is replaced by the inverse of the tracking efficiency $1/f_{\text{eff}}$. Tracking efficiency affects the value of the scaled variance by 1.5% at the most. The scaled variance has been corrected for tracking inefficiency as a function of centrality for all species. The uncertainty of the tracking efficiency estimate is typically 2% and has been propagated into the systematic error estimate on a point-by-point basis.

Because of the nonzero width of the centrality bin selection from the data, each centrality bin necessarily selects a range of impact parameters. This introduces a nondynamical fluctuation component to the measured multiplicity fluctuations due to the resulting fluctuations in the geometry of the collisions [26,37]. Therefore, it is necessary to estimate the magnitude of the geometry fluctuation component so that only the interesting dynamical fluctuations remain. The most practical method for estimating the geometry fluctuation component is with a model of heavy ion collisions. The URQMD [38] and HSD [39,40] models have previously been applied for this purpose. Here, the HIJING event generator [41] is chosen for this estimate, because it reproduces well the mean multiplicity in heavy ion collisions [33] as measured by the PHENIX detector. HIJING includes multiple minijet production based upon QCD-inspired models, soft excitation, nuclear shadowing of parton distribution functions, and the interaction of jets in dense nuclear matter. The estimate is performed individually for each centrality bin, collision system, and p_T range using the following procedure. First, HIJING is run with an impact parameter distribution that is sampled from a Gaussian distribution with a mean and standard deviation that, for a given centrality bin, reproduces the distributions of the charge deposited in the BBC and the energy deposited in the ZDC (for 200 GeV Au+Au). Second, HIJING is run at a fixed impact parameter with a value identical to the mean of the Gaussian distribution in the first run. For each centrality bin, 12,000 HIJING events are processed for each impact parameter selection. The scaled variance for each impact parameter selection, ω_{Gauss} and ω_{fixed}, is extracted and the measured scaled variance is corrected as the fractional deviation from a scaled variance of 1.0 of a Poisson distribution as follows:

$$\omega_{\text{ch,dyn}} - 1 = \frac{\omega_{\text{fixed}} - 1}{\omega_{\text{Gauss}} - 1}(\omega_{\text{ch,raw}} - 1) = f_{\text{geo}}(\omega_{\text{ch,raw}} - 1), \tag{11}$$

where $\omega_{\text{ch,dyn}}$ represents the estimate of the remaining dynamical multiplicity fluctuations and $\omega_{\text{ch,raw}}$ represents the uncorrected multiplicity fluctuations. Since the correction f_{geo} is calculated as a ratio of the two running conditions of the simulation, most multiplicity fluctuations intrinsic to the model should be canceled. The correction always reduces the magnitude of the measured scaled variance. Note that the value of f_{geo} is mathematically identical when applied to the inverse of k_{NBD}:

$$k^{-1}_{\text{NBD,dyn}} = f_{\text{geo}} k^{-1}_{\text{NBD}}. \tag{12}$$

The resulting geometrical correction factors for each species are constant as a function of centrality, therefore a single correction factor is calculated for each transverse momentum range by fitting the correction factors as a function of N_{part} to a constant. This behavior is expected, since centrality bins are defined to be constant percentages of the total geometric cross section. The correction factors for each transverse momentum range for a given collision species are consistent with each other, that is, they are independent of transverse momentum. The standard deviation of the individual geometrical correction factors from the linear fits as a function of N_{part} are included in the systematic error of the correction factor estimation and propagated

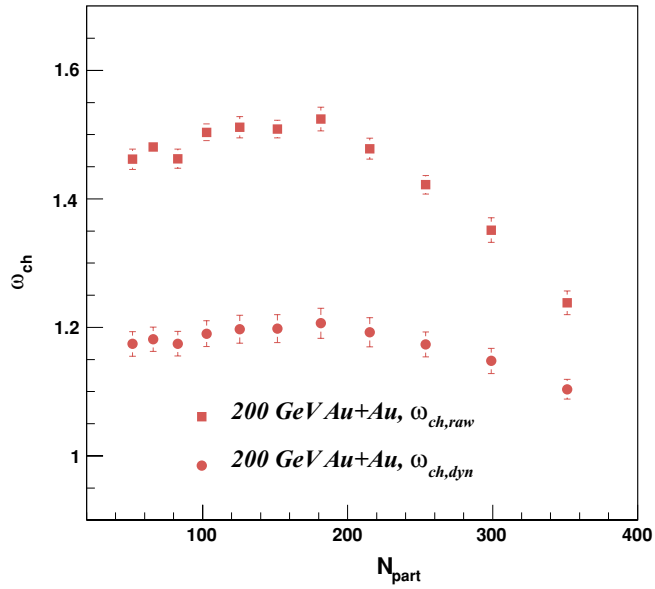

FIG. 4. (Color online) Fluctuations expressed as the scaled variance as a function of centrality for 200 GeV Au+Au collisions in the range $0.2 < p_T < 2.0$ GeV/c. Shown are the uncorrected fluctuations, $\omega_{\mathrm{ch,raw}}$, along with fluctuations after correcting for the estimated contribution from geometry fluctuations using Eq. (11), $\omega_{\mathrm{ch,dyn}}$.

into the total systematic error for each point in $\omega_{\mathrm{ch,dyn}}$ and $k_{\mathrm{NBD,dyn}}$. For $0.2 < p_T < 2.0$ GeV/c, the geometrical correction factors f_{geo} and systematic errors from the fit are 0.37 ± 0.027 for 200 GeV Au+Au, 0.33 ± 0.031 for 62.4 GeV Au+Au, 0.40 ± 0.047 for 200 GeV Cu+Cu, 0.32 ± 0.063 for 62.4 GeV Cu+Cu, and 0.30 ± 0.064 for 22.5 GeV Cu+Cu. The extraction of the geometrical correction factors are inherently model dependent and are also dependent on the accuracy with which the centrality detectors are modeled. The effect of the latter dependence has been studied by also calculating the correction factors using constant but nonoverlapping impact parameter distributions for each centrality bin and comparing them with the correction factors using the Gaussian impact parameter distributions. For all p_T ranges, an additional fraction of the value of $\omega_{\mathrm{ch,dyn}}$ or $k^{-1}_{\mathrm{NBD,dyn}}$ has been included in the final systematic errors for these quantities. The magnitude of this systematic error is 8% for 200 GeV Au+Au, 8% for 62.4 GeV Au+Au, 11% for 200 GeV Cu+Cu, 17% for 62.4 GeV Cu+Cu, and 25% for 22.5 GeV Cu+Cu. A sample comparison of the scaled variance before and after the application of the geometrical correction factor is shown for the 200 GeV Au+Au dataset in Fig. 4.

IV. RESULTS

The scaled variance as a function of the number of participating nucleons N_{part} over the p_T range $0.2 < p_T < 2.0$ GeV/c is shown in Fig. 5. For all centralities, the scaled variance values consistently lie above the Poisson distribution value of 1.0. In all collision systems, the minimum scaled variance occurs in the most central collisions and then begins to increase as the centrality decreases. In 200 GeV Au+Au

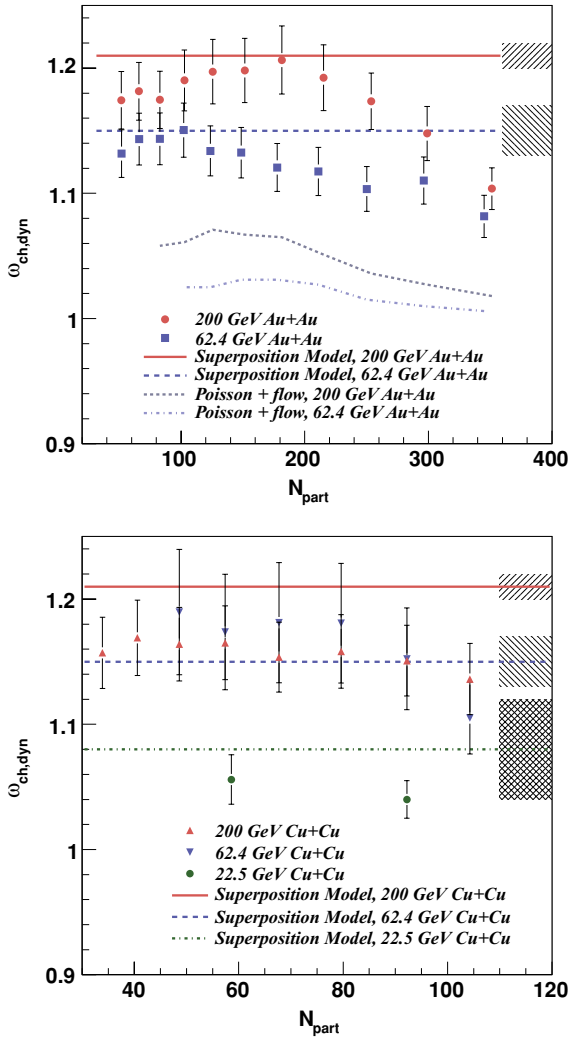

FIG. 5. (Color online) Fluctuations expressed as the scaled variance as a function of N_{part} for Au+Au (upper) and Cu+Cu (lower) collisions for $0.2 < p_T < 2.0$ GeV/c. The estimated contribution from geometry fluctuations has been removed. Results from the superposition model are overlaid with the shaded regions representing a one standard deviation range of the prediction for the fluctuation magnitude derived from $p+p$ collision data. Also shown (upper) is the estimated contribution from noncorrelated particle emission with the Poisson distribution of the scaled variance of 1.0 with the addition of elliptic flow in 200 and 62 GeV Au+Au collisions.

collisions, this increase is only observed for $N_{\mathrm{part}} > 200$. For $N_{\mathrm{part}} < 200$, the magnitude of $\omega_{\mathrm{ch,dyn}}$ suggests a slight decrease but is consistent with a constant value. In 62.4 GeV Au+Au collisions, the increase in $\omega_{\mathrm{ch,dyn}}$ with decreasing centrality is observed only over the range $N_{\mathrm{part}} > 110$. The source of the qualitative differences between the 200 and 62.4 GeV Au+Au collisions are not known, although some of the differences could be explained by the increased contribution from hard scattering processes at 200 GeV compared to 62.4 GeV. Studies performed by varying the centrality selection cuts establish that the differences are not due to the differences in the centrality selection algorithm. A similar centrality-dependent trend of the scaled variance has also been observed at the

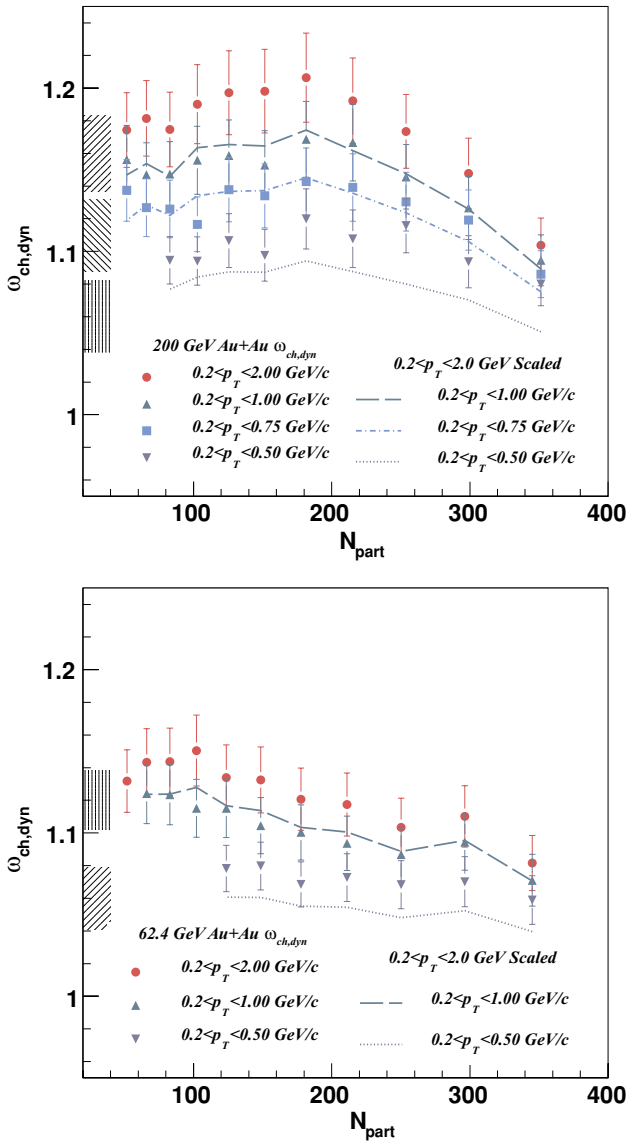

FIG. 6. (Color online) Scaled variance for 200 and 62.4 GeV Au+Au collisions plotted as a function of N_{part} for several p_T ranges. The lines represent the data for the reference range $0.2 < p_T < 2.0$ scaled down using the mean multiplicity in each successive p_T range. The shaded areas represent the systematic errors from the reference range.

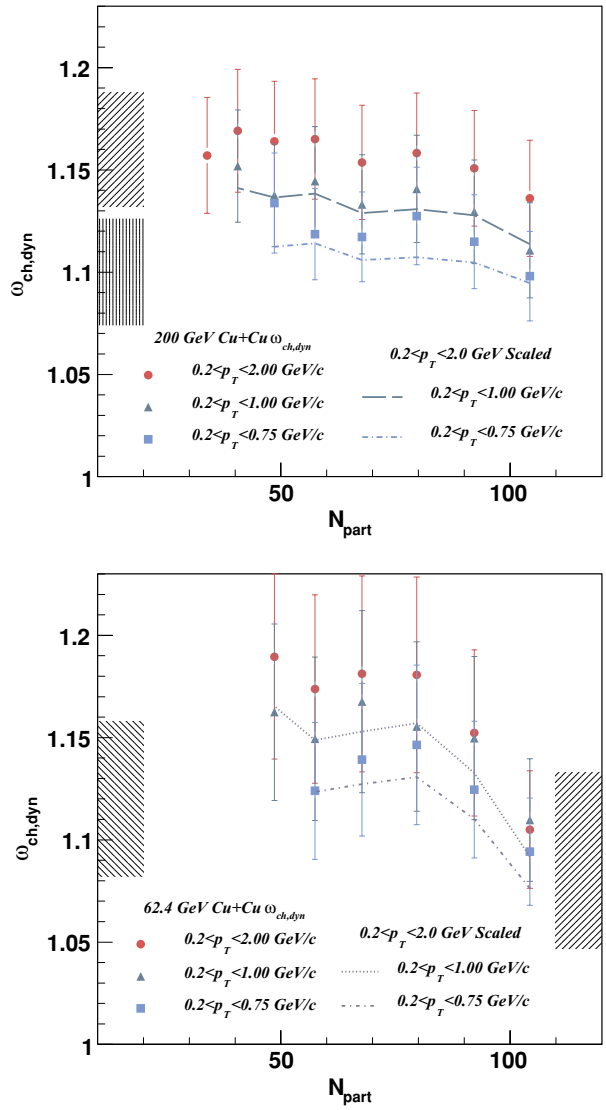

FIG. 7. (Color online) Same as Fig. 6, but for Cu+Cu collisions.

CERN Super Proton Synchrotron (SPS) in low-energy Pb+Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV and at forward rapidities ($1.1 < y_{\text{c.m.}} < 2.6$), measured by experiment NA49 [25], where the hard scattering contribution is expected to be small. The 200 GeV Cu+Cu data exhibit a weaker decrease in the scaled variance for more central collisions. The 62.4 GeV Cu+Cu scaled variance values are consistently above those from the 200 GeV Cu+Cu dataset, but the two are consistent within the systematic errors for all centralities.

The scaled variance has been studied as a function of the p_T range over which the multiplicity distributions are measured in order to determine if any significant p_T-dependent dynamical fluctuations are present. Results for several p_T ranges from $0.2 < p_T < 2.0$ down to $0.2 < p_T < 0.5$ GeV/c are shown in Figs. 6 and 7. In the absence of p_T-dependent dynamical fluctuations, restricting the p_T range should reduce the scaled variance in the same manner as for a fractional acceptance. Similar to Eq. (10),

$$\omega_{p_T} = 1 + f_{p_T}(\omega_{\text{ref}} - 1), \tag{13}$$

where ω_{p_T} represents the fluctuations in the p_T range of interest, ω_{ref} represents the fluctuations in the reference p_T range, and $f_{p_T} = \mu_{p_T}/\mu_{\text{ref}}$ is the ratio of the mean multiplicity in the two ranges. Also shown are curves representing the expected scaling of the fluctuations using the range $0.2 < p_T < 2.0$ GeV/c as the reference range. The shaded regions reflect the systematic errors of the reference range. For all p_T ranges, the scaled fluctuation curves are consistent with the data, indicating that no significant p_T dependence is observed, although the data in the range $0.2 < p_T < 0.5$ GeV are consistently above the scaled reference curves. The p_T dependence can also be examined more directly with the parameter k_{NBD} from the NBD fits. Substitution of the scaled variance in Eq. (8) into Eq. (13) shows that k_{NBD} should be

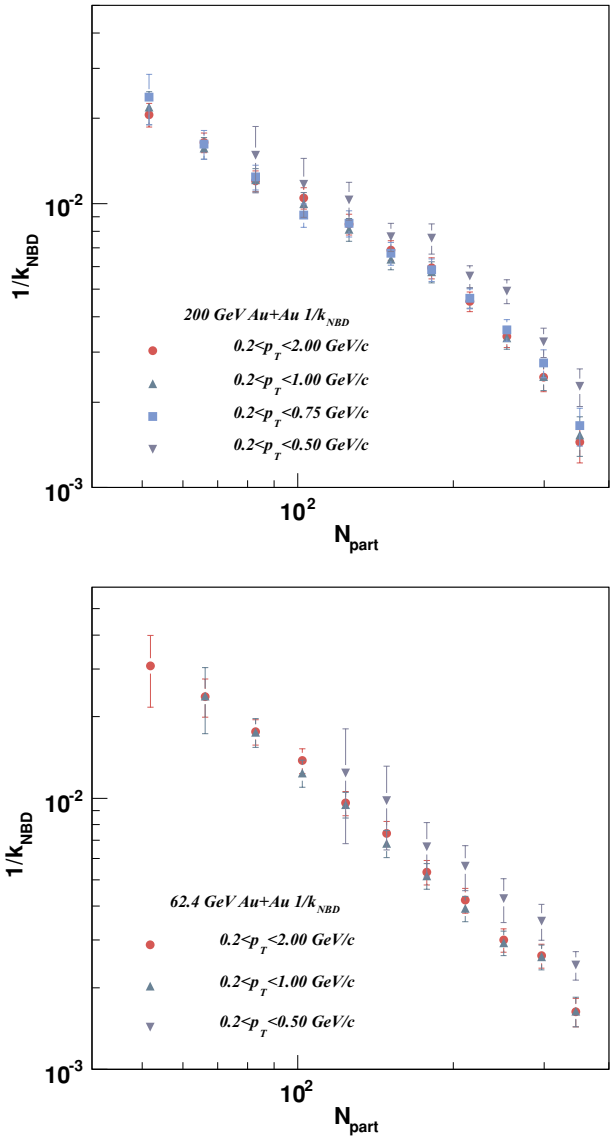

FIG. 8. (Color online) Inverse of the parameter k_{NBD} from the NBD fits for 200 and 62.4 GeV Au+Au collisions. The fluctuations are plotted as a function of N_{part} for several p_T ranges.

independent of p_T in the absence of p_T-dependent dynamical fluctuations. As shown in Figs. 8 and 9, there is no significant p_T-dependence of the observed values of k_{NBD}.

The scaled variance as a function of the charge sign of the charged hadrons is shown in Fig. 10 for 200 GeV Au+Au collisions in the p_T range $0.2 < p_T < 2.0$ GeV/c in order to investigate any Coulomb-based contributions to the fluctuations. In the absence of additional dynamic fluctuations, the scaled variance for positively or negatively charged hadrons should be reduced from the inclusive charged hadron value by

$$\omega_{+-} = 1 + f_{+-}(\omega_{\mathrm{ch}} - 1), \tag{14}$$

where ω_{+-} are the fluctuations for positive or negative particles, ω_{ch} are the fluctuations for inclusive charged hadrons, and $f_{+-} = \mu_{+-}/\mu_{\mathrm{ch}}$ is the ratio of the mean multiplicities. The scaled variance from the positive and negative hadrons

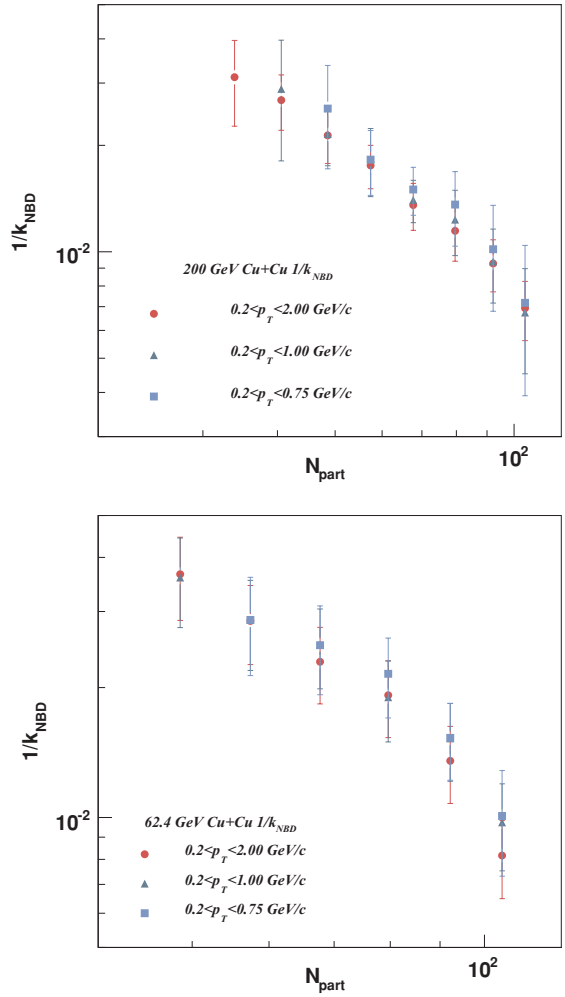

FIG. 9. (Color online) Same as Fig. 8, but for Cu+Cu collisions.

are consistent with each other and with the expected reduction of the inclusive charged hadron fluctuations.

V. DISCUSSION

A. Comparisons with a participant superposition model

It is informative to compare fluctuations in relativistic heavy ion collisions to what can be expected from the superposition of individual participant nucleon-nucleon collisions. For this purpose, PHENIX data will be compared with a participant superposition, or wounded nucleon, model [42] based upon data from elementary collisions. In the participant superposition model, the total multiplicity fluctuations can be expressed in terms of the scaled variance [35],

$$\omega_{\mathrm{N}} = \omega_{\nu} + \mu_{\mathrm{WN}}\omega_{N_{\mathrm{part}}}, \tag{15}$$

where ω_{ν} are the fluctuations from each individual source, e.g., from each elementary collision, $\omega_{N_{\mathrm{part}}}$ are the fluctuations of the number of sources, and μ_{WN} is the mean multiplicity per wounded nucleon. The second term includes nondynamic contributions from geometry fluctuations due to the width of the centrality bin along with additional fluctuations in the number of participants for a fixed impact parameter. Ideally, the second term is nearly nullified after applying the geometry

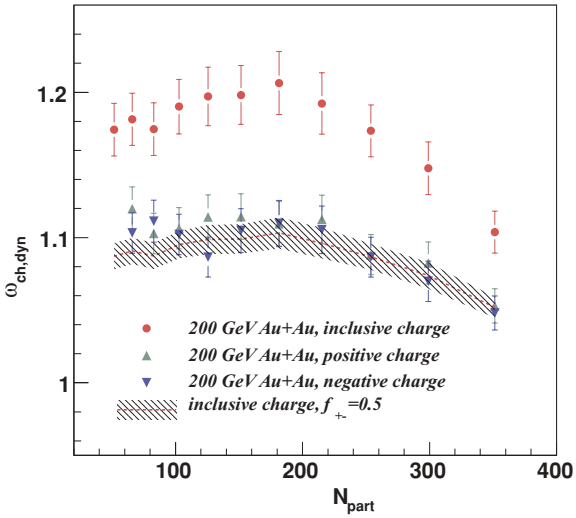

FIG. 10. (Color online) Scaled variance as a function of N_{part} for 200 GeV Au+Au collisions in the range $0.2 < p_T < 2.0$ GeV/c. Shown are measurements for inclusive charged particles, positive particles, and negative particles. The line represents the inclusive data scaled down in acceptance by 50% with the shaded area representing the systematic error.

corrections described previously, so the resulting fluctuations are independent of centrality as well as collision species.

Baseline comparisons are facilitated by PHENIX measurements of charged particle multiplicity fluctuations in minimum-bias 200 GeV $p+p$ collisions. The $p+p$ data and the NBD distribution to the multiplicity distribution are shown in Fig. 2. The NBD fit yields $\mu_{\text{ch}} = 0.32 \pm 0.003$, $\omega_{\text{ch}} = 1.17 \pm 0.01$, and $k_{\text{NBD}} = 1.88 \pm 0.01$. These results are in agreement within errors with previous measurements in the same pseudorapidity range of $k_{\text{NBD}} = 1.9 \pm 0.2 \pm 0.2$ by the UA5 Collaboration [20] in collisions of protons and antiprotons at 200 GeV. Comparisons between the participant superposition model predictions and the 22.5 GeV Cu+Cu data can be made using multiplicity fluctuations measured in 20 GeV $p+p$ collisions by the NA22 Collaboration [19] over the same pseudorapidity range as the PHENIX Cu+Cu measurement. After scaling the NA22 scaled variance to the PHENIX azimuthal acceptance, the participant superposition model scaled variance is expected to be constant as a function of centrality with a value of 1.08 ± 0.04. Lacking multiplicity distribution data from elementary collisions at 62.4 GeV within the PHENIX pseudorapidity acceptance, it is assumed that as a function of collision energy, the scaled variance in the PHENIX pseudorapidity acceptance scales in the same manner as in an acceptance of 4π, which can be parametrized from existing $p+p$ and $p+\bar{p}$ data as follows [17]:

$$\mu_{\text{ch}} \approx -4.2 + 4.69 \left(\frac{s}{\text{GeV}^2} \right)^{0.155}. \tag{16}$$

Given the mean charged particle multiplicity, the scaled variance in $p+p$ and $p+\bar{p}$ can be parametrized as follows [35]:

$$\omega_{\text{ch}} \approx 0.35 \frac{(\mu_{\text{ch}} - 1)^2}{\mu_{\text{ch}}}. \tag{17}$$

Scaling this parametrization to match the values of ω_{ch} at 200 and 22.5 GeV, the estimated value of ω_{ch} at 62.4 GeV is 1.15 ± 0.02.

Comparisons of the data with the predictions of the participant superposition model are shown in Fig. 5 for Au+Au and Cu+Cu collisions. The shaded regions about the participant superposition model lines represent the systematic error of the estimates described above. All of the data points are consistent with or below the participant superposition model estimate. This suggests that the data do not show any indications of the presence of a critical point, where the fluctuations are expected to be much larger than the participant superposition model expectation.

B. Comparisons to the HIJING model

Shown in Fig. 11 are the scaled variance curves from HIJING simulations into the PHENIX acceptance. The HIJING simulations are performed with a fixed impact parameter corresponding to the mean of the impact parameter distribution for each bin as determined by the Glauber model in order to minimize the geometry fluctuation component of the result. The mean and variance of the resulting multiplicity distributions from HIJING are extracted from fits to negative binomial distributions. The HIJING simulation multiplicity fluctuations with the jet production parameter turned on are consistently above the data and increase continuously through the most peripheral collisions. This behavior is not consistent with the data, where the fluctuations do not increase in the most peripheral collisions. Although HIJING reproduces the total charged particle multiplicity well, it consistently overpredicts the amount of fluctuations in multiplicity. When the jet production parameter in HIJING is turned off, the scaled variance as a function of centrality is independent of collision energy, illustrating that jet production accounts for the energy dependence of the HIJING results. Note that the HIJING results with jet production turned off are in better agreement with the data for all collision energies. Together with the observation that the multiplicity fluctuations demonstrate no significant p_T dependence, this may be an indication that correlated emission of particles from jet production do not significantly contribute to the multiplicity fluctuations observed in the data.

C. Comparisons to the clan model

The clan model [43] has been developed to interpret the fact that negative binomial distributions describe charged hadron multiplicity distributions in elementary and heavy ion collisions. In this model, hadron production is modeled as the independent emission of a number of hadronic clusters N_c, each with a mean number of hadrons n_c. The independent emission is described by a Poisson distribution with an average cluster, or clan, multiplicity of $\bar{N}_c$. After the clusters are emitted, they fragment into the final state hadrons. The measured value of the mean multiplicity μ_{ch} is related to the cluster multiplicities by $\mu_{\text{ch}} = \bar{N}_c \bar{n}_c$. In this model, the cluster multiplicity parameters can be simply related to the NBD parameters

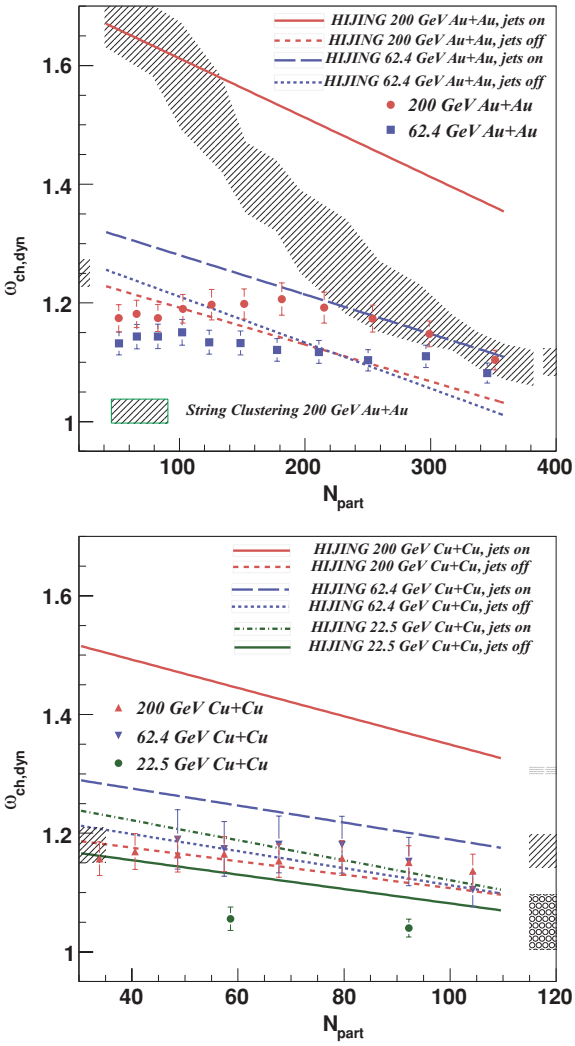

FIG. 11. (Color online) Fluctuations expressed as the scaled variance as a function of N_{part} for Au+Au and Cu+Cu collisions for $0.2 < p_T < 2.0$ GeV/c. The estimated contribution from geometry fluctuations has been removed. Results from the HIJING model code with jets turned on and jets turned off are overlaid with the shaded regions representing the systematic error for each curve.

of the measured multiplicity distribution as follows:

$$\bar{N}_c = k_{\text{NBD}} \ln(1 + \mu_{\text{ch}}/k_{\text{NBD}}), \tag{18}$$

and

$$\bar{n}_c = (\mu_{\text{ch}}/k_{\text{NBD}})/\ln(1 + \mu_{\text{ch}}/k_{\text{NBD}}). \tag{19}$$

The results from the NBD fits to the data are plotted in Fig. 12 for all collision species. Also shown are data from elementary and heavy ion collisions at various collision energies. The individual data points from all but the PHENIX data are taken from multiplicity distributions measured over varying ranges of pseudorapidity, while the PHENIX data are taken as a function of centrality. The characteristics of all of the heavy ion datasets are the same. The value of $\bar{n}_c$ varies little within the range 1.0–1.1. The heavy ion data universally exhibit only weak clustering characteristics as interpreted by the clan model. There is also no significant variation seen with collision energy. However, $\bar{n}_c$ is consistently significantly higher in elementary collisions. In elementary collisions, it is less probable to produce events with a high multiplicity, which can reveal rare sources of clusters such as jet production or multiple parton interactions.

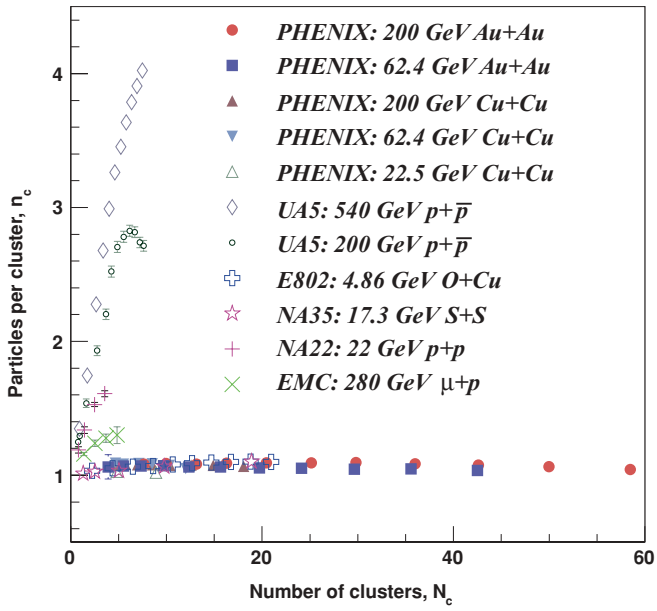

FIG. 12. (Color online) Correlation of the clan model parameters $\bar{n}_c$ and $\bar{N}_c$ for all collision species measured as a function of centrality. Also shown are results from pseudorapidity-dependent studies from elementary collisions (UA5 [17], EMC [18], and NA22 [19]) and heavy ion collisions (E802 [21] and NA35 [23]).

A feature that is especially apparent in the Au+Au data is the fact that the scaled variance decreases with increasing centrality, with the most central point lying below the participant superposition model expectation. The clan model provides one possible explanation for this effect whereby there is a higher probability for contributions from cluster sources such as jet production in the lower multiplicity peripheral events. The cluster sources introduce correlations that can increase the value of $1/k_{\text{NBD}}$ and hence the value of the scaled variance of the multiplicity distribution. Another possible explanation for this feature can be addressed with a string percolation model in heavy ion collisions [44]. In general, percolation theory considers the formation of clusters within a random spatial distribution of individual objects that are allowed to overlap with each other. The clusters are formed by the geometrical connection of one or more of the individual objects. This can be applied to estimate multiplicity fluctuations in heavy ion collisions whereby the objects are the circular cross sections of strings in the transverse plane [45] and the strings form clusters of overlapping strings that then each emit a number of particles related to the number of strings in each cluster. As the centrality increases, the number of individual clusters decreases along with the variance of the number of strings per cluster, which can result in a decrease in the magnitude of the resulting multiplicity fluctuations. The prediction of the scaled variance from the string percolation model for 200 GeV Au+Au collisions scaled down to the PHENIX acceptance in azimuth and pseudorapidity [45] is shown in

Fig. 11. Although percolation describes the trend observed at the four highest centralities very well, the scaled variance from the model continues to increase well above the data as centrality decreases. The implementation of the HIJING model contains merging of strings that are in close spatial proximity, so percolation can explain the trends in the scaled variance from HIJING.

An additional contribution to multiplicity fluctuations within the PHENIX acceptance arises from the presence of elliptic flow. This contribution has been estimated using a simple Monte Carlo simulation. In this simulation, a random reaction plane angle is assigned to each event. The multiplicity distribution due to the elliptic flow component is given by

$$dN/d\phi = C[1 + 2v_2 \cos(2\Delta\phi)], \tag{20}$$

where C is a normalization factor, v_2 is the measured magnitude of the elliptic flow, and $\Delta\phi$ is the difference between the particle emission angle and the reaction plane angle. For each event, this multiplicity distribution function is integrated over the PHENIX azimuthal acceptance and the resulting scaled variance from 1×10^6 events is calculated. The value of v_2 used in the simulation is taken from PHENIX measurements of elliptic flow at the mean transverse momentum of the inclusive charged hadron spectra [46,47]. The estimated contribution from elliptic flow to the observed scaled variance is shown in Fig. 5 for 200 and 62 GeV Au+Au collisions. This flow contribution also exhibits an increasing trend when moving from central to midcentral collisions. The estimated flow contribution increases from 18% of the signal in the most central 200 GeV Au+Au collisions to 35% of the signal at $N_{\text{part}} = 125$. In 62 GeV Au+Au collisions, the estimated flow contribution rises from 8% in the most central collisions to 25% at $N_{\text{part}} = 181$. The presence of elliptic flow can account for the majority of the centrality-dependent shapes observed in the Au+Au data.

VI. SUMMARY

PHENIX has completed a survey of multiplicity fluctuations of charged hadrons in Au+Au and Cu+Cu collisions at three collision energies. The motivation for the analysis is to search for signs of a phase transition or the presence of the predicted critical point on the QCD phase diagram by looking for increased multiplicity fluctuations as a function of system energy and system volume. After correcting for nondynamical fluctuations due to fluctuations of the collision geometry within a centrality bin, the multiplicity fluctuations in 200 and 62.4 GeV Au+Au collisions are consistent with or below the expectation from the superposition model of participant nucleons. The multiplicity fluctuations decrease as the collision centrality increases, dropping below the participant superposition model expectation for the most central Au+Au collisions. Fluctuations from Cu+Cu collisions exhibit a weaker centrality dependence that also is consistent with or below the expectation from the participant superposition model. The absence of large dynamical fluctuations in excess of the participant superposition model expectation indicate that there is no evidence of critical behavior related to the compressibility observable in this dataset. There is also no significant evidence of dynamical fluctuations that are dependent on the transverse momentum or the charge of the particles measured. As interpreted by the clan model, the observed fluctuations demonstrate only weak clustering characteristics for all of the heavy ion collision systems discussed here. The majority of the decreasing scaled variance with increasing centrality trend in Au+Au collisions can be explained by contributions from elliptic flow. Although this analysis does not observe evidence of critical behavior, it does not rule out the existence of a QCD critical point. Further measurements will be possible during the upcoming low-energy scan program at RHIC, allowing a more comprehensive search for critical behavior.

(Dated: April 25, 2008)

The production of e^+e^- pairs for $m_{e^+e^-} < 300$ MeV/c^2 and $1 < p_{\rm T} < 5$ GeV/c is measured in $p+p$ and Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Enhanced e^+e^- pair yield above hadronic sources is observed.Treating the excess as photon internal conversion photons, the invariant yield of direct photons is deduced. In central Au+Au collisions, the excess over $p+p$ is exponential in $p_{\rm T}$, with inverse slope $T = 221 \pm 23(\text{stat}) \pm 18(\text{sys})$ MeV. Hydrodynamical models with initial temperatures $T_{init} \approx 300 - 600$ MeV at times of 0.6 - 0.15 fm/c after the collision are in qualitative agreement with the data. Lattice QCD predicts a phase transition at ≈ 170 MeV.

PACS numbers: 13.85.Qk, 13.20.Fc, 13.20.He, 25.75.Dw

Experimental results from the Relativistic Heavy Ion Collider (RHIC) have established the formation of dense partonic matter in Au+Au collisions at $\sqrt{s_{NN}}$=200 GeV [1]. The large energy loss of light quarks and gluons [2] as well as that of heavy quarks [3] indicates that the matter has a very high density. The strong elliptic flow of light [4, 5] and charmed [3] hadrons indicates that the matter thermalizes rapidly. Such a high-density thermalized medium is expected to emit thermal radiation [6]. Thermal photons from the partonic phase are predicted to be the dominant source of direct photons for $1 < p_{\rm T} < 3$ GeV/c in Au+Au collisions at RHIC [7].

The measurement of direct photons for $1 < p_{\rm T} < 3$ GeV/c is notoriously difficult due to a large background from hadronic decay photons. The expected yield is only $\simeq 10$ % of the yield of the background photons [7]. An alternative approach is to measure "quasi-real" virtual photons which appear as low invariant mass e^+e^- pairs. In general, any source of high energy photons can also emit virtual photons which convert to low mass e^+e^- pairs. For example, a direct photon production process, such as gluon Compton scattering ($q + g \rightarrow q + \gamma$) has an associated process that produces low mass e^+e^- pairs through internal conversion ($q+g \rightarrow q+\gamma^* \rightarrow q+e^+e^-$).

The relation between photon production and the associated e^+e^- pair production can be written as

$$\frac{d^2n_{ee}}{dm_{ee}} = \frac{2\alpha}{3\pi}\frac{1}{m_{ee}}\sqrt{1-\frac{4m_e^2}{m_{ee}^2}}\left(1+\frac{2m_e^2}{m_{ee}^2}\right)Sdn_\gamma \qquad (1)$$

Here α is the fine structure constant, m_e and m_{ee} are the masses of the electron and the e^+e^- pair respectively, and S is a process dependent factor that goes to 1 as $m_{ee} \rightarrow 0$ or $m_{ee} \ll p_T$. Eq. (1) also describes the relation between the photons from hadron decays (e.g. $\pi^0, \eta \rightarrow \gamma\gamma$, and $\omega \rightarrow \gamma\pi^0$) and the e^+e^- pairs from Dalitz decays ($\pi^0, \eta \rightarrow e^+e^-\gamma$ and $\omega \rightarrow e^+e^-\pi^0$). For π^0 and η, the factor S is given by $S = |F(m_{ee}^2)|^2(1-\frac{m_{ee}^2}{M_h^2})^3$ [8], where M_h is the meson mass and $F(m_{ee}^2)$ is the form factor.

The factor S for a hadron h is zero for $m_{ee} > M_h$. We exploit this cut-off to separate the direct photon signal from the hadronic background. Since 80% of the hadronic photons are from π^0 decays, the signal to background (S/B) ratio for the direct photon signal improves by a factor of five for $m_{ee} > M_{\pi^0}$=135 MeV/c^2, thereby allowing a direct photon signal that is 10% of the background to be observed as a 50% excess of e^+e^- pairs.

In this Letter we present the analysis of e^+e^- pairs for $m_{ee} < 300$ MeV/c^2 and for $1 < p_{\rm T} < 5$ GeV/c in Au+Au and p+p collisions at $\sqrt{s_{NN}} = 200$ GeV recorded during 2004 and 2005, respectively. The PHENIX detector [9] measures electrons in the two central arms, each covering $|\Delta\eta| \leq 0.35$ in pseudorapidity and $\pi/2$ in azimuthal angle. The Au+Au analysis [10, 11] uses 8×10^8 minimum bias events corresponding to $92.2^{+2.5}_{-3.0}$% of the inelastic Au+Au cross section. The $p+p$ analysis [12] uses 43 nb^{-1} of minimum bias (MB) data recorded using the beam-beam counter trigger (BBC), and 2.25 pb^{-1} of single electron triggered data. Helium bags in both runs reduced the total conversion material, including the beam pipe, to $\sim$0.4% of a radiation length.

All electrons and positrons with $p_{\rm T} > 0.2$ GeV/c are combined into pairs. Pairs from photon conversions in the detector material are removed by a cut on the orientation of the pair in the magnetic field [10]. The combinatorial background is computed with a mixed-event technique and is subtracted [10, 11]. The S/B ratio of the pair signal is typically greater than 1 and is at least 0.1 in the kinematic range of this analysis. There are two sources of correlated background, one originating from two e^+e^- pairs from a meson decay and one from two hadrons decaying into e^+e^- pairs, either within the same jet or in back-to-back jets. The magnitude of the correlated background, about 10% of the signal in $p+p$, is determined from the like-sign pair data and subtracted [12]. The pair signal is corrected for the electron reconstruction efficiency and in p+p also for trigger efficiency, determined as a function of mass and pair $p_{\rm T}$ using a GEANT-based Monte Carlo simulation [13] of the PHENIX detector.

Fig. 1 shows the mass spectra of e^+e^- pairs in $p+p$ and Au+Au collisions for different ranges of pair $p_{\rm T}$,

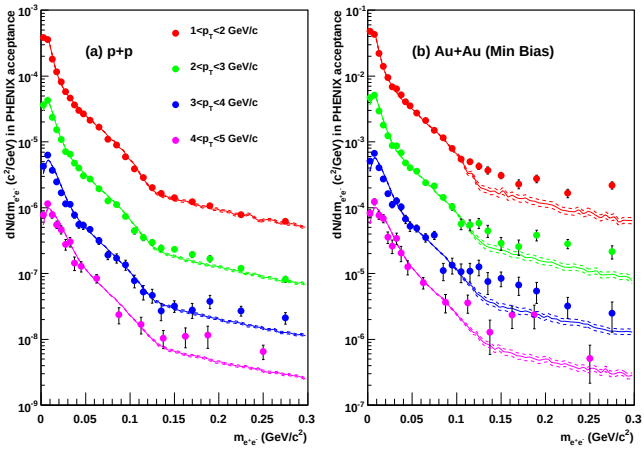

FIG. 1: (color online) The e^+e^- pair invariant mass distributions in (a) $p+p$ and (b) minimum bias Au+Au collisions. The $p_{\rm T}$ ranges are shown in the legend. The solid curves represent an estimate of hadronic sources; the dashed curves represent the uncertainty in the estimate.

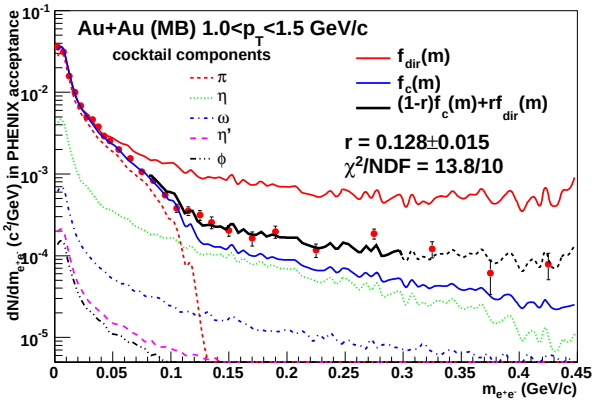

FIG. 2: (color online) Electron pair mass distribution for Au+Au minimum bias events for $1.0 < p_{\rm T} < 1.5$ GeV/c. The two-component fit is explained in the text. The fit range is $80 < m_{ee} < 300$ MeV/c^2. Black dashed curve shows $f(m_{ee})$ outside of the fit range.

comparing them to expected yields from a "cocktail" of hadron decays calculated using a Monte Carlo hadron decay generator based on meson production as measured by PHENIX [11, 12]. Detector resolution effects, which broaden the low mass peak for high $p_{\rm T}$, are included in the cocktail calculation. The open charm contribution, calculated with PYTHIA [14], is included in the cocktail, but is negligible. The cocktail is normalized to the data for $m_{ee} < 30$ MeV/c^2. A cocktail with absolute normalization agrees with the data within a 20% systematic uncertainty [11, 12]. The "knee" beginning at $m_{ee} \simeq 100$ MeV/c^2 corresponds to the π^0 cut-off, leading to an 80% reduction of background above this point. The $p+p$ data are consistent with the background for the lowest $p_{\rm T}$, but reveal a small excess over the background at higher $p_{\rm T}$ for $m_{ee} \geq M_{\pi^0}$. The Au+Au data show a much greater excess for all $p_{\rm T}$, which indicates an enhanced production of virtual photons in Au+Au collisions.

Internal conversion of direct photons is a possible source of the excess. Little contribution from other conventional sources of e^+e^- pairs is expected in this mass region since $\pi^+\pi^- \rightarrow e^+e^-$ can only contribute for $m_{ee} \geq 2M_{\pi}$. PHENIX has observed a strong enhancement of e^+e^- pairs for $150 < m_{ee} < 750$ MeV/c^2 in Au+Au, peaked at low $p_{\rm T}$ [11]. However, as shown in Fig. 2, the shape of the excess is consistent with that expected from internal conversion alone for $m_{ee} < 450$ MeV/c^2 and there is no significant indication of contributions from this "low mass enhancement" to the kinematic region of this analysis. Thus, we treat the excess entirely as internal conversion of photons and deduce the real direct photon yield from the e^+e^- pair using Eq. (1).

In order to quantify the excess, we fit a two-component function, $f(m_{ee}) = (1-r)f_c(m_{ee}) + rf_{dir}(m_{ee})$, to the mass distribution. Here $f_c(m_{ee})$ is the shape of the cocktail mass distribution (shown in Fig. 1), $f_{dir}(m_{ee})$ is the expected shape of the direct photon internal conversion, and r is the fit parameter. Since both $f_c(m_{ee})$ and $f_{dir}(m_{ee})$ are separately normalized to the data for $m_{ee} < 30$ MeV/c^2, where their shapes are nearly identical, this procedure preserves the normalization to the data in this region and determines the direct photon fraction r. We assume that the form factor for direct photons is $F(m_{ee}^2) = 1$, as one would expect from a purely point-like process. For direct photons from parton fragmentation or from hadronic gas, $F(m_{ee}^2)$ may be greater than one. If we arbitrarily set the form factor in $f_{dir}(m_{ee})$ to be the same as that in $f_\eta(m_{ee})$, r would decrease by $\simeq 10\%$.

For each $p_{\rm T}$ bin, $f(m_{ee})$ is fit to the data for several mass ranges $m_{low} < m_{ee} < 300$ MeV/c^2, with r the only fit parameter. Fig. 2 shows $f_{dir}(m_{ee})$ and $f_c(m_{ee})$ together with a fit result for Au+Au MB data for $1.0 < p_{\rm T} < 1.5$ GeV/c. The fit has $\chi^2/DOF = 13.8/10$. We note that the χ^2/DOF of the fit increases to 21.1/10 if $f_\eta(m_{ee})$ is used in place of $f_{dir}(m_{ee})$, demonstrating that the shape of the excess is inconsistent with $f_\eta(m_{ee})$. All fits to the Au+Au data for all centralities and for all $p_{\rm T}$ bins give a similarly good χ^2/DOF for $m_{low} > 80$ MeV/c^2.

This analysis measures the difference in *shape* of the spectra (the data, $f_c(m_{ee})$, and $f_{dir}(m_{ee})$). Therefore, we have focused on the uncertainties which can cause distortions in the mass distribution, namely (i) the particle composition in the hadronic background, (ii) the background (from mixed events and correlated pairs), (iii) the geometric acceptance due to detector active areas, and (iv) the efficiency corrections. These were

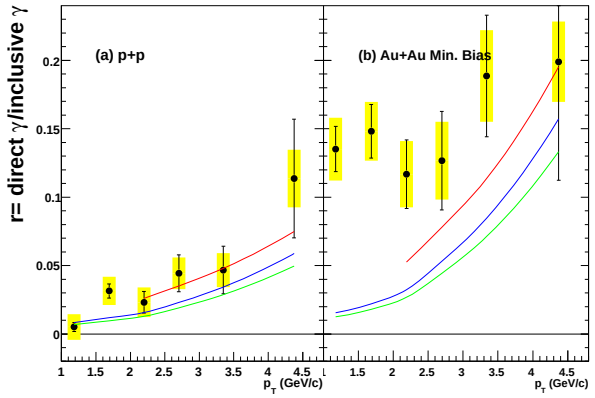

FIG. 3: (color online) The fraction of the direct photon component as a function of $p_{\rm T}$ in (a) $p+p$ and (b) Au+Au (min. bias). The error bars and the error band represent the statistical and systematic uncertainties, respectively. The curves are from a NLO pQCD calculation (see text).

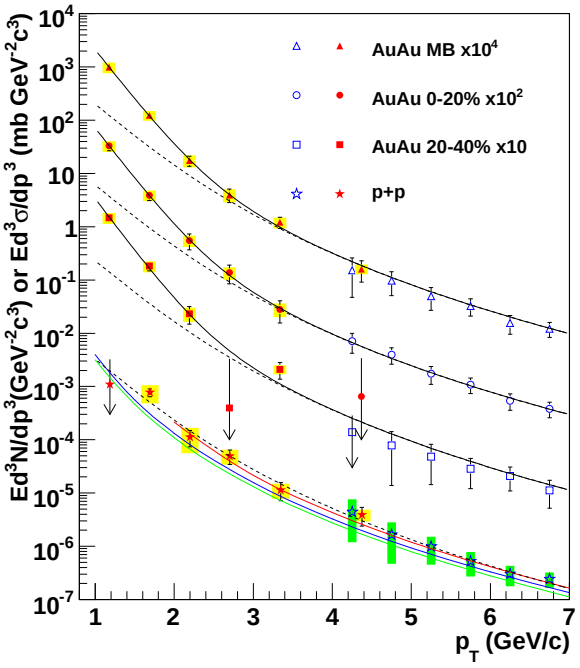

FIG. 4: (color online) Invariant cross section ($p+p$) and invariant yield (Au+Au) of direct photons as a function of $p_{\rm T}$. The filled points are from this analysis and open points are from [17, 18]. The three curves on the $p+p$ data represent NLO pQCD calculations, and the dashed curves show a modified power-law fit to the $p+p$ data, scaled by $T_{\rm AA}$. The black curves are exponential plus the $T_{\rm AA}$ scaled $p+p$ fit.

studied by a Monte Carlo simulation. First, the mass spectrum is distorted within the systematic uncertainties, and the fitting procedure is applied to the distorted spectrum to determine the systematic uncertainties in r. The systematic uncertainty due to the variation of m_{low} from 80 to 120 MeV/c^2 is also included. The largest source of the uncertainty is the particle composition in the hadronic cocktail, namely the η/π^0 ratio which is $0.48 \pm 0.03(0.08)$ at high $p_{\rm T}$ for $p+p$ (Au+Au) based on PHENIX measurements [15]. This corresponds to a $\simeq$ 7% ($\simeq$ 17%) uncertainty in the $p+p$ (Au+Au) cocktail for $100 < m_{ee} < 300$ MeV/c^2. Other sources cause only a few percent uncertainty in the data to cocktail ratio in the mass range once the cocktail is normalized to the data for $m_{ee} < 30$ MeV/c^2. Since the η/π^0 ratio is the largest source of uncertainty, we also studied fits with a three component function, $f_3(m_{ee}) = (1-r-r_\eta)f_c(m_{ee}) + r f_{dir}(m_{ee}) + r_\eta f_\eta(m_{ee})$, with a constraint on r_η such that $\eta/\pi^0 = 0.48 \pm 0.03(0.08)$ for $p+p$ (Au+Au). These alternative fits give consistent results for r within statistical uncertainties.

Figure 3(a) and (b) show the fraction r of the direct photon component determined by the two-component fit in $p+p$ and Au+Au, respectively. The curves represent the expectations from a next-to-leading-order perturbative QCD (NLO pQCD) calculation. For $p+p$, the curves show the ratio $d\sigma_\gamma^{NLO}(p_{\rm T})/d\sigma_\gamma^{incl}(p_{\rm T})$, where $d\sigma_\gamma^{NLO}(p_{\rm T})$ is the direct photon cross section from a NLO pQCD calculation [16] and $d\sigma_\gamma^{incl}(p_{\rm T})$ is the inclusive photon cross section. For Au+Au, the curves represent $T_{\rm AA} d\sigma_\gamma^{NLO}(p_{\rm T})/dN_\gamma^{incl}(p_{\rm T})$, where $T_{\rm AA}$ is the Glauber nuclear overlap function and $dN_\gamma^{incl}(p_{\rm T})$ is the inclusive photon yield. Inclusive spectra $d\sigma_\gamma^{incl}$ and dN_γ^{incl} are determined as described later. The three curves correspond, from top to bottom, to the theory scale $\mu = 0.5\ p_{\rm T}$, $p_{\rm T}$, and $2\ p_{\rm T}$, respectively, showing the scale dependence of the theory. While the fraction r is consistent with the NLO pQCD calculation in $p+p$, it is larger than the calculation in Au+Au for $p_{\rm T} < 3.5$ GeV/c.

The direct photon fraction r in Fig. 3 is converted to the direct photon yield as $dN^{dir}(p_{\rm T}) = r \times dN^{incl}(p_{\rm T})$. The inclusive photon yield for each $p_{\rm T}$ bin is determined by $dN_\gamma^{incl} = N_{ee}^{data} \times (dN_\gamma^c/N_{ee}^c)$, where N_{ee}^{data} and N_{ee}^c are the measured and the absolutely normalized cocktail e^+e^- pair yields, respectively, both for $m_{ee} < 30$ MeV/c^2 and dN_γ^c is the yield of photons from the cocktail. Here we use the fact the ratio of the photon yield to the e^+e^- pair yield for $m_{ee} < 30$ MeV/c^2 calculated from Eq. (1) is the same within a few percent for any photon sources.

In Fig. 4 the direct photon spectra thus obtained are compared with the direct photon data from [17, 18] and NLO pQCD calculations. The systematic uncertainty of the inclusive photon (14% from the uncertainty in the e^+e^- pair acceptance correction[11]) is added in quadrature with the systematic uncertainties of the data. The $p+p$ data are shown as an invariant cross section using $d\sigma = \sigma_{pp}^{inel} dN$. The direct photon data of this analysis are obtained from the yield of e^+e^- pairs using Eq. (1)

under the assumption that other contributions are negligible. In the mass range of the analysis, Eq. (1) implies $\frac{d^2n_{ee}}{dm_{ee}} = \frac{2\alpha}{3\pi}\frac{1}{m_{ee}}dn_\gamma$. Thus the yield of e^+e^- pairs for $100 < m_{ee} < 300$ MeV/c^2 can be obtained by multiplying the photon yield by a factor of $\frac{2\alpha}{3\pi}\log\frac{300}{100} = 1.7\times10^{-3}$.

The pQCD calculation is consistent with the $p+p$ data within the theoretical uncertainties for $p_{\rm T} > 2$ GeV/c. A similarly good agreement is observed for π^0 [19]. The $p+p$ data can be well described by a modified power-law function ($A_{pp}(1+p_{\rm T}^2/b)^{-n}$) as shown by the dashed curve in the figure. The Au+Au data are above the $p+p$ fit curve scaled by $T_{\rm AA}$ for $p_{\rm T} < 2.5$ GeV/c, indicating that the direct photon yield in the low $p_{\rm T}$ range increases faster than the binary-scaled $p+p$ cross section.

We fit an exponential plus the $T_{\rm AA}$-scaled $p+p$ fit function ($Ae^{-p_{\rm T}/T} + T_{\rm AA}\times A_{pp}(1+p_{\rm T}^2/b)^{-n}$) to the Au+Au data. The only free parameters in the fit are A and the inverse slope T of the exponential term. The systematic uncertainties in T are estimated by changing the $p+p$ fit component and the Au+Au data points within the systematic uncertainties. The results of the fits are summarized in Table I, where A is converted to dN/dy for $p_T > 1$GeV/c. For central collisions, $T = 221 \pm 23 \pm 18$ MeV. If a power-law function ($\propto p_T^{-n}$) is used to fit the $p+p$ spectrum, T is higher by 24 MeV. If the direct photons in Au+Au collisions are of thermal origin, the inverse slope T is related to the initial temperature T_{init} of the dense matter. In hydrodynamical models, T_{init} is 1.5 to 3 times T due to the space-time evolution [20]. Several hydrodynamical models can reproduce the central Au+Au data within a factor of two. These assume formation of a hot system with initial temperature ranging from $T_{init} = 300$ MeV at thermalization time $\tau_0 = 0.6$ fm/c to $T_{init} = 600$ MeV at $\tau_0 = 0.15$ fm/c [7, 20].

In conclusion, we have measured e^+e^- pairs with $m_{ee} < 300$ MeV/c^2 and $1 < p_{\rm T} < 5$ GeV/c in $p+p$ and Au+Au collisions. The $p+p$ data show a small excess over the hadronic background while the Au+Au data show a much larger excess. Treating the excess as internal conversion of direct photons, the direct photon yield is deduced. The direct photon yields are consistent with a NLO pQCD calculation in $p+p$. In central Au+Au collisions the shape of the direct photon spectrum above the $T_{\rm AA}$-scaled $p+p$ spectrum is exponential in $p_{\rm T}$, with an inverse slope $T = 221 \pm 23({\rm stat}) \pm 18({\rm sys})$ MeV. Hydrodynamical models with $T_{init} \approx 300 - 600$ MeV at $\tau_0 \approx 0.6 - 0.15$ fm/c are in qualitative agreement with the data. Lattice QCD predicts a phase transition at $\approx$ 170 MeV[1].

TABLE I: Summary of the fits. The first and second errors are statistical and systematical, respectively.

centrality	$dN/dy(p_T > 1{\rm GeV}/c)$	T(MeV)	χ^2/DOF
0-20%	$1.10 \pm 0.20 \pm 0.30$	$221 \pm 23 \pm 18$	3.6/4
20-40%	$0.52 \pm 0.08 \pm 0.14$	$215 \pm 20 \pm 15$	5.2/3
MB	$0.33 \pm 0.04 \pm 0.09$	$224 \pm 16 \pm 19$	0.9/4

ABSTRACT

PHENIX has measured the electron–positron pair mass spectrum from 0 to 8 GeV/c^2 in $p+p$ collisions at $\sqrt{s}=200$ GeV. The contributions from light meson decays to e^+e^- pairs have been determined based on measurements of hadron production cross sections by PHENIX. Within the systematic uncertainty of $\sim 20\%$ they account for all e^+e^- pairs in the mass region below ~ 1 GeV/c^2. The e^+e^- pair yield

Editor: V. Metag

remaining after subtracting these contributions is dominated by semileptonic decays of charmed hadrons correlated through flavor conservation. Using the spectral shape predicted by PYTHIA, we estimate the charm production cross section to be $544 \pm 39(\text{stat}) \pm 142(\text{syst}) \pm 200(\text{model})$ μb, which is consistent with QCD calculations and measurements of single leptons by PHENIX.

Because of the large mass of the charm quark, approximately 1.3 GeV/c^2, it is commonly expected that the charm production cross section can be calculated in quantum chromo-dynamics (QCD) using perturbative methods (pQCD). Comparing such calculations with experimental data serves as a test of pQCD and helps to quantify the importance of higher order terms. Perturbative calculations suggest that charm production at RHIC energies results primarily from gluon fusion, so charm can probe gluonic interactions in the matter formed in heavy ion collisions at RHIC [1]. Medium modifications of heavy quark production and the suppression of bound charmonium states like the J/ψ have received considerable attention and are thought to be keys to better understanding properties of strongly interacting matter. Experiments at RHIC with polarized proton beams will allow the measurement of spin asymmetries in charm production, which gives access to the spin contribution of the gluons to the proton in a new channel [2].

To date, charm production has been calculated in next-to-leading-order (NLO) and fixed-order plus next-to-leading-log approximations (FONLL) [3]. These calculations are consistent with the measured D meson cross sections in 1.96 TeV $p\bar{p}$ collisions published by CDF [4] as well as with single lepton measurements, electrons [5] and muons [6], in 200 GeV $p+p$ collisions from PHENIX. However, the theoretical uncertainties are considerable, at least a factor of two [3] or even larger [7], and the data prefer larger cross sections within these uncertainties.[3] In this Letter we present a different method to determine the charm cross section using electron–positron pairs measured with PHENIX during the RHIC $p+p$ run in 2005.

Electrons are measured in the two PHENIX central arm spectrometers [10], which each cover $|\eta| \leqslant 0.35$ in pseudo-rapidity and $\Delta\phi = \pi/2$ in azimuth in a nearly back-to-back configuration. For charged particles drift chambers (DC) measure the deflection angles in a magnetic field to determine their momenta. Ring imaging Cherenkov counters (RICH) as well as electromagnetic calorimeters (EMCal) distinguish electrons from other particles. The electron analysis is described in detail in [5].

Two data sets are used in the analysis. A reference sample of events was selected with a minimum bias interaction trigger (MB) that was based on beam–beam counters (BBC). The BBC trigger cross section is 23.0 ± 2.2 mb or $55 \pm 5\%$ of the inelastic $p+p$ cross section. Simulations, and data collected without requiring the BBC trigger, indicate that the triggered events include $79 \pm 2\%$ of events with particles in the central arm acceptance. This number coincides with the fraction of non-diffractive events triggered by the BBC from which we conclude that for non-diffractive collisions the BBC trigger can have only little bias towards events with particles produced in the central arms. The bulk of the data sample was recorded requiring a coincidence of the BBC trigger with a single electron trigger (ERT) that matches hits in the RICH to 2×2 trigger tiles in the EMCal with a minimum energy of 400 MeV. In the active area the ERT trigger has a very high efficiency for electrons; around 500 MeV it reaches approximately 50% and then saturates around 1 GeV close to 100%. After applying an interaction-vertex cut of ±30 cm the total integrated luminosities were 43 nb^{-1} and 2.25 pb^{-1} for the MB and ERT trigger, respectively.

All electrons and positrons with $p_T > 200$ MeV/c are combined into like- and unlike-sign pairs. For each pair we check that at least one of the tracks was registered by the ERT trigger. The event is rejected if the two tracks of the pair overlap in any of the detectors; this cut removes 2% of the e^+e^- pairs. This cut is necessary to assure that the combinatorial pair background is reproduced from mixed events. Pairs originating from photon conversions in the detector material are removed by a cut on the orientation of the opening angle of the pairs with respect to the magnetic field; this cut removes 98% of the pairs from photon conversions [11]. Fig. 1 shows the raw yields as a function of pair mass for both like- and unlike-sign pairs. The unlike-sign spectrum measures the signal from hadron decays and open charm plus background, while the like-sign spectrum measures only the background. The PHENIX central arms accept equal number of electrons and positrons, however, because of the two-arm geometry and the magnetic field, the acceptance for electrons and positrons covers a different range in azimuthal angle. Therefore the shape of the mass distribution is different for like- and unlike-sign pairs.

We have developed two independent methods to subtract the background. In the first method we decompose the background into two components: a combinatorial background made of uncorrelated pairs and a background of correlated pairs. The combinatorial background is determined from mixed events using the procedure described in more detail in [11,12] and in Appendix A of [13]. The mixed events are generated from the MB sample. For each pair we check that at least one of the two partners fulfill the ERT trigger condition. The mass distribution for the like-sign mixed event background does not have the same shape as the measured distribution, which indicates the presence of additional correlated background in the data. This can be studied in more detail investigating the pair distributions in mass versus transverse momentum. The biggest differences in shape are at low mass and large p_T as well as at low p_T and large mass, where the data show more yield than the mixed events. We therefore use a region, roughly corresponding to a mass of 300 MeV/c^2, p_T above 400 MeV/c and a transverse mass $m_T = \sqrt{m^2 + (p_T/c)^2}$ below 1.2 GeV/c^2, to normalize the mixed event background to the data.[4] In this region also the shape of the mass distributions are very similar. After normalizing the like-sign mass distribution from mixed events we determine the number of uncorrelated like-sign background pairs N_{++} and N_{--} by integrating the distributions. The normalization of the uncorrelated unlike-sign mixed event background is then given by $2\sqrt{N_{++}N_{--}}$.

The mixed event backgrounds as well as the distributions after subtraction are also shown in Fig. 1. The remaining pairs, like and unlike, are considered correlated pairs, where the like-sign distribution only contains correlated background pairs while the unlike contains also the signal. The correlated background pairs

[3] The STAR Collaboration reports an even larger cross section [8,9], which is about a factor of 2–3 above of what can be accommodated in pQCD calculations.

[4] The exact region used for the normalization is given by the following four conditions $m > 300$ MeV/c^2, $m_T < 1.2$ MeV/c^2, $p_T/c - 1.5m \leqslant 200$ MeV/c^2, and $p_T/c - 0.75m \geqslant -150$ MeV/c^2.

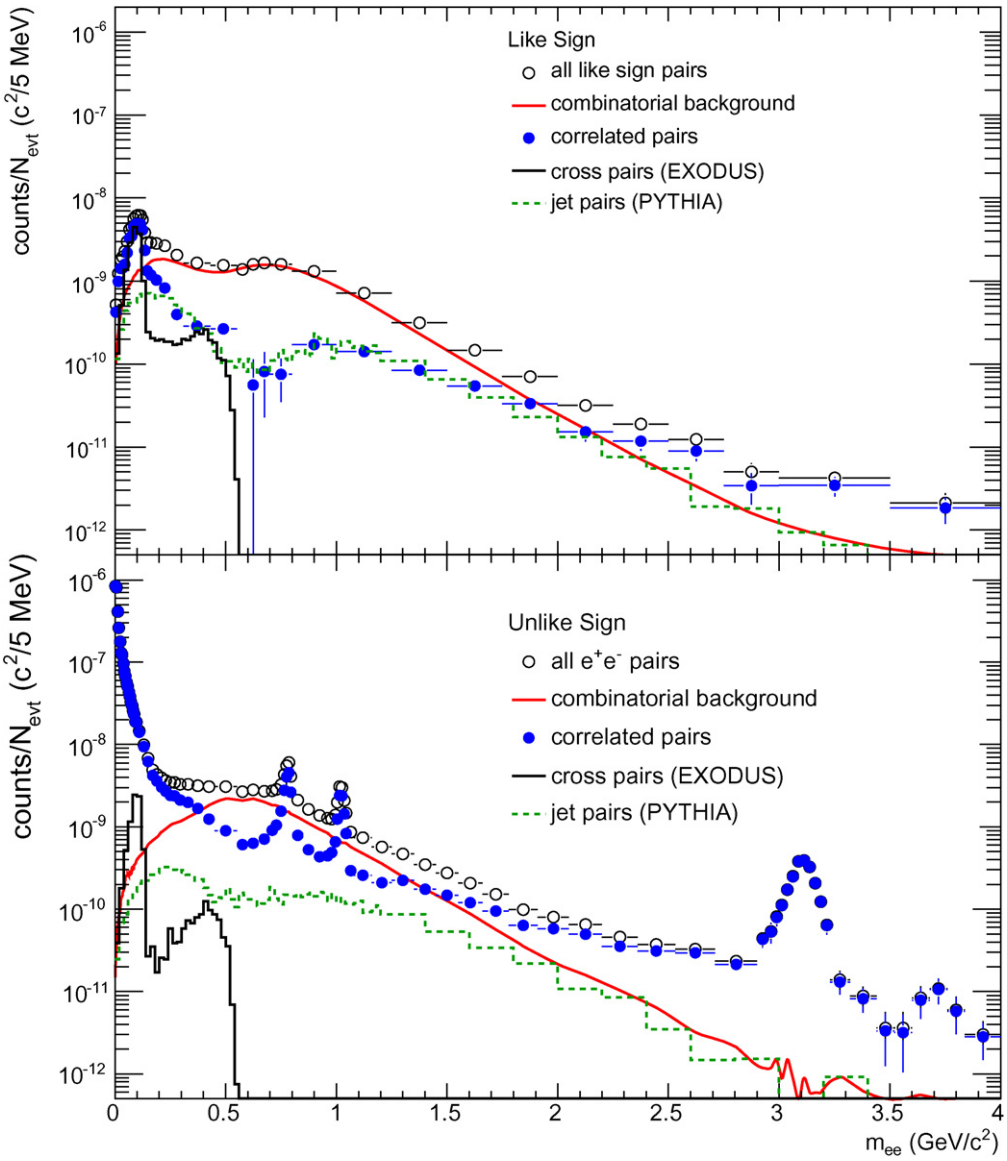

Fig. 1. Raw dielectron spectra. The top panel shows like-sign pairs as measured in the experiment, the combinatorial background from mixed events, the correlated pair background obtained by subtracting the combinatorial background, and the individual contributions from cross and jet pairs to the correlated background (see text). The bottom panel shows the same distributions for unlike-sign pairs.

stem from two sources. "Cross pairs" result from decays of single π^0 or η mesons with two electron pairs in the final state, such as double Dalitz decays, Dalitz decays plus conversion of the accompanying photon, and $\gamma\gamma$ decays where both photons convert. These pairs have a mass lower than the η mass of 548 MeV/c^2. Cross pairs were simulated using our hadron decay generator EXODUS including the PHENIX acceptance.[5] "Jet pairs" are produced by two independent hadron decays yielding electron pairs, either within the same jet or in the back-to-back jets. Jet pairs were simulated using minimum bias events generated with PYTHIA[6] with the branching ratio of the π^0 Dalitz decay set to 100% to enhance the sample of jet pairs per event. We exclude all pairs from single hadron decays so that cross pairs as well as any signal in the unlike-sign pairs are removed. Electrons and positrons from cross and jet pairs are filtered through the PHENIX acceptance and weighted according to the electron identification and ERT trigger efficiency. Pairs from simulated mixed events are subtracted from the like- and unlike-sign pair distributions to find the correlated pair distributions. The mixed event background is normalized by the same method used in the data analysis, described previously. It was found that correlated pairs from the same jet typically have small mass and large p_T while those from back-to-back jets have large mass and smaller p_T.

Correlated background pairs occur in all charge combinations. The simulated correlated like-sign background is then normalized to the measured correlated like-sign background by simultaneously fitting simulated cross and jet pair mass distributions to the measured correlated like-sign pair mass spectrum. Since the Monte Carlo simulation preserves the relative abundance of like- and unlike-sign pairs after filtering them through the

[5] The PHENIX acceptance is parameterized as function of the azimuthal angle ϕ of a track, its p_T, and charge sign q by conditions for the DC and the RICH for each spectrometer arm separately: $\phi_{\min} < \phi + qk_{\rm DC}/p_T < \phi_{\max}$ and $\phi_{\min} < \phi + qk_{\rm RICH}/p_T < \phi_{\max}$. The parameters are $k_{\rm DC} = 0.206$ rad GeV c^{-1}, $k_{\rm RICH} = 0.309$ rad GeV c^{-1}, $\phi_{\min} = -3/16\pi$ to $\phi_{\max} = 5/16\pi$, and $\phi_{\min} = 11/16\pi$ to $\phi_{\max} = 19/16\pi$.

[6] We used PYTHIA 6.319 changing PYTHIA parameters as follows: MSEL = 0 with the following processes switched on MSUB 11, 12, 13, 28, 53, 68, PARP(91) = 1.5 (k_T), MSTP(32) = 4 (Q^2 scale), and CKIN(3) = 2.0 (min. parton p_T).

PHENIX acceptance, we apply the same two normalization factors, one for cross- the other for jet-pairs, to the unlike-sign correlated background. The normalized contributions of both correlated background sources are also shown in Fig. 1. The unlike-sign dilepton signal is extracted by subtracting the simulated unlike-sign correlated backgrounds from the distribution of all correlated pairs.

In our second method to estimate the unlike-sign pair background we make no assumptions about the shape of the correlated background nor about the decomposition of correlated and uncorrelated background (see pp. 85–86 in [13]). We use the measured like-sign distribution which contains only the background, but with a different acceptance than the unlike-sign. We correct for this acceptance difference with the ratio of the mixed event distributions, $N_{+-}/2\sqrt{N_{++}N_{--}}$ as a function of mass and p_T. Projected onto the mass axis the relative acceptance can be estimated by dividing the mixed event background shown in Fig. 1. Since the acceptance for pairs is a function of mass and p_T, we have checked that for different e^+e^- pair sources, which span reasonable variations in mass and p_T shapes of the e^+e^- pairs, the relative acceptance is unchanged. The corrected like-sign distribution is then subtracted from the unlike-sign pairs without further normalization. Up to 3.5 GeV/c^2 the difference between the signal extracted using the two background subtraction techniques agrees to better than ±10%. Above 3.5 GeV/c the difference becomes much larger, which may indicate additional correlated background. In this region we subtract the measured like-sign yield, the larger of our two background estimates, and include the difference of the two methods as asymmetric systematic uncertainty on the signal yield.

In the next step the signal is corrected for electron reconstruction efficiency and trigger efficiency. The electron reconstruction efficiency was determined with a Monte Carlo simulation of the PHENIX detector (similar to [12]). The trigger efficiency for single electrons was measured using the MB sample. For each of the 8 calorimeter sectors we determine the ratio of electrons that fired the ERT trigger to all electrons reconstructed as function of p_T. Pairs from hadron decays simulated with EXODUS are filtered by the acceptance and then folded with the ERT trigger efficiency to extract the pair trigger efficiency as function of mass. At high masses the trigger efficiency saturates at 72%, limited by the active area of the trigger, from 1.5 to 0.5 GeV/c^2 the pair efficiency gradually drops to 32% and remains approximately constant at lower masses. In addition, the yield is divided by $0.79/0.55 = 1.44$ to account for the fraction of the inelastic $p+p$ cross section missed by our interaction trigger. The systematic uncertainties on the fully corrected spectrum shown in Fig. 2 are summarized in Table 1.

We model the e^+e^- pair contributions from hadron decays using the EXODUS decay generator. We follow closely the approach given in [5,14], however, we have updated all input to match the most recent PHENIX data. We assume that all hadrons have a constant rapidity density in the range $|\Delta\eta| \leqslant 0.35$ and a homogeneous distribution in azimuthal angle. Transverse momentum distributions are based on measurements in the same experiment where possible. The key input is the rapidity density $dN/dy = 1.06 \pm 0.11$ of neutral pions, which we determine from a fit to PHENIX data on charged and neutral pions, as shown in Fig. 3. The functional form of the pion transverse momentum distribution is given by:

$$E\frac{d^3\sigma}{dp^3} = A\left(e^{-(ap_T+bp_T^2)} + p_T/p_0\right)^{-n} \quad (1)$$

with $A = 377 \pm 60$ mb GeV$^{-2}\,c^3$, $a = 0.356 \pm 0.014$ (GeV/c)$^{-1}$, $b = 0.068 \pm 0.019$ (GeV/c)$^{-2}$, $p_0 = 0.7 \pm 0.02$ GeV/c and the power $n = 8.25 \pm 0.04$. For all other mesons we assume m_T scaling, replacing p_T by $\sqrt{m^2 - m_\pi^2 + (p_T/c)^2}$, where m is the mass of the meson. For the η, ω, ϕ, and J/ψ we fit a normalization factor to PHENIX data. In Fig. 3 the results are compared to published PHENIX data; excellent agreement with the data is achieved. The η meson is measured only at higher p_T, however, the fit is in good agreement with the p_T distribution of kaons, which have similar mass.

In order to extract the meson yield per inelastic $p+p$ collision we integrate the fits over all p_T. Results, systematic uncertainties, and references to data are given in Table 2. For the ρ meson we assume $\sigma_\rho/\sigma_\omega = 1.15 \pm 0.15$, consistent with values found in jet fragmentation [15]. The η' yield is scaled to be consistent with jet fragmentation $\sigma_{\eta'}/\sigma_\eta = 0.15 \pm 0.15$ [15]. The ψ' is adjusted to the value of $\sigma_{\psi'}/\sigma_{J/\psi} = 0.14 \pm 0.03$ [22]. For the η, ω, ϕ, and J/ψ the quoted uncertainties include those on the data as well as those using different shapes of the p_T distributions to extrapolate to zero p_T. Specifically we have fitted the functional form given in Eq. (1) with all parameters free and also an exponential distribution in m_T. For the ρ, η', and ψ' the uncertainty is given by the uncertainty we assumed for the cross section ratios. We note that the dilepton spectra from meson decays are rather insensitive to the exact shape of the p_T distribution.

Once the meson yields and p_T spectra are known the dilepton spectrum is given by decay kinematics and branching ratios, which are implemented in our decay generator EXODUS following earlier work published in [5,14]. The branching ratios are taken from the compilation of particle properties in [15]. For the Dalitz decays π^0, η, $\eta' \to e^+e^-\gamma$ and the decay $\omega \to e^+e^-\pi^0$ we use the Kroll–Wada expression [23] with electromagnetic transition form factors measured by the Lepton-G Collaboration [24,25]. For the decays of the vector mesons ρ, ω, $\phi \to e^+e^-$ we use the expression derived by Gounaris and Sakurai [26], extending it to 2 GeV/c^2, slightly beyond its validity range. For the J/ψ and $\psi' \to e^+e^-$ we use the same expression modified to include radiative corrections as discussed in [21]. All vector mesons are assumed to be unpolarized. The resulting dilepton spectra are compared to our data in Fig. 2 with the systematic uncertainties shown as a band. They are calculated as a function of mass and are dominated by the uncertainties on the meson yield tabulated in Table 2. The uncertainty from the measured electromagnetic transition form factors, in particular for the $\omega \to e^+e^-\pi^0$ decay, is also included but contributes visibly only in the range around 500 to 600 MeV/c^2. Also shown on Fig. 2 are the contributions from open charm and bottom production, discussed in more detail below, as well as from the Drell–Yan process, which is negligible. The bottom panel shows the ratio of data to the sum of all sources, hadronic cocktail, charm, bottom and Drell–Yan. The data agree very well with the sum of all known sources within the quoted systematic uncertainties.

Except for the vector meson peaks, the dilepton yield in the mass range above 1.1 GeV/c^2 is dominated by semileptonic decays of D and B mesons correlated through flavor conservation. To determine this contribution we subtract the meson decay cocktail from the dilepton data, the resulting mass spectrum is shown in Fig. 4. In the PHENIX acceptance the integrated e^+e^- pair yield per event from heavy flavor decays in the range from 1.1 to 2.5 GeV/c^2 is $4.21 \pm 0.28(\text{stat}) \pm 1.02(\text{syst}) \times 10^{-8}$. The systematic uncertainties are those tabulated in Table 1 plus the uncertainty on the cocktail subtraction. The cocktail subtraction is dominated by the high mass end of the broad ρ resonance. The ρ contribution in this region is not very well known and we therefore assume 100% systematic uncertainty on the ρ contribution. To estimate the rapidity density of $c\bar{c}$ pairs the measured e^+e^- pair yield is corrected for the geometrical acceptance, i.e., corrected from requiring both electron and positron within the PHENIX central arm acceptance to having the electron pair within one unit of rapidity at mid-rapidity. It then is extrapolated to zero e^+e^- pair mass and converted to $c\bar{c}$ using known branching ratios of semileptonic decays [15]. This

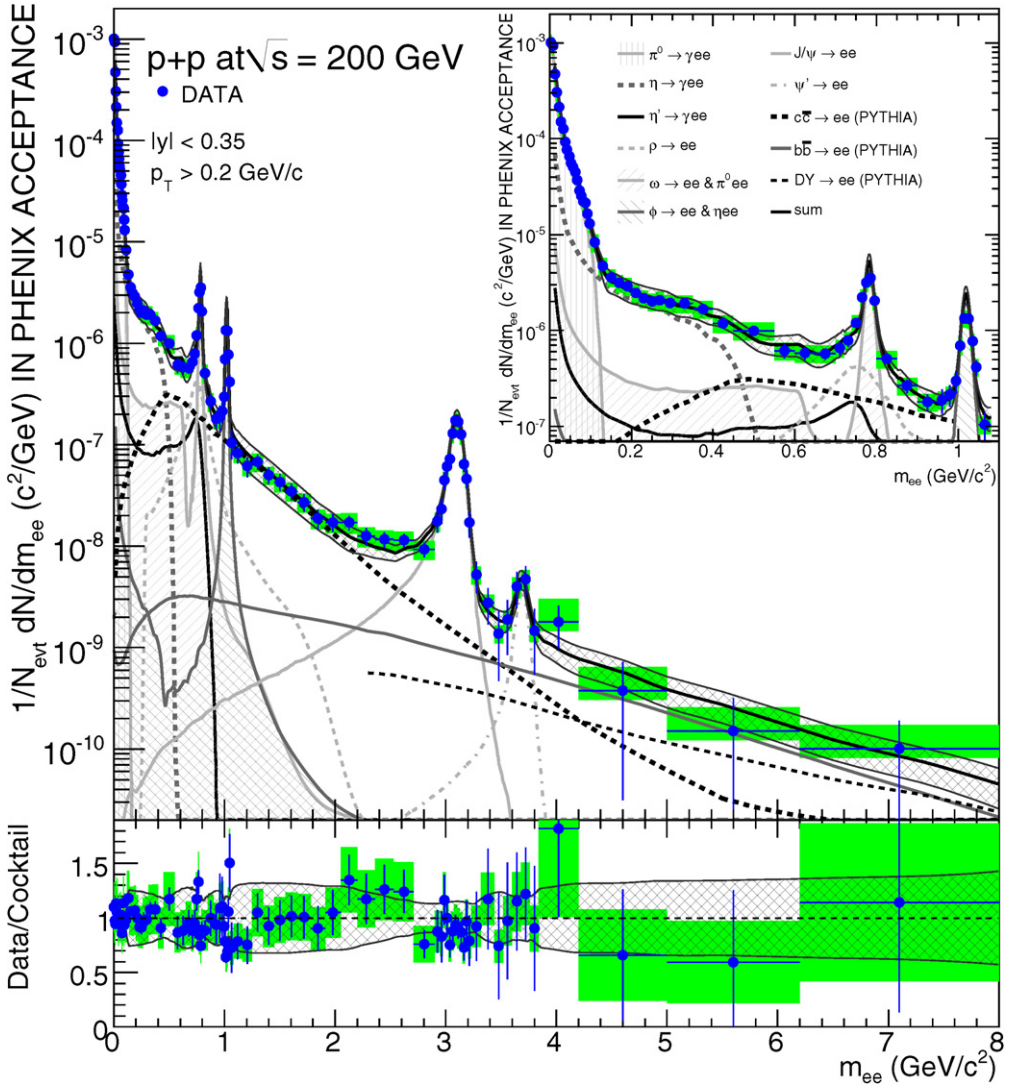

Fig. 2. Electron–positron pair yield per inelastic $p + p$ collision as function of pair mass. Data show statistical (bars) and systematic (shades) errors separately. The yield per event can be converted to a cross section by multiplying with the inelastic $p + p$ cross section of 42.2 mb. The data are compared to a cocktail of known sources. The contribution from hadron decays is independently normalized based on meson measurements in PHENIX, the systematic uncertainties are given by the error band. The contribution from open charm production is scaled to match the data ($\sigma_{c\bar{c}} = 544 \pm 39(\text{stat}) \pm 142(\text{syst}) \pm 200(\text{model})$ μb). The inset shows the same data but focuses on the low mass region. The bottom panel shows the ratio of data to the cocktail of known sources. The systematic uncertainties of the data are shown as boxes, while the uncertainty on the cocktail is shown as band around 1.

Table 1
Systematic uncertainties of the dilepton yield due to different sources and for different mass ranges. The uncertainties vary with mass and the largest uncertainties are quoted for each mass range. The contribution quoted for the jet pair subtraction also accounts for the difference in the signal observed between our two background subtraction techniques.

	< 0.4 GeV/c^2	0.4–1.1 GeV/c^2	1.1–3.5 GeV/c^2	> 3.5 GeV/c^2
Minimum bias trigger	11.3%	11.3%	11.3%	11.3%

Jet pair subtraction	2%	3%	11%	+70%
Reconstruction efficiency	14.4%	14.4%	14.4%	14.4%
Total	19.8%	20.8%	22.3%	+73%, −19%

correction is model dependent; we used our tuned PYTHIA simulation[7] to directly relate e^+e^- pairs from charm in the PHENIX acceptance and in the mass range from 1.1 to 2.5 GeV/c^2 to the $c\bar{c}$ rapidity density.[8]

[7] We used PYTHIA 6.205 with CTEQ5L parton distribution function [31]. We changed PYTHIA parameters as follows: PARP(91) = 1.5 (k_T), PARP(31) = 3.5 (K factor), MSTP(33) = 1, MSTP(32) = 4 (Q^2 scale) and in addition for charm production we use MSEL = 11 and PMAS(4, 1) = 1.25 (mass), for bottom MSEL = 5 and PMAS(5, 1) = 4.1 (mass), and for Drell–Yan MSEL = 11, PARP(31) = 1.8, and CKIN(3) = 2.0 (min. parton p_T).

[8] It is known that lowest order PYTHIA calculations, as we use, fail to describe single electron production from charmed quarks produced with large p_T. This is

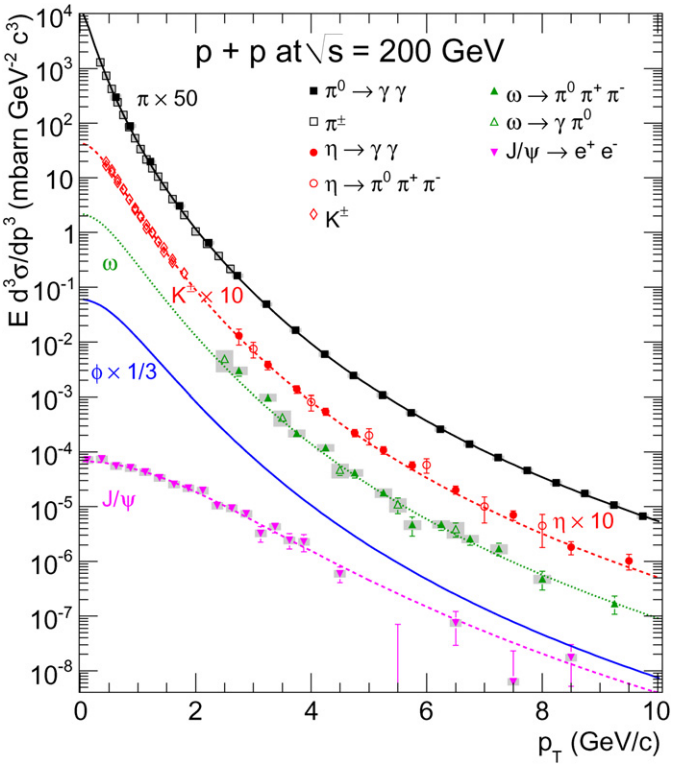

Fig. 3. Compilation of meson production cross sections in $p+p$ collisions at $\sqrt{s}=200$ GeV. Shown are data for neutral [16] and charged pions [17], η [18], kaons [17], ω [19], and J/ψ [21]. The data are compared to the parameterization based on m_T scaling of the measured pion distribution, as used in our hadron decay generator.

Table 2
Hadron rapidity densities used in our hadron decay generator. For the ω and ϕ meson data from this analysis were used together with data from the quoted references.

	$\frac{dN}{dy}\|_{y=0}$	Relative err.	Data used
π^0	1.065 ± 0.11	10%	PHENIX [16,17]
η	0.11 ± 0.03	30%	PHENIX [18]
ρ	0.089 ± 0.025	28%	jet fragmentation [15]
ω	0.078 ± 0.018	23%	PHENIX [19]
ϕ	0.009 ± 0.002	24%	PHENIX [20]
η'	0.016 ± 0.016	100%	jet fragmentation [15]
J/ψ	$(1.77 \pm 0.27) \times 10^{-5}$	15%	PHENIX [21]
ψ'	$(2.5 \pm 0.7) \times 10^{-6}$	27%	world average [22]

For single tracks the acceptance is known to better than 5%. Neglecting correlations between the electron and positron this implies an uncertainty of less than 10% for pairs. However, the fraction of e^+e^- pairs from correlated heavy flavor decays at mid-rapidity depends on the dynamical correlations between the quarks. These are not very accurately known [27], in particular in the azimuthal direction. Therefore additional systematic uncertainties need to be considered. In PYTHIA the intrinsic k_T parameter modifies the azimuthal correlation between c and $\bar{c}$. We have varied k_T between 1 and 3 GeV/c and reevaluate the fraction of e^+e^- pairs at mid-rapidity. A $\pm 20\%$ variation was found. Different choices of parton distribution functions (PDFs) lead to modifications of the longitudinal correlation of the pair, often expressed as the rapidity gap between the c and $\bar{c}$ quarks. We used different

not a concern for our analysis, since the majority of the e^+e^- pairs in our mass spectrum result from $c\bar{c}$ pairs where the c and $\bar{c}$ have low p_T and large opening angle. Future analysis of the pair p_T dependence, however, will need to take this into account.

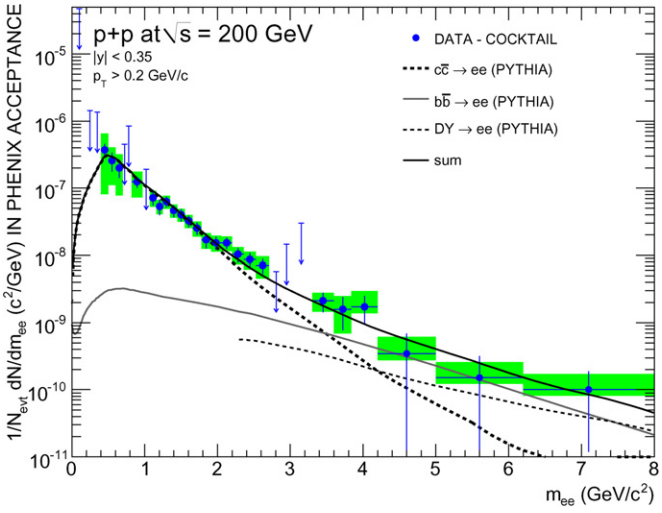

Fig. 4. Electron–positron mass distributions from semileptonic decays of heavy flavor, obtained by subtracting the contribution from π^0, η, ω, ρ, ϕ, η', J/ψ and ψ' mesons from the inclusive e^+e^- pair yield. The arrows indicate upper limits (95% CL) in the mass regions where the charm contribution is smaller or comparable to the systematic uncertainties. For all data points statistical error bars and systematic uncertainty boxes, including data and model contributions, are shown. Also shown is the contribution from charm ($\sigma_{c\bar{c}} = 544 \pm 39(\text{stat}) \pm 142(\text{syst}) \pm 200(\text{model})$ μb), as well as expected contributions from bottom ($\sigma_{b\bar{b}} = 3.7$ μb) and Drell–Yan ($\sigma_{b\bar{b}} = 0.04$ μb).

parton distribution functions available in PYTHIA, specifically we have used CTEQ5L, CTEQ4L, GRV94LO, GRV98LO, and MRST(c-g). We find $\pm 11\%$ deviations for the e^+e^- pair yield in the PHENIX acceptance. When converting the e^+e^- pair yield to $c\bar{c}$ pairs there is also a $\pm 21\%$ uncertainty resulting from uncertainties of relative abundance of charmed hadrons and of the branching ratios to semileptonic decays. We use an effective branching ratio for $c \to e$ of $9.5\% \pm 1\%$, which was calculated from $D^+/D^0 = 0.45 \pm 0.1$, $D_s/D^0 = 0.25 \pm 0.1$, and $\Lambda_c/D^0 = 0.1 \pm 0.05$ and the branching ratios from [15]. The overall uncertainty on the extrapolation is approximately 33%.

We also subtract a 7% contribution from bottom decays and the Drell–Yan mechanism for which we assign a 100% systematic uncertainty. For the bottom cross section we assume 3.7 μb [29], in agreement with our data above 4 GeV/c^2. Though negligible, we have also included the contribution from the Drell–Yan mechanism based on a cross section of 0.04 μb [28]. For the rapidity density of $c\bar{c}$ pairs at mid-rapidity we find:

$$\left.\frac{d\sigma_{c\bar{c}}}{dy}\right|_{y=0} = 118.1 \pm 8.4(\text{stat}) \pm 30.7(\text{syst}) \pm 39.5(\text{model})\ \mu\text{b}. \quad (2)$$

The systematic uncertainties on the data analysis and on the model dependent extrapolation are quoted separately. Using the rapidity distribution from HVQMNR [30] with CTEQ5M [31] PDF as in [5], the total charm cross section is $\sigma_{c\bar{c}} = 544 \pm 39(\text{stat}) \pm 142(\text{syst}) \pm 200(\text{model})$ μb. The extrapolation to 4π adds another 15% systematic uncertainty, which is included in the last term. The charm contribution as shown in Figs. 2 and 4 has been scaled to this result, which is compatible with our previous measurement of single electrons, which gave $\sigma_{c\bar{c}} = 567 \pm 57(\text{stat}) \pm 224(\text{syst})$ μb [5], and with the FONLL prediction of 256^{+400}_{-146} μb [3].

Instead of fixing the bottom cross section, we have tried an alternative approach. We take the shape of the bottom and charm e^+e^- pair distributions from PYTHIA filtered into the PHENIX acceptance and then fit the charm and bottom contribution to the data. For the charm cross section we obtain $\sigma_{c\bar{c}} = 518 \pm 47(\text{stat}) \pm 135(\text{syst}) \pm 190(\text{model})$ μb, consistent with our earlier analysis. The bottom cross section is $\sigma_{b\bar{b}} = 3.9 \pm 2.5(\text{stat})^{+3}_{-2}(\text{syst})$ μb. In addition

to the model dependent systematic uncertainties, which are similar to those on the charm extraction, the subtraction of e^+e^- pairs from the Drell–Yan mechanism contributes an extra 10–20% [32]. We estimate that the combined systematic uncertainty is about 50% and thus similar to the statistical error. The value for the bottom cross section is consistent with our earlier assumption of 3.7 μb as well as with the FONLL prediction of $1.87^{+0.99}_{-0.67}$ μb [3].

In conclusion, we have measured e^+e^- pairs in the mass range from 0 to 8 GeV/c^2 in $p+p$ collisions at $\sqrt{s}=200$ GeV. Within the systematic uncertainties the data can be described by known contributions from light meson decays, mostly measured in the same experiment, as well as from semileptonic decays of mesons carrying heavy flavor. The required charm and bottom production cross sections are consistent with the upper FONLL predictions and with the PHENIX measurement of single electrons.

Acknowledgements

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We acknowledge support from the Department of Energy and NSF (USA), MEXT and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), IN2P3/CNRS, and CEA (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE (India), ISF (Israel), KRF and KOSEF (Korea), MES, RAS, and FAAE (Russia), VR and KAW (Sweden), US CRDF for the FSU, US–Hungarian NSF-OTKA-MTA, and US–Israel BSF.

(Received 30 January 2008; published 15 October 2008)

Neutral pion transverse momentum (p_T) spectra at midrapidity ($|y| \lesssim 0.35$) were measured in Cu + Cu collisions at $\sqrt{s_{NN}} = 22.4$, 62.4, and 200 GeV. Relative to π^0 yields in $p + p$ collisions scaled by the number of inelastic nucleon-nucleon collisions (N_{coll}) the π^0 yields for $p_T \gtrsim 2$ GeV/c in central Cu + Cu collisions are suppressed at 62.4 and 200 GeV whereas an enhancement is observed at 22.4 GeV. A comparison with a jet-quenching model suggests that final state parton energy loss dominates in central Cu + Cu collisions at 62.4 and 200 GeV, while the enhancement at 22.4 GeV is consistent with nuclear modifications in the initial state alone.

DOI: 10.1103/PhysRevLett.101.162301 PACS numbers: 25.75.Dw

The measurement of particle yields at high transverse momentum ($p_T \gtrsim 2$ GeV/c) has played a key role in characterizing the medium created in nucleus-nucleus collisions at the Relativistic Heavy Ion Collider (RHIC) [1,2]. Hadrons produced at sufficiently high p_T result from the interaction of quarks and gluons with high momentum transfer (''hard scattering'') which can be described by perturbative quantum chromodynamics (pQCD). These hadrons are produced as particle jets in the fragmentation of the scattered partons. A scattered parton propagating through a medium with high color-charge density such as a quark-gluon plasma loses energy (''jet quenching'') resulting in hadron yields at high p_T being suppressed [3]. Such a suppression was indeed observed in central Au + Au collisions at $\sqrt{s_{NN}} = 130$ and 200 GeV at RHIC, providing evidence for large color-charge densities in these systems [4–6]. This Letter presents results on the onset of π^0 suppression in Cu + Cu collisions as a function of $\sqrt{s_{NN}}$.

Characteristic properties of the suppression of hadrons at high p_T, e.g., the dependence on p_T and centrality, were studied in detail in Au + Au collisions at $\sqrt{s_{NN}} =$ 200 GeV [5]. However, the energy dependence of hadron production in $A + A$ collisions as predicted by jet-quenching models [7–9] is not well constrained by measurements. Work in this direction was presented in [10–13]. To study the energy dependence of jet quenching it is desirable to measure identified particles in the same colliding system over a large $\sqrt{s_{NN}}$ range and to compare to $p + p$ reference data measured in the same experimental setup. Identified particles provide an advantage over unidentified hadrons in that the interpretation is not complicated by the different contributions from baryons and mesons. The study of Cu + Cu collisions is particularly useful because hadron suppression in Au + Au collisions is observed for rather peripheral collisions with a number of participating nucleons of $N_{\text{part}} \sim 50$–100 [5]. This N_{part} range can be studied with reduced uncertainties in N_{coll} with the smaller ^{63}Cu nucleus.

A critical parameter in jet-quenching models is the initial color-charge density of the medium. By studying Cu + Cu collisions in the range $\sqrt{s_{NN}} \sim 20$–200 GeV this parameter can be varied with essentially no change in transverse size and shape of the reaction zone. Moreover, the enhancement of hadron yields due to multiple soft scattering of the incoming partons (''nuclear k_T'' or ''Cronin enhancement'') is expected to increase towards smaller $\sqrt{s_{NN}}$ [8], thus the interplay between this enhancement and the suppression due to parton energy loss can be studied.

In this Letter we present π^0 yields for Cu + Cu collisions at $\sqrt{s_{NN}} = 22.4$, 62.4, and 200 GeV. Reference data for $p + p$ collisions at $\sqrt{s} = 62.4$ and 200 GeV were taken with the same experiment [14,15]. At $\sqrt{s_{NN}} = 22.4$ GeV a $p + p$ reference was obtained from a parametrization of the world's data on pion production [16].

Neutral pions were measured via their $\pi^0 \to \gamma\gamma$ decay branch with the electromagnetic calorimeter (EMCal) of the PHENIX experiment [17]. The EMCal comprises two calorimeter types: 6 sectors of a lead scintillator sampling calorimeter (PbSc) and 2 sectors of a lead glass Cherenkov calorimeter (PbGl). Each sector is located ~5 m from the beam line and subtends $|\eta| < 0.35$ in pseudorapidity and

$\Delta\varphi = 22.5°$ in azimuth. Owing to the PbSc (PbGl) granularity of $\Delta\eta \times \Delta\varphi = 0.011 \times 0.011$ (0.008×0.008) the probability that the two photon showers from a π^0 decay result in partially overlapping clusters is negligible up to a π^0 p_T of 12 GeV/c (15 GeV/c). The energy calibration of the EMCal was corroborated by the position of the π^0 invariant mass peak, the energy deposited by minimum ionizing charged particles traversing the EMCal (PbSc), and the correlation between the measured momenta of electron and positron tracks identified by the ring-imaging Cherenkov detector and the associated energy deposited in the EMCal. These studies showed that the accuracy of the energy measurement was better than 1.5%.

The total number of analyzed Cu + Cu events for the three energies is shown in Table I. The minimum bias (MB) trigger for all reaction systems was provided by beam-beam counters (BBCs) located at $3.0 \lesssim |\eta| \lesssim 3.9$. The reaction vertex along the beam axis, determined from the arrival time differences in the BBCs, was required to be in the range $|z| \leq 30$ cm. An additional high-p_T trigger was employed in Cu + Cu at $\sqrt{s_{NN}} = 200$ GeV. This trigger was based on the analog energy signal measured in overlapping 4×4 towers of the EMCal in coincidence with the MB trigger condition. It reached an efficiency plateau for photon energies $E \gtrsim 4$ GeV.

The centrality selection in Cu + Cu at $\sqrt{s_{NN}} = 200$ GeV and $\sqrt{s_{NN}} = 62$ GeV was based on the charge signal of the BBCs which is proportional to the charged-particle multiplicity. The BBC trigger efficiency ($\varepsilon_{\text{trig}}$) for these systems was determined with the aid of the HIJING event generator and a full GEANT simulation of the BBC response (see Table I). At $\sqrt{s_{NN}} = 22.4$ GeV centrality classes were defined based on the charged-particle multiplicity N_{PC1} measured with the pad chamber (PC1) detector ($|\eta| < 0.35$). The measured N_{PC1} distribution was accurately reproduced in a Glauber Monte Carlo calculation [18] and centrality classes were determined by identical cuts on the measured and simulated PC1 multiplicities. In the Glauber calculation N_{PC1} was assumed to scale with N_{part}^{α} and multiplicity fluctuations were described with a negative binomial distribution. Varying α and the negative binomial distribution parameters, the measured N_{PC1} distribution could be reproduced with $\varepsilon_{\text{trig}}$ values between 0.75 and 0.90. Possible autocorrelations between N_{PC1} and the π^0 yield resulting from measuring these quantities in the same pseudorapidity range were studied with HIJING and found to be negligible. Results of the Glauber calculations for $\sqrt{s_{NN}} = 22.4$, 62.4, and 200 GeV are shown in Table II.

Neutral pion yields were measured on a statistical basis by calculating the invariant mass of all photon pairs in a given event and counting those within the π^0 mass range. The background of combinatorial pairs was calculated by pairing photon hits from different events. Only photon pairs with an energy asymmetry $|E_1 - E_2|/(E_1 + E_2) < 0.7$ were accepted. The raw π^0 yields were corrected for the geometrical acceptance and reconstruction efficiency. The latter takes into account the loss of π^0's due to photon identification cuts, the energy asymmetry cut, inactive detector areas, and photon conversions. Moreover, it corrects the distortion of the π^0 spectrum which results from the finite energy resolution in conjunction with the steeply falling spectra and shower overlap effects. The reconstruction efficiency was determined in a Monte Carlo simulation and is typically on the order of $\varepsilon_{\pi^0} \approx 0.7$–$0.8$. For Cu + Cu at $\sqrt{s_{NN}} = 200$ GeV the transition between the minimum bias and the high-p_T sample occurs at $p_T = 8$ GeV/c. The final spectra were calculated as the weighted average of the PbSc and PbGl results, which agree within 15%, a deviation well covered by the uncertainties.

The main systematic uncertainties of the π^0 spectra result from the π^0 peak extraction, the reconstruction efficiency, and the EMCal energy calibration. For $p_T \gtrsim 2$ GeV/c the peak extraction uncertainty is ~4% for all systems, approximately independent of p_T. The uncertainty in the reconstruction efficiency was estimated to be ~15% for the three Cu + Cu analyses. The uncertainty in the EMCal energy scale of 1.5% translates into an uncer-

TABLE I. Cu + Cu data sets presented with the number of analyzed events. For the data taken with the high-p_T trigger, the number of equivalent minimum bias events is given. At 22.4 GeV the given $\varepsilon_{\text{trig}}$ range indicates the uncertainty.

$\sqrt{s_{NN}}$ (GeV)	$\varepsilon_{\text{trig}}$	$N_{\text{evt}}^{\text{MB}}$	$N_{\text{evt}}^{\text{high}-p_T}$ ($N_{\text{evt}}^{\text{sampled}}$)
22.4	75%–90%	5.8×10^6	···
62.4	(88 ± 4)%	192×10^6	···
200	(94 ± 2)%	794×10^6	15.5×10^6 (4720×10^6)

TABLE II. Glauber Monte Carlo calculations for Cu + Cu collisions at 22.4, 62.4, and 200 GeV using inelastic cross sections of 32.3, 35.6, and 42 mb, respectively. The N_{coll} systematic uncertainty at 62.4 and 200 GeV is ~12%, almost independent of N_{coll}. At 22.4 GeV the relative uncertainty of N_{coll} can be parametrized as $0.094 + 0.173e^{-0.0272N_{\text{coll}}}$.

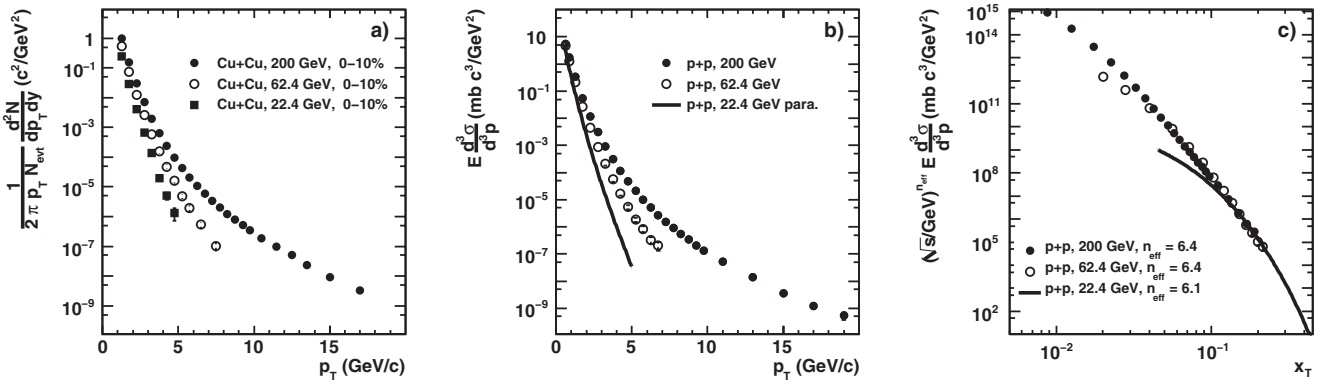

FIG. 1. For $\sqrt{s_{NN}} = 22.4$, 62.4, and 200 GeV are plotted (a) invariant π^0 yields in central Cu + Cu collisions, (b) invariant π^0 cross sections in $p + p$ collisions [14–16], and (c) the $p + p$ data plotted as a function of $x_T = 2p_T/\sqrt{s}$, which exhibit an approximate x_T scaling. The error bars represent the quadratic sum of the statistical and total systematic uncertainties.

tainty in the yields that increases from ~8% at $p_T = 3$ GeV/c to 15% at $p_T = 6$ GeV/c. The part of the spectra in Cu + Cu at 200 GeV measured with the high-p_T trigger is subject to an additional uncertainty of 10% related to the trigger efficiency.

PHENIX has not yet acquired a $p + p$ data set at $\sqrt{s} = 22.4$ GeV. In [16] the world's data on charged and neutral pion production for $21.7 \leq \sqrt{s} \leq 23.8$ GeV were scaled to $\sqrt{s} = 22.4$ GeV and fit with $Ed^3\sigma/d^3p = A(1 + p_T/p_0)^n(1 - 2p_T/\sqrt{s})^m$ where $A = 174.4$ mb GeV$^{-2}c^3$, $p_0 = 2.59$ GeV/c, $n = -17.43$, $m = 6.15$. The scaling correction was determined with a next-to-leading-order pQCD calculation. The correction is largest for $\sqrt{s} = 23.8$ GeV and reduces these spectra by ~30%. The systematic uncertainty of the fit increases from ~12% at $p_T = 1.5$ GeV/c to ~23% at $p_T = 4.0$ GeV/c [16].

The π^0 p_T spectra for $p + p$ and central Cu + Cu collisions (0%–10% of $\sigma_{\text{inel}}^{\text{Cu+Cu}}$) at $\sqrt{s_{NN}} = 22.4, 62.4$ [14], and 200 GeV [6] are shown in Figs. 1(a) and 1(b). At sufficiently high p_T where pion production in $p + p$ collisions is dominated by fragmentation of jets, QCD predicts a scaling law $\sqrt{s}^{n_{\text{eff}}(x_T,\sqrt{s})} Ed^3\sigma/d^3p = G(x_T)$ with a universal function $G(x_T)$ where $x_T = 2p_T/\sqrt{s}$ [19]. Figure 1(c) shows that such a scaling in x_T is indeed observed for $p + p$ collisions at 22.4, 62.4, and 200 GeV, consistent with previous observations [20]. The x_T values at which the universal curve $G(x_T)$ is reached indicate that particle production is dominated by hard processes for $p_T \gtrsim 2$ GeV/c.

Nuclear effects on high-p_T π^0 production can be quantified with the nuclear modification factor

$$R_{AA}(p_T) = \frac{(1/N_{AA}^{\text{evt}})d^2N_{AA}/dp_T dy}{\langle T_{AA}\rangle d^2\sigma_{pp}/dp_T dy}, \qquad (1)$$

where $\langle T_{AA}\rangle = \langle N_{\text{coll}}\rangle/\sigma_{pp}^{\text{inel}}$. Figure 2 shows $R_{AA}(p_T)$ for the 0%–10% most central Cu + Cu collisions. The suppression at 62.4 GeV ($R_{AA} \approx 0.6$ for $p_T \gtrsim 3$ GeV/c) and 200 GeV ($R_{AA} \approx 0.5$–0.6 for $p_T \gtrsim 3$ GeV/c) is consistent with expectations from parton energy loss. The $R_{AA} > 1$ in Cu + Cu at 22.4 GeV is similar to the enhancement by a factor ~1.5 (at $p_T \approx 3$ GeV/c) observed in p + W relative to p + Be collisions at $\sqrt{s_{NN}} = 19.4$ and 23.8 GeV [21]. For similar N_{part} values the R_{AA} in Cu + Cu at 22.4 GeV agrees with the R_{AA} in Pb + Pb collisions at 17.3 GeV [12].

For $p_T \gtrsim 3$ GeV/c the measured R_{AA} values at 62.4 and 200 GeV are consistent with a numerically evaluated parton energy-loss model described in [22,23]; see Fig. 2. This calculation takes into account shadowing from coherent final state interactions in nuclei [24], Cronin enhancement

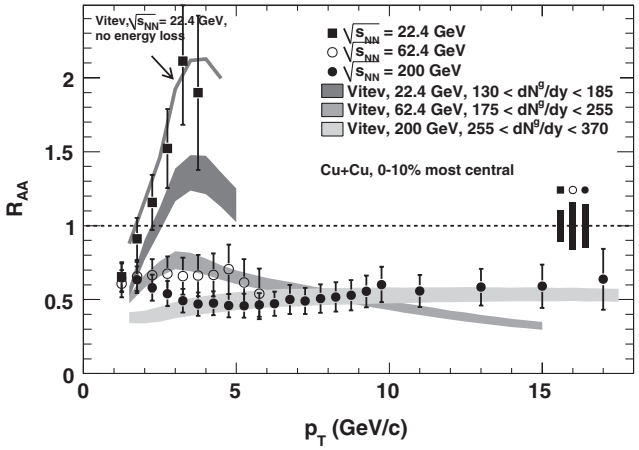

FIG. 2. Measured π^0 R_{AA} are compared to a jet quenching calculation [22,23]. The error bars (here and in Fig. 3) represent the quadratic sum of the statistical and the point-to-point uncorrelated and correlated systematic uncertainties. For $\sqrt{s_{NN}} = 22.4$ GeV the error bars also include the systematic error of the fit of the $p + p$ spectra. The boxes around unity indicate uncertainties related to $\langle N_{\text{coll}}\rangle$ and absolute normalization. The bands for the calculation correspond to the assumed range of the initial gluon density dN^g/dy.

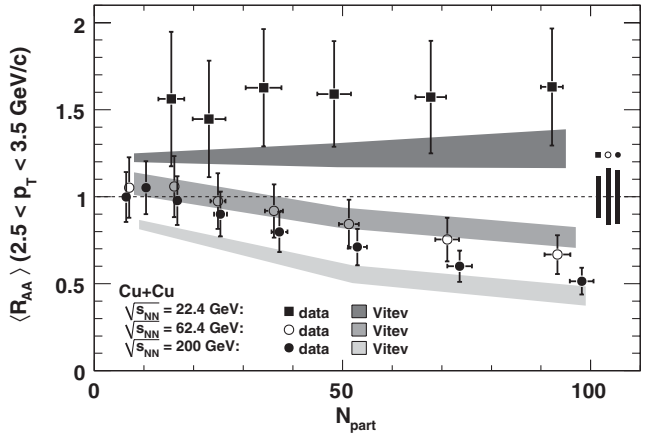

FIG. 3. The average R_{AA} in the interval $2.5 < p_T < 3.5$ GeV/c as a function of centrality for Cu + Cu collisions at $\sqrt{s_{NN}} =$ 22.4, 62.4, and 200 GeV. The shaded bands represent jet-quenching calculations at three discrete centralities ($N_{\text{part}} \sim$ 10, 50, 100) [22,23]. The boxes around unity represent the normalization and $\langle N_{\text{coll}} \rangle$ uncertainties for a typical N_{coll} uncertainty of 12%.

[25], initial state parton energy loss in cold nuclear matter [26], and final state parton energy loss in dense partonic matter [9,22,23]. The Cronin enhancement measured in $p + A$ collisions is described well by this model [25]. The initial gluon rapidity density dN^g/dy which characterizes the medium was not fit to the R_{AA} values, but instead was constrained by measured charged-particle multiplicities and the assumption of parton-hadron duality ($dN^g/dy = \kappa d\eta/dy dN_{ch}/d\eta$ with $\kappa = 3/2 \pm 30\%$ and $d\eta/dy \equiv 1.2$ at all energies) [22,23]. The average fractional energy losses $\Delta E/E$ for a quark (gluon) with $E =$ 6 GeV corresponding to the dN^g/dy ranges in Fig. 2 are 0.13–0.19 (0.29–0.42), 0.16–0.20 (0.35–0.44), 0.20–0.28 (0.44–0.63) in central Cu + Cu collisions at 22.4, 62.4, and 200 GeV, respectively [23]. For Cu + Cu at $\sqrt{s_{NN}} =$ 22.4 GeV the calculation is also shown without final state parton energy loss. The measurement is consistent with this calculation but does not rule out a scenario with parton energy loss.

Figure 3 shows that the π^0 suppression in the range $2.5 < p_T < 3.5$ GeV/c increases towards more central Cu + Cu collisions for $\sqrt{s_{NN}} = 62.4$, 200 GeV. On the other hand, R_{AA} at $\sqrt{s_{NN}} = 22.4$ GeV remains approximately constant as a function of N_{part}, suggesting either that the Cronin enhancement depends only weakly on centrality or that in this energy range parton energy loss is offset by the larger effect of Cronin enhancement.

In conclusion, high-p_T π^0 yields in central Cu + Cu collisions at 62.4 and 200 GeV are suppressed, suggesting that parton energy loss is significant, while at 22.4 GeV the π^0 yields for $p_T \gtrsim 2$ GeV/c are not suppressed. The R_{AA} measured in central Cu + Cu at 22.4 GeV is consistent with Cronin enhancement alone but does not rule out parton energy-loss effects. These measurements provide a unique constraint for jet-quenching models and demonstrate that parton energy loss starts to prevail over the Cronin enhancement between $\sqrt{s_{NN}} = 22.4$ and 62.4 GeV.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We thank Ivan Vitev for providing the jet-quenching calculations. We acknowledge support from the Office of Nuclear Physics in DOE Office of Science, NSF, and a sponsored research grant from Renaissance Technologies (U.S.), MEXT and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), MSMT (Czech Republic), IN2P3/CNRS, and CEA (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE (India), ISF (Israel), KRF and KOSEF (Korea), MES, RAS, and FAAE (Russia), VR and KAW (Sweden), U.S. CRDF for the FSU, U.S.-Hungary Fulbright, and U.S.-Israel BSF.

(Received 30 January 2008; published 2 July 2008)

Azimuthal angle ($\Delta\phi$) correlations are presented for a broad range of transverse momentum ($0.4 < p_T < 10$ GeV/c) and centrality (0–92%) selections for charged hadrons from dijets in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. With increasing p_T, the away-side $\Delta\phi$ distribution evolves from a broad and relatively flat shape to a concave shape, then to a convex shape. Comparisons with $p + p$ data suggest that the away-side distribution can be divided into a partially suppressed "head" region centered at $\Delta\phi \sim \pi$, and an enhanced "shoulder" region centered at $\Delta\phi \sim \pi \pm 1.1$. The p_T spectrum for the associated hadrons in the head region softens toward central collisions. The spectral slope for the shoulder region is independent of centrality and trigger p_T. The properties of the near-side distributions are also modified relative to those in $p + p$ collisions, reflected by the broadening of the jet shape in $\Delta\phi$ and $\Delta\eta$, and an enhancement of the per-trigger yield. However, these modifications seem to be limited to $p_T \lesssim 4$ GeV/c, above which both the hadron pair shape and per-trigger yield become similar to $p + p$ collisions. These observations suggest that both the away- and near-side distributions contain a jet fragmentation component which dominates for $p_T \gtrsim 5$ GeV/c and a medium-induced component which is important for $p_T \lesssim 4$ GeV/c. We also quantify the role of jets at intermediate and low p_T through the yield of jet-induced pairs in comparison with binary scaled $p + p$ pair yield. The yield of jet-induced pairs is suppressed at high pair proxy energy (sum of the p_T magnitudes of the two hadrons) and is enhanced at low pair proxy energy. The former is consistent with jet quenching; the latter is consistent with the enhancement of soft hadron pairs due to transport of lost energy to lower p_T.

I. INTRODUCTION

High transverse momentum (p_T) partons are informative probes of the high energy density matter created in nuclear collisions at the BNL Relativistic Heavy-Ion Collider (RHIC). These partons lose a large fraction of their energy in the matter prior to forming final state hadrons. Such an energy loss is predicted to lead to a reduction of both single hadron and correlated dihadron yields at high p_T [1–3], a phenomenon known as jet quenching. Indeed, current results for high p_T have revealed a strong suppression of inclusive hadron yields [4–6], as well as the suppression of correlated away-side hadron pairs [7].

Despite this strong suppression, particle production for $p_T \gtrsim 5$ GeV/c appears to have a significant contribution from in-vacuum jet fragmentation. This is suggested by a p_T-independent suppression factor for single hadrons [4–6,8], which implies a $p + p$-like power law spectral shape in Au+Au collisions, and similar π^0 to η meson [9,10] and proton to pion [6,11] ratios between Au+Au and $p + p$ collisions. More direct evidence has been provided by high-p_T dihadron azimuthal angle ($\Delta\phi$) correlation measurements. In particular, our current measurements, as well as prior ones [12,13], reveal characteristic jet-like peaks for the near-side ($\Delta\phi \sim 0$) and the away-side ($\Delta\phi \sim \pi$) at high p_T.

In most energy loss models, the stopping power of the medium is normally characterized by the transport coefficient $\hat{q}$, defined as the squared average momentum transfer from the medium to the hard parton per unit path length. However, because of the steeply falling parton spectra and strong jet quenching, the observed high-p_T single hadrons and hadron pairs mainly come from (di)jets that suffer minimal interaction with the medium. Thus, the overall suppression factor is sensitive to the full energy loss probability distribution instead of just the average energy loss itself. In fact, simple calculations [14] with different energy loss probability distributions have been shown to match the data quite well. However, the extracted $\langle\hat{q}\rangle$ values are sensitive to the theoretical models and their associated assumptions [15]. Additional experimental constraints on the dynamics of the energy loss processes are clearly needed.

To improve our understanding of the parton-medium interactions, it is important to study the fate of partons that suffer energy loss in the medium. These partons are quenched by the medium and their energy is believed to be transported to lower-p_T hadrons ($p_T \lesssim 4$ GeV/c). Prior measurements [7,16–20] in this p_T region, as well as the present study, indicate strong modifications of the near- and away-side $\Delta\phi$ distributions. The near-side jet-induced pairs peak at $\Delta\phi \sim 0$, but the peak is broadened and enhanced with respect to $p + p$ collisions. The away-side jet-induced pairs are observed to peak at $\Delta\phi \sim \pi \pm 1.1$ [13,18,19] with a local minimum at $\Delta\phi \sim \pi$. These modification patterns reflect characteristics of the energy transport of the quenched partons in both p_T and $\Delta\phi$. Many mechanisms for this energy transport have been proposed for the near-side [21–28] and away-side [23–25,29–36].

Such energy transport is expected to enhance jet contributions to the production of low-p_T hadrons. However, jet-induced hadron pair correlations can be affected by soft processes such as hydrodynamic flow [37] and quark coalescence [38–41], which dominate hadron production in the intermediate-p_T region. The coupling of partons with hydrodynamic flow could modify the jet shape and yield. Similarly, quark coalescence could modify the particle composition in the near- and away-side jets [42,43]. Therefore, detailed correlation studies for $p_T \lesssim 4$ GeV/c can improve our knowledge of the interplay between soft and hard processes for hadron production.

In this paper, we present a detailed survey of the trigger p_T, partner p_T, and centrality dependence of the near- and away-side jet shapes and yields from Au+Au collisions.

†PHENIX spokesperson: jacak@skipper.physics.sunysb.edu

These measurements provide a comprehensive overview of the different physical features that come into play for different p_T ranges, and provide new insights on the interplay between the processes leading to jet energy loss and the response of the medium to the lost energy. In addition, they allow a detailed study of the similarities and differences between the correlation patterns for the near- and away-side jets. When coupled with inclusive hadron production, these measurements also allow quantification of the role of jets at intermediate p_T, where the particle production is believed to be dominated by the soft processes.

The results reported here comprise significant extensions to results published earlier [13,19]. In Sec. II, we introduce variables used to quantify the jet properties and their in-medium modifications. In Sec. III, we present data analysis details, jet signal extraction and background subtraction, and several sources of systematic errors related to the measurements. The main results are presented in Sec. IV, and model comparisons and discussions are given in Sec. V. Several technical issues related to the correlation analysis are addressed in Appendixes A–C, and tabulated data are given in Appendix A.

II. JET AZIMUTHAL CORRELATIONS

The defining characteristic of a jet is the collimated production of hadrons in the direction of a fragmenting parton. Traditionally, such energetic jets have been identified using standard jet reconstruction algorithms. However, direct jet reconstruction in heavy-ion collisions is difficult because of the large amount of soft background. Measurements in a relatively limited acceptance also pose additional challenges because of possible leakage of the jet fragments outside of the detectors acceptance.

The two-particle (dihadron) relative azimuthal angle ($\Delta\phi$) correlation technique provides an alternative approach for accessing the properties of jets. Two classes of hadrons, trigger hadrons (denoted as type a) and partner hadrons (denoted as type b), typically from different p_T ranges, are correlated with each other. Jet properties are extracted on a statistical basis from the $\Delta\phi$ distribution built of many events. This approach overcomes problems due to background and limited acceptance and allows the study of jets to be extended to low p_T where soft processes dominate.

To leading order in QCD, high-p_T jets are produced back-to-back in azimuth. This back-to-back correlation is, however, smeared by the fragmentation process and initial and final state radiation, to give a characteristic $\Delta\phi$ distribution schematically shown in Fig. 1 [44]. Hadron pairs from the same jet (near-side) dominate at $\Delta\phi = \phi^a - \phi^b \sim 0$, and those from back-to-back dijets (away-side) tend to appear at $\Delta\phi \sim \pi$.

Two observables commonly exploited in dihadron correlation studies are the hadron-pair yield (the rate of jet-induced hadron pairs per event, JPY) and the per-trigger yield (jet-induced hadron-pair yield divided by trigger yield, $Y_{\text{jet_ind}}$) in a given event sample. The former is related to the two-particle cross section for jet production; the latter is related to the ratio

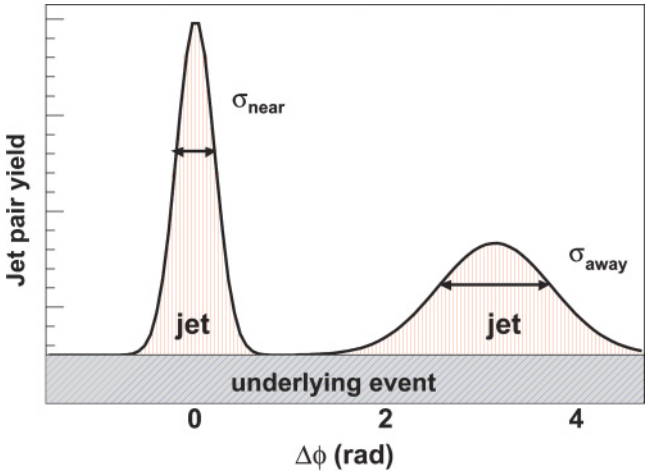

FIG. 1. (Color online) Cartoon of hadron pair distribution in $\Delta\phi$ for $p + p$ collisions. It has two peaks corresponding to near- and away-side jet, and a flat component representing the underlying event pairs.

of the two-particle to single-particle cross sections:

$$\text{JPY}\left(p_T^a, p_T^b, \Delta\phi\right) \equiv \frac{1}{N_{\text{evts}}} \frac{d^3N^{ab}}{dp_T^a dp_T^b d\Delta\phi} = \frac{1}{\sigma_{\text{tot}}} \frac{d^3\sigma_{\text{jet_ind}}}{dp_T^a dp_T^b d\Delta\phi}, \tag{1}$$

$$Y_{\text{jet_ind}}\left(p_T^a, p_T^b, \Delta\phi\right) \equiv \text{JPY}\left(p_T^a, p_T^b, \Delta\phi\right) \Big/ \frac{dN^a}{N_{\text{evts}} dp_T^a} = \frac{d^3\sigma_{\text{jet_ind}}}{dp_T^a dp_T^b d\Delta\phi} \Big/ \frac{d\sigma}{dp_T^a}, \tag{2}$$

where N^{ab} is the number of jet-induced hadron pairs, N_{evts} is the number of events, and σ_{tot} is the semi-inclusive cross section for that event sample. Thus, JPY is simply the product of the per-trigger yield and the number of triggers. To first order, the two-particle cross section for the near-side jet is governed by the dihadron fragmentation function. By contrast, the cross section for the away-side jet is governed by two independent fragmentation functions; i.e., one parton produces a hadron with p_T^a and the other scattered parton produces a hadron with p_T^b.

In $A + A$ collisions, the single-hadron and dihadron cross sections can be modified by the medium. This modification can be quantified by comparing the yield in $A + A$ collisions to that for $p + p$ collisions. Thus, modification to the single-hadron cross section is characterized by the nuclear modification factor R_{AA}

$$R_{AA}(p_T) = \frac{1/\sigma_{A+A}(d\sigma^{A+A}/dp_T)}{\langle N_{\text{coll}}\rangle/\sigma_{p+p}(d\sigma^{p+p}/dp_T)}, \tag{3}$$

where σ_{A+A} and σ_{p+p} are the semi-inclusive cross sections in $A + A$ and $p + p$ collisions, respectively. $\langle N_{\text{coll}}\rangle$ is the average number of binary collisions for a given centrality selection in $A + A$ collisions. Modification of the dihadron cross section

can be characterized by J_{AA}, which is defined as

$$J_{AA}(p_T^a, p_T^b, \Delta\phi) = \frac{\mathrm{JPY}^{A+A}}{\langle N_{\mathrm{coll}}\rangle\, \mathrm{JPY}^{p+p}} = \frac{1}{\sigma_{A+A}} \frac{d^3\sigma_{\mathrm{jet_ind}}^{A+A}}{dp_T^a\, dp_T^b\, d\Delta\phi} \Big/ \times \frac{\langle N_{\mathrm{coll}}\rangle}{\sigma_{p+p}} \frac{d^3\sigma_{\mathrm{jet_ind}}^{p+p}}{dp_T^a\, dp_T^b\, d\Delta\phi}. \quad (4)$$

In the absence of nuclear effects, both the single-hadron and dihadron cross sections from jets are expected to scale with $\langle N_{\mathrm{coll}}\rangle$. Therefore, R_{AA} and J_{AA} should be equal to unity.

The medium modifications of jets are also characterized by the per-trigger yield and its corresponding modification factor I_{AA}, that is,

$$I_{AA}(p_T^a, p_T^b) = \frac{Y_{\mathrm{jet_ind}}^{A+A}(p_T^a, p_T^b)}{Y_{\mathrm{jet_ind}}^{p+p}(p_T^a, p_T^b)}. \quad (5)$$

In general, the value of I_{AA} depends on modifications to both the hadron-pair yield and the trigger yield. For high-p_T correlation measurements, the per-trigger yield is a convenient choice, since each jet typically produces at most one high-p_T trigger. Because of the steeply falling parton spectrum, the probability of having a high-p_T parton that produces multiple trigger hadrons is small. Thus the per-trigger yield effectively represents the per-jet yield in $p + p$ collisions, and I_{AA} represents the modification of the partner yield per-jet. For intermediate and low p_T, however, jet fragmentation is not the only source of triggers, and this can lead to an artificial reduction of the per-trigger yield (see discussion in Sec. IV E). For such situations, J_{AA} is a more robust variable for correlation analysis since it is only sensitive to the modification of jet-induced hadron pairs.

JPY and J_{AA} are symmetric with respect to p_T^a and p_T^b. By contrast, the per-trigger yield and I_{AA} are not because of the appearance of the normalization factor N^a in Eq. (2). This normalization factor is the only distinction between triggers and the partners in this analysis. In addition, JPY can be expressed in terms of the per-trigger yield and the inclusive yield as

$$\mathrm{JPY}(p_T^a, p_T^b) = Y_{\mathrm{jet_ind}}(p_T^a, p_T^b) \frac{dN^a}{N_{\mathrm{evts}} dp_T^a} = Y_{\mathrm{jet_ind}}(p_T^b, p_T^a) \frac{dN^b}{N_{\mathrm{evts}} dp_T^b}. \quad (6)$$

Similarly, J_{AA} can be expressed in terms of R_{AA} and I_{AA} as

$$J_{AA}(p_T^a, p_T^b) = I_{AA}(p_T^a, p_T^b) R_{AA}(p_T^a) = I_{AA}(p_T^b, p_T^a) R_{AA}(p_T^b). \quad (7)$$

Thus, $I_{AA}(p_T^b, p_T^a)$ can be calculated from $I_{AA}(p_T^a, p_T^b)$, $R_{AA}(p_T^a)$, and $R_{AA}(p_T^b)$.

In the current analysis, the in-medium modifications of the jet shape and yield are characterized via comparisons of the per-trigger yield and hadron-pair yield in Au+Au and $p + p$ collisions, i.e., via I_{AA} and J_{AA}. As discussed earlier, these quantities are defined in their differential form in $\Delta\phi$, p_T^a, and p_T^b. Operationally, this means that the hadron-pair yields and the per-trigger yields are measured in a finite p_T range and/or integrated over a limited $\Delta\phi$ range. I_{AA} and J_{AA} are then obtained from these integrated yields.

III. EXPERIMENTAL ANALYSIS

A. Dataset and centrality

The results presented in this article are based on three datasets collected with the PHENIX detector [45] at $\sqrt{s_{NN}} =$ 200 GeV, during the 2004–2005 RHIC running periods. The first is comprised of a minimum-bias (MB) Au+Au dataset triggered by the beam-beam counters (BBCs) and the zero-degree calorimeters (ZDCs) and taken in 2004. The second is a MB $p + p$ dataset triggered by the BBCs and taken in 2005, and the third is a level-1 triggered (LVL1) $p + p$ dataset also obtained in 2005. The level-1 trigger requirement is an energy threshold of 1.4 GeV in 4×4 electromagnetic calorimeter (EMC) towers in coincidence with the BBC trigger [46]. The MB and LVL1 $p + p$ datasets serve as baseline measurements for the Au+Au dataset; they are used to select triggers for $p_T < 5$ and $p_T > 5$ GeV/c, respectively.

The collision vertex along the beam direction, z, was measured by the BBCs. After making an offline vertex cut of $|z| < 30$ cm and selecting good runs, a total of 840 million or 136 $\mu\mathrm{b}^{-1}$ Au+Au events were obtained. This is a 30 times higher than obtained in a previous analysis [18]. The total statistics for MB $p + p$ and LVL1 $p + p$ datasets are equivalent to 73 nb^{-1} and 2.5 pb^{-1} sampled luminosities, respectively.

The event centrality was determined via cuts in the space of BBC charge vs ZDC energy [47]. The efficiency of the MB triggered events is estimated to be $92.2^{+2.5}_{-3.0}$% of the total Au+Au inelastic cross section (6.9 b) [6]. To optimize the p_T reach of our results, relatively *coarse* centrality selections of 0–20%, 20–40%, 40–60%, and 60–92.2% were chosen. However for $p_T < 4$ GeV/c, excellent statistical significance of the measurements allows the results to be presented in *fine* centrality selections of 0–5%, 5–10%, 10–20%, 20–30%, 30–40%, 40–50%, 50–60%, 60–70%, and 70–92.2%.

A Glauber model Monte Carlo simulation [48,49] that includes the responses of the BBCs and ZDCs was used to estimate the average number of binary collisions $\langle N_{\mathrm{coll}}\rangle$ and participating nucleons $\langle N_{\mathrm{part}}\rangle$ for each centrality class. These values are listed in Table I.

B. Tracking and background estimation

Charged hadrons were reconstructed in the two central arms of PHENIX, each covering −0.35 to 0.35 in pseudorapidity and 90° in azimuth. Tracks were measured outside the PHENIX central magnetic field by the drift chambers, located at a radius of 2.0 m from the vertex, and two layers of multiwire proportional chamber (PC1 and PC3), located 2.5 and 5.0 m, respectively, from the vertex [47]. The momentum resolution was determined to be 0.7% ⊕ 1.0% p (GeV/c) [6].

TABLE I. Average number of nucleon-nucleon collisions $\langle N_{\rm coll}\rangle$ and participant nucleons $\langle N_{\rm part}\rangle$ for several centrality classes. $\langle N_{\rm coll}\rangle$ and $\langle N_{\rm part}\rangle$ are obtained from a Glauber Monte Carlo simulation of the response of the BBCs and ZDCs in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The errors for these centrality classes are correlated.

Centrality	$\langle N_{\rm coll}\rangle$	$\langle N_{\rm part}\rangle$

To reduce background particles that do not originate from the event vertex, such as weak decays and conversion electrons, tracks were required to have a matching hit within a $\pm 2.3\sigma$ window in PC3. For $p_T > 4$ GeV/c, an additional matching hit at the EMC was required to suppress background tracks that randomly associate with a hit in PC3 [6]. For triggers with $p_T > 5$ GeV/c, a p_T-dependent energy cut in the EMC and a tight $\pm 1.5\sigma$ matching cut at the PC3 were applied to reduce the physical background from post-field photon conversions and weak decays to a level $<10\%$ of real tracks [50]. This energy cut helps to suppress any level-1 bias for the LVL1 $p + p$ dataset. We checked the consistency between the MB and LVL1 $p + p$ datasets for triggers with $p_T > 5$ GeV/c by performing the same analysis separately on the two $p + p$ datasets. Any remaining biases due to level-1 trigger selection were found to be within the quoted errors. With these cuts, the background level for triggers was estimated to be $\lesssim 5\%$ for $p_T \lesssim 3$ GeV/c, and increases to $\sim 10\%$ for $p_T > 4$ GeV/c [6]. A p_T-dependent correction to the per-trigger yield was used to account for this background.

For partner hadrons, the same matching cuts used for trigger hadrons were applied. However, the p_T-dependent energy cut for $5-10$ GeV/c partners was found to be unnecessary. The jet-associated partner charged hadron spectrum is much flatter than that for the trigger hadrons. Thus, the background contamination of partners is much reduced relative to that for the trigger hadrons. In addition, the background tracks contributing to combinatoric pairs do not affect the jet signal and can be subtracted out.

A full GEANT-based simulation of PYTHIA-generated jet events in the PHENIX detector, as detailed in Ref. [50], was used to evaluate the effects of this high-p_T background for partner hadrons. Partner yields were extracted following the same procedures used for the actual data analysis. These were then compared with the input partner hadron spectra. For high-p_T triggered events, the background contributions to the partner hadrons were found to be less than 10% for integrated partner yields in the 5–10 GeV/c cut.

The single particle efficiency for triggers and partners, ϵ^a and ϵ^b in Eqs. (15) and (17), were determined such that the single unidentified hadron p_T spectra reproduce the previously published data for Au+Au [6] and $p + p$ [51]. It includes detector acceptance, reconstruction efficiency, occupancy, and background [6]. The detector acceptance and reconstruction efficiency were estimated with a Monte Carlo simulation in which simulated single tracks were reconstructed in the PHENIX detector, using the same analysis chain employed for the real data. The efficiency loss due to detector occupancy in Au+Au collisions was estimated by reconstructing simulated single tracks embedded into real events. More details can be found in the Au+Au [6] and $p + p$ [51] analyses.

C. Jet signal extraction

The dihadron correlation technique is commonly employed in PHENIX for jet measurements, because it surmounts the challenges posed by the detector's limited azimuthal acceptance for single hadrons. Even so, physical correlations due to anisotropic production of hadrons relative to the reaction plane in Au+Au collisions, i.e., the elliptic flow, need to be distinguished from the jet correlations. In what follows, we lay out the framework for our correlation analysis and an associated decomposition procedure used to separate the elliptic flow and jet correlation contributions. We define the azimuthal correlation function as

$$C(\Delta\phi) \equiv \frac{N^{\rm same}(\Delta\phi)}{N^{\rm mixed}(\Delta\phi)}, \tag{8}$$

where $N^{\rm same}(\Delta\phi)$ and $N^{\rm mixed}(\Delta\phi)$ are pair distributions from the same and mixed events, respectively. Each mixed event is constructed by combining triggers from a real event with partners from a different, randomly selected event with similar centrality and collision vertex as the real event.

The shape of the mixed-event pair distribution reflects the pair $\Delta\phi$ acceptance of the PHENIX detector, but it does not contain physical correlations. The integral of mixed-event pairs reflects the rate of the combinatoric pairs,

$$\int d\Delta\phi N^{\rm mixed}(\Delta\phi) = N_{\rm evts}\langle n^a\rangle\langle n^b\rangle, \tag{9}$$

where $N_{\rm evts}$ is the number of events and $\langle n^a\rangle$, $\langle n^b\rangle$ represent the average number of triggers and partners per event in the PHENIX acceptance. Both $N^{\rm same}(\Delta\phi)$ and $N^{\rm mixed}(\Delta\phi)$ are affected by the pair efficiency, which cancels out in the ratio (see Appendix A). Therefore, the correlation function in Eq. (8) contains only physical correlations.

The elliptic flow correlation leads to a harmonic modulation of the combinatoric pair distribution by a factor that is proportional to $(1 + 2v_2^a v_2^b \cos 2\Delta\phi)$, where v_2^a and v_2^b are the average elliptic flow values for triggers and partners, respectively. To extract the jet-induced pairs, we follow a two-source ansatz in which each particle is assumed to come from a jet-induced source and an underlying event containing

elliptic flow. The pair distribution can be expressed as

$$N^{\text{same}}(\Delta\phi) = \xi\left(1 + 2v_2^a v_2^b \cos 2\Delta\phi\right) N^{\text{mixed}}(\Delta\phi) + \text{Jet}(\Delta\phi) \tag{10}$$

Where the Jet($\Delta\phi$) represents all pairs from (di)jets. The integral of N^{same} can be written as

$$\int d\Delta\phi N^{\text{same}}(\Delta\phi) = N_{\text{evts}}\langle n^a n^b\rangle + \int d\Delta\phi \text{Jet}(\Delta\phi). \tag{11}$$

Comparing to Eq. (9), we obtain

$$\xi = \frac{\langle n^a n^b\rangle}{\langle n^a\rangle\langle n^b\rangle}. \tag{12}$$

Thus, ξ is simply the ratio of the trigger-partner combinatoric rate in the same event to that in mixed events, which can be bigger than unity because of centrality smearing (see discussion in Sec. III E). An alternative approach used to fix ξ is to assume that the jet function has zero yield at its minimum $\Delta\phi_{\text{min}}$ (ZYAM) [18,52].

Finally, the ratio of jet-induced pairs to combinatoric pairs from mixed events, the jet-induced hadron-pair ratio (JPR) is given by

$$\begin{aligned}\text{JPR}(\Delta\phi) &\equiv \frac{\text{Jet}(\Delta\phi)}{N^{\text{mixed}}(\Delta\phi)} \\ &= \frac{N^{\text{same}}(\Delta\phi)}{N^{\text{mixed}}(\Delta\phi)} - \xi\left(1 + 2v_2^a v_2^b \cos 2\Delta\phi\right).\end{aligned} \tag{13}$$

A representative correlation function is given in Fig. 2 for 0–5% Au+Au collisions and for triggers and partners in 2–3 and 1–2 GeV/c, respectively. It shows a peak around $\Delta\phi \sim 0$ and a broad structure around $\Delta\phi \sim \pi$. The dashed line indicates the estimated elliptic flow modulated background via the ZYAM method. The area between the data points and the dashed line reflects the jet-induced pair ratio. It is only a few percent relative to the background level.

We define $\varepsilon^a, \varepsilon^b$ as the single particle efficiency within the PHENIX pseudorapidity acceptance ($|\eta| < 0.35$). The true numbers of triggers and partners are given by

$$\langle n_0^a\rangle = \langle n^{\text{a}}\rangle/\varepsilon^a; \quad \langle n_0^b\rangle = \langle n^b\rangle/\varepsilon^b. \tag{14}$$

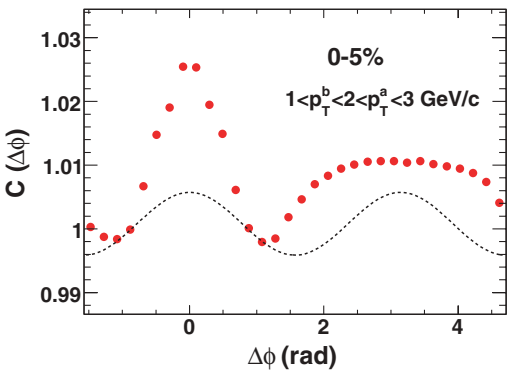

FIG. 2. (Color online) Correlation function for $2 < p_T^a < 3$, $1 < p_T^b < 2$ GeV/c in 0–5% Au+Au collisions. The dashed line represents the estimated elliptic flow modulated combinatoric background using zero yield at minimum (ZYAM) method (see Sec. III E).

For uncorrelated sources, the triggers and partners are uniform in azimuth. Thus the true combinatoric pair distribution for mixed events is flat with $\Delta\phi$ with a density of $\langle n_0^a\rangle\langle n_0^b\rangle/(2\pi)$. The yield of jet-induced pairs per event (JPY) is given as the product of the combinatoric pair rate and the hadron-pair ratio,

$$\begin{aligned}\text{JPY}(\Delta\phi) &= \frac{\langle n_0^a\rangle\langle n_0^b\rangle}{2\pi}\text{JPR}(\Delta\phi) = \frac{\langle n^a\rangle\langle n^{\text{b}}\rangle}{2\pi\,\varepsilon^a\varepsilon^{\text{b}}}\text{JPR}(\Delta\phi) \\ &= \frac{\int d\Delta\phi N^{\text{mixed}}(\Delta\phi)}{2\pi\, N_{\text{evts}}\varepsilon^a\varepsilon^{\text{b}}}\left[\frac{N^{\text{same}}(\Delta\phi)}{N^{\text{mixed}}(\Delta\phi)}\right. \\ &\quad \left. - \xi\left(1 + 2v_2^{\text{a}} v_2^b \cos 2\Delta\phi\right)\right].\end{aligned} \tag{15}$$

Thus far, we have made no distinction between trigger and partner hadrons. As discussed earlier in Sec. II, the correlation function, hadron-pair ratio, and hadron-pair yield are symmetric between the trigger and partner p_T, i.e.,

$$\begin{aligned}C\left(p_T^a, p_T^b\right) &= C\left(p_T^b, p_T^a\right), \\ \text{JPR}\left(p_T^a, p_T^b\right) &= \text{JPR}\left(p_T^b, p_T^a\right), \\ \text{JPY}\left(p_T^a, p_T^b\right) &= \text{JPY}\left(p_T^b, p_T^a\right).\end{aligned} \tag{16}$$

The associated partner yield per trigger, $Y_{\text{jet_ind}}(\Delta\phi)$ is obtained by dividing the hadron-pair yield per event with the number of triggers per event,

$$\begin{aligned}Y_{\text{jet_ind}}(\Delta\phi) &= \frac{\text{JPY}(\Delta\phi)}{n_0^a} = \frac{\int d\Delta\phi N^{\text{mixed}}(\Delta\phi)}{2\pi N^a\varepsilon^b} \\ &\quad \times\left[\frac{N^{\text{same}}(\Delta\phi)}{N^{\text{mixed}}(\Delta\phi)} - \xi\left(1 + 2v_2^a v_2^b \cos 2\Delta\phi\right)\right].\end{aligned} \tag{17}$$

$Y_{\text{jet_ind}}$ is often referred to as the per-trigger yield or conditional yield. It is clearly not invariant to the exchange of trigger and partner p_T.

The analysis proceeds in the following steps. We first measure the correlation function of Eq. (8). We then obtain the efficiency for partner hadrons (ε^b) and the elliptic flow coefficients for the two hadron categories (v_2^a, v_2^b). We then determine the background level (ξ) via the ZYAM background subtraction method (see Sec. III E), followed by a calculation of the per-trigger yield according to Eq. (17). Subsequently, we obtain the hadron-pair yield by multiplying the per-trigger yield with the inclusive charged hadron yield [6] integrated in the corresponding trigger p_T range.

According to Eq. (6), the hadron-pair yields calculated from the per-trigger yields are independent of which hadron, from the pair, is used as trigger. We used this fact to cross-check the efficacy of our analysis. Figure 3 compares the hadron-pair yields obtained when the trigger and partner p_T is exchanged in $p + p$ collisions (in $p_T^a \otimes p_T^b$). The open symbols indicate the results for low-p_T trigger hadrons in association with high-p_T partners. The filled symbols show the converse. A similar comparison for 0–20% Au+Au collisions is shown in Fig. 4. Overall good agreement is indicated by these distributions. It is important to emphasize here that there is no *a priori* reason for these distributions to be identical, since the cuts on trigger and partner hadrons are a little different (cf. Sec. III B) and therefore could lead to somewhat different

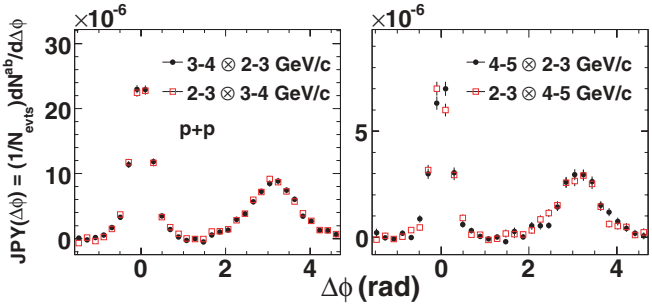

FIG. 3. (Color online) $p+p$ jet-induced hadron-pair yield $\Delta\phi$ distributions calculated from the per-trigger yield using low-p_T hadrons as triggers (solid symbols) and high-p_T hadrons as triggers (open symbols).

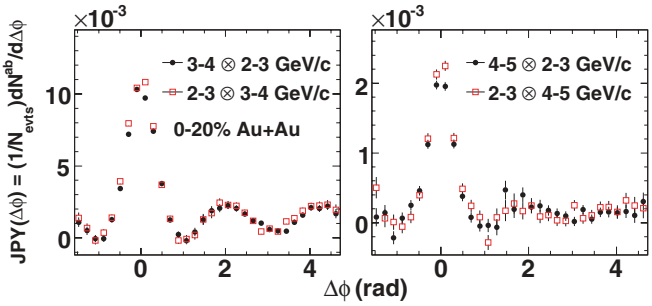

FIG. 4. (Color online) Same as Fig. 3, but for 0–20% Au+Au.

systematic errors for each measurement. We also note that the hadron-pair yield is almost three orders of magnitude stronger in Au+Au collisions than in $p+p$ reactions. This feature reflects the enhanced contributions from the medium response to quenched jets; the hadron-pair yields scale faster than $N_{\rm coll}$ at low $p_T^{a,b}$ (see discussions for Figs. 28–31).

D. Elliptic flow measurement

The differential elliptic flow measurements for charged hadrons were carried out with the reaction plane method [53]. The event plane (EP), which is the experimental estimate of the reaction plane (RP), is determined via the two BBCs positioned symmetrically along the beamline. They cover full azimuth and $3 < |\eta| < 3.9$ in pseudorapidity. The BBCs allow an unbiased measurement of the event plane and ensure that there are no residual distortions on the correlation function that could result from the limited azimuthal coverage of the PHENIX central arms. A detailed analytical proof of this latter point is provided in Appendix B.

We determine the value of elliptic flow v_2 as

$$v_2 = \frac{v_{2,\rm raw}}{c_{v_2}} = \frac{\langle\langle\cos 2(\phi - \Phi_{\rm EP})\rangle\rangle}{\langle\cos 2(\Phi_{\rm EP} - \Phi_{\rm RP})\rangle}, \qquad (18)$$

where $\Phi_{\rm EP}$ is the event plane angle and $\Phi_{\rm RP}$ is the true reaction plane angle, $v_{2,\rm raw} = \langle\langle\cos 2(\phi - \phi_{\rm EP})\rangle\rangle$ is the raw v_2, and $c_{v_2} = \langle\cos 2(\Phi_{\rm EP} - \Phi_{\rm RP})\rangle$ is the estimated reaction plane resolution. The former is obtained by averaging over all tracks and all events; the latter, by averaging over all events. The resolution is estimated from the event plane angle of the north and south BBC as $c_{v_2} = \sqrt{2\langle\cos 2(\Phi_{\rm EP,north} - \Phi_{\rm EP,south})\rangle}$ [54,55]. It is 0.3 for minimum bias events and reaches a maximum of 0.42 in the 20–30% centrality bin. Further details are given in Ref. [55].

Reliable extraction of the jet signal requires accurate determination of v_2^a and v_2^b. To this end, nonflow effects that lead to azimuthal correlations unrelated to the true RP direction need to be studied. These effects include various long- or short-range correlations among clusters of particles, such as momentum conservation effects, resonance decays, Hanbury-Brown–Twiss correlations, and jets [56,57]. While jets potentially bias the v_2 measurement at high p_T, other nonflow effects may be important at low and intermediate p_T. The values of v_2 are also sensitive to event-by-event fluctuations of the collision geometry [58–61] (so-called v_2 fluctuations), which affect all p_T regions.

A bias to v_2 resulting from jets has been reported for high-p_T hadrons [62]. However, the relative significance of other nonflow effects and v_2 fluctuations is still under debate. Recent studies from PHOBOS [63] and STAR [64] suggest that the fluctuations dominate over the nonflow effects for the p_T integral v_2.

Following the two-source assumption in Eq. (11), any correlations other than jets are attributed to the background term, i.e., $1 + 2v_2^a v_2^b \cos 2\Delta\phi$. These naturally include most nonflow correlations and v_2 fluctuations. To estimate the potential biases from jets and dijets, we carried out a detailed study in Appendix C, in which we embedded dijet PYTHIA events into flow-modulated events generated with the HIJING code. Our study shows that the large rapidity separation between the PHENIX BBCs and central arms greatly reduces the influence of jets on our v_2 measurements. Consequently, we use the BBC reaction plane v_2 measurements to evaluate and subtract the elliptic flow modulated background.

E. Combinatoric background subtraction

The background level ξ can be determined precisely if we know the exact functional form for the near- and away-side jets, or if we can independently measure the underlying event rate. However, due to in-medium modifications, the near- and away-side jets are not necessarily Gaussian, especially for $\Delta\phi$ values away from 0 and π. Even in $p+p$ collisions, the underlying event can include contributions from multiple-parton interaction, beam remnants, and initial and final state radiation effects [65], which are related to the hard-scattering but not necessarily correlated in $\Delta\phi$. Such effects have been studied at the Tevatron [65,66] and RHIC [44] energies. For illustration purposes, Fig. 5 shows the dihadron correlation from PYTHIA [67] with and without initial and final state radiation effects. The difference between the two is clearly significant.

Rigorous decomposition of the jet from its underlying event currently requires assumptions about the jet shape or the physics of the underlying event. As discussed earlier, a simple approach to fix ξ is to follow the subtraction procedure outlined in Refs. [18,52]. That is, one assumes that the jet function has zero yield at its minimum $\Delta\phi_{\rm min}$ (ZYAM), after subtraction of

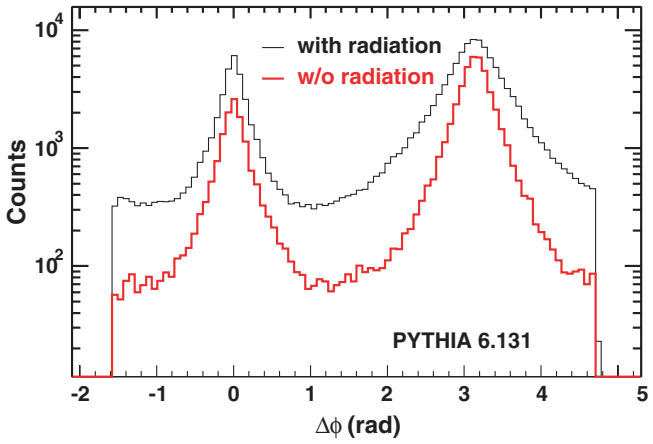

FIG. 5. (Color online) PYTHIA simulation showing jet-induced hadron pair $\Delta\phi$ distribution for $3 < p_T^a, p_T^b < 5$ GeV/c with (top histogram) and without (bottom histogram) initial and final state radiation. The radiation accounts for the increase of the background level.

the underlying event. The uncertainty on ξ from this procedure is related to the statistical accuracy of the data around $\Delta\phi_{\min}$. In the present analysis, this uncertainty is negligible at low p_T, but becomes important for $p_T^{a,b} > 4$ GeV/c in central collisions.

The ZYAM procedure, by definition, provides only a lower limit on the jet yield. To estimate the possible over-subtraction of jet yield at $\Delta\phi_{\min}$, we also made independent estimates of ξ via an absolute combinatoric background subtraction method (ABS) [68] and by a fitting method. In the ABS method, ξ, as defined by Eq. (12), is assumed to reflect only a residual multiplicity smearing effect caused by intrinsic positive correlations between the n_0^a and n_0^b in real events; i.e., a larger n_0^a implies a larger n_0^b and vice versa. Because of this positive correlation, the average of the product can become larger than the product of the average; i.e., $\langle n_0^a n_0^b\rangle > \langle n_0^a\rangle\langle n_0^b\rangle$ or $\xi > 1$.

To estimate ξ, we parametrize the centrality dependence of the trigger and partner rate from the measured single particle spectra in relevant momentum range, as a function of either $N_{\rm part}$ or $N_{\rm coll}$

$$\langle n_0^{a,b}\rangle = f(N_{\rm part}) = g(N_{\rm coll}). \tag{19}$$

We then assume the event-by-event fluctuation of trigger and partner hadrons to follow a Poisson distribution around their mean values,

$$n_0^{a,b} = \text{Poisson}\left(\langle n_0^{a,b}\rangle\right). \tag{20}$$

However, we have verified that that our estimates are not very sensitive to the functional forms of the fluctuations.

For each centrality bin, we determine the distribution of $N_{\rm part}$ and $N_{\rm coll}$ from the standard PHENIX Glauber calculation [48,49]. For each simulated event, we sample randomly from the $N_{\rm part}$ distribution, calculate the corresponding mean value $\langle n_0^{a,b}\rangle$ and then the actual value $n_0^{a,b}$ after taking into account the fluctuation. The same exercise is repeated for the $N_{\rm coll}$ distributions. The final ξ is given by the average of the two, and their difference is taken as the systematic error. The correction modifies the background level by 0.2% in the most central and 25% in the 60–92% centrality bin. The ABS and ZYAM methods give consistent ξ values in central collisions, but the ABS method gives somewhat lower values in peripheral collisions.

TABLE II. Comparison of the ξ values obtained for three different normalization methods for several centrality selections. They are calculated for the $2.5 < p_T^a < 4.0$ and $1.0 < p_T^b < 2.0$ GeV/c bins.

Cent.	ZYAM	ABS	Constrained fit
0–5%	1.0018 ± 0.0004	1.0023 ± 0.0002	0.998 ± 0.002
20–30%	1.015 ± 0.0015	1.012 ± 0.003	1.004 ± 0.006
50–60%	1.076 ± 0.009	1.07 ± 0.02	1.054 ± 0.009

In the fit method, $Y_{\rm jet_ind}(\Delta\phi)$ is fitted with a function comprised of one near- and two symmetric away-side Gaussians, following a procedure similar to that reported in Ref. [19]. One important difference is that a region around $\pi(|\Delta\phi - \pi| < 1)$ is excluded to avoid the punch-through jet contributions (see Fig. 6). Thus, the fit uses the near-side and the falling edge of the away-side to estimate the overlap of the near- and away-side Gaussians at $\Delta\phi_{\min}$. This approach gives systematically lower ξ values than those obtained from the ZYAM and ABS methods.

Table II summarizes the ξ values from the three methods. The results for the ZYAM and ABS methods are close, but the values from the fitting method are systematically lower. This could be due to the correlations between the fitting parameters or a limitation in the Gaussian assumptions for the jet shape. To avoid a possible overestimation of the jet yield in the $\Delta\phi$ region where the near- and away-side Gaussians overlap, we constrain the ξ to be $\geqslant 1$. This is a reasonable assumption in the absence of anticorrelation in trigger and partner hadron multiplicity. We assign the differences with the ZYAM method as a one-sided systematic error on ξ. This error is important in central collisions and for $p_T^{a,b} < 3$ GeV/c.

F. Systematic uncertainties

We classify the systematic errors associated with the jet yield into three main categories: (1) uncertainties in the single particle efficiency correction, ϵ^a and ϵ^b, for Au+Au and $p + p$, (2) statistical and systematic uncertainties associated with the determination of the elliptic flow values, v_2^a and v_2^b, in Au+Au collisions, and (3) uncertainties associated with the determination of the combinatoric background level ξ in both Au+Au and $p + p$ collisions.

The uncertainties associated with the efficiency corrections include contributions from the detector acceptance (5%), matching cuts (4%), and momentum scale and momentum resolution (5%). The background contamination is estimated to be 5% for $p_T < 5$ GeV/c, increasing to 10% for the 5–10 GeV/c bin. This leads to an overall systematic error of ~10% for $p_T < 5$ and 13% for the 5–10 GeV/c bin. For

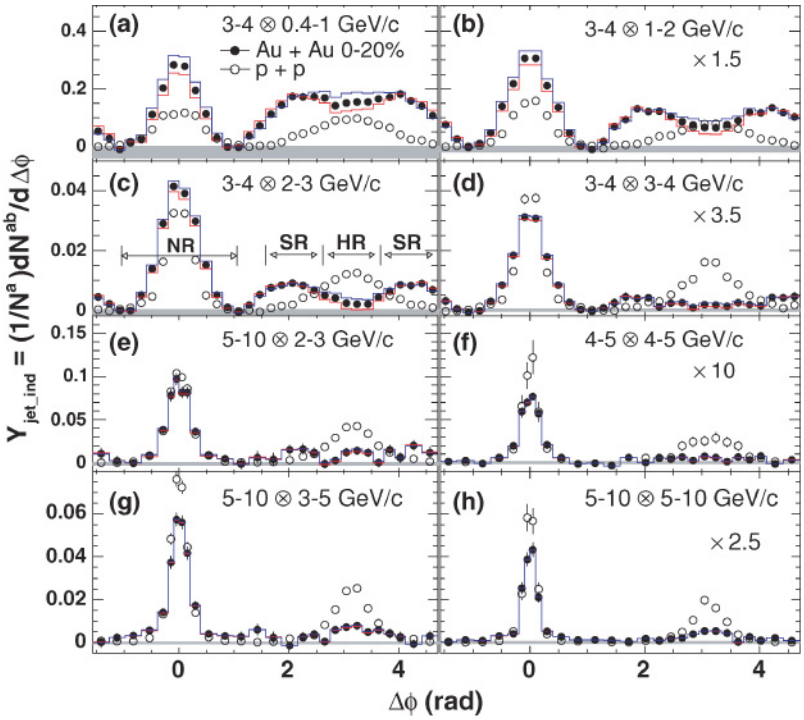

FIG. 6. (Color online) Per-trigger yield vs $\Delta\phi$ for various trigger and partner p_T ($p_T^a \otimes p_T^b$), arranged by increasing pair proxy energy (sum of p_T^a and p_T^b), in $p+p$ and 0–20% Au+Au collisions. The data in several panels are scaled as indicated. Solid histograms (shaded bands) indicate elliptic flow (ZYAM) uncertainties. Arrows in Fig. 6(c) depict the "head" region (HR), the "shoulder" region (SR) and the "near-side" region (NR).

central Au+Au collisions, there is an additional maximally 5%, centrality-dependent uncertainty due to occupancy effect.

The propagation of uncertainties arising from the single particle efficiency are different for different jet variables. For the per-trigger yield, it depends on the errors associated with the efficiency estimated for the partners (ε^b). For the hadron-pair yields, it depends on the errors related to efficiencies for both trigger (ε^a) and partner (ε^b) hadrons. Since the efficiency correction uncertainties are similar for trigger and partner hadrons in both Au+Au and $p+p$ collisions, we can use a single variable ε to represent them. If the uncertainties are independent between Au+Au and $p+p$, the total uncertainty would be $\sim\sqrt{2}\delta\varepsilon/\varepsilon$ for JPY and I_{AA} and $2\delta\varepsilon/\varepsilon$ for J_{AA}. However, some systematic errors partially cancel between Au+Au and $p+p$, especially those for the matching cut, momentum scale, and momentum resolution. The total uncertainties are estimated to be 12% for I_{AA} and JPY and 17% for J_{AA}.

The statistical uncertainties for v_2 are important in the most central and most peripheral centrality bins for $p_T > 4$ GeV/c. The systematic uncertainties are, however, driven by the uncertainty associated with the determination of the reaction plane resolution; they are estimated to be ∼6% for central and midcentral collisions and ∼10% for peripheral collisions [18]. This error is nearly independent of p_T, i.e., $\delta v_2^a/v_2^a \approx \delta v_2^b/v_2^b$, and the resulting error for the hadron-pair ratio is

$$\begin{aligned}\delta\mathrm{JPR}(\Delta\phi) &= 2\xi\left(\delta v_2^a v_2^b + \delta v_2^b v_2^a\right)\cos 2\Delta\phi \\ &\approx (\delta v_2/v_2) 4 v_2^a v_2^b \cos 2\Delta\phi, \end{aligned} \tag{21}$$

where the last approximation takes into account the fact that ξ is close to 1. Additional systematic errors related to v_4 and the factorization assumption that $\langle v_2^a v_2^b\rangle = \langle v_2^a\rangle\langle v_2^b\rangle$ were also estimated and found to be small [19].

The uncertainty due to ξ (ZYAM uncertainty) can be expressed as

$$\delta\mathrm{JPR}(\Delta\phi) = \delta\xi\left(1 + 2v_2^a v_2^b \cos 2\Delta\phi\right) \approx \delta\xi, \tag{22}$$

where we ignored the $\cos 2\Delta\phi$ term, since $2v_2^a v_2^b \ll 1$. The uncertainty of ξ includes both the statistical error of the data points around $\Delta\phi_{\min}$ and the systematic error from the fitting procedure.

Table III summarizes the systematic errors for the jet yield in 0–20% Au+Au collisions due to v_2 and ZYAM subtraction. Errors for several combinations of trigger and partner p_T (in $p_T^a \otimes p_T^b$) are given. The uncertainties are $\Delta\phi$ dependent, so we present them separately for the three regions used in this analysis: a "head" region ($|\Delta\phi - \pi| < \pi/6$, HR), a "shoulder" region ($\pi/6 < |\Delta\phi - \pi| < \pi/2$, SR), and the near-side region ($|\Delta\phi| < \pi/3$, NR). These regions are indicated in Fig. 6(c).

The three types of systematic errors impact the jet shape and jet yield differently. The single particle efficiency correction is a multiplicative factor, so its uncertainty influences the normalization of the jet yield but does not influence its shape. The uncertainties associated with the elliptic flow varies with $\Delta\phi$. It is largest for regions around 0 and π, but reaches a minimum in the shoulder region. The influence of the ξ uncertainty on the jet yield also depends on $\Delta\phi$. It is the dominant uncertainty for the away-side yield at high p_T.

IV. RESULTS

A. Jet-induced dihadron azimuthal ($\Delta\phi$) distributions

Figure 6 shows a representative subset of the per-trigger yield distributions $Y_{\mathrm{jet_ind}}(\Delta\phi)$ for various combinations of

trigger and partner p_T ($p_T^a \otimes p_T^b$) for $p + p$ and 0–20% Au+Au collisions, arranged by increasing pair proxy energy, i.e., by $p_T^{\rm sum} = p_T^a + p_T^b$. The comprehensive array of results, covering the momentum range of 0.4 to 10 GeV/c from which this subset is derived, are summarized in Appendix D (Figs. 36–38). From Eq. (6), one can see that the distributions for $p_T^a \otimes p_T^b$ and $p_T^b \otimes p_T^a$ are related to each other by a normalization factor n_0^a/n_0^b, i.e, the ratio of the number of hadrons in the two p_T ranges. We have checked that these distributions, when rescaled by n_0^a or n_0^b, are consistent with each other. These $\Delta\phi$ distributions not only carry detailed jet shape and yield information but also serve as a basis for our systematic study of the p_T dependence of the contributions from various physical processes.

The results in Fig. 6 constitute one of many possible ways of illustrating the evolution from low p_T to high p_T in the two-dimensional space of p_T^a and p_T^b. It is designed to highlight the main features of an evolution from the soft-process-dominated low-p_T region to the hard-process-dominated high-p_T region. As shown in the figure, the $p + p$ data show essentially Gaussian away-side peaks centered at $\Delta\phi \sim \pi$ for all p_T^a and p_T^b. By contrast, the Au+Au data show substantial modifications relative to those for $p + p$ collisions, and these modifications vary nontrivially with p_T^a and p_T^b. For a fixed value of p_T^a, Figs. 6(a)–6(d) reveal a striking evolution from a broad, roughly flat away-side peak to a local minimum at $\Delta\phi \sim \pi$ with side peaks at $\Delta\phi \sim \pi \pm 1.1$. Interestingly, the location of the side peaks in $\Delta\phi$ is found to be roughly constant with increasing p_T^b (see Fig. 11). Such p_T independence is compatible with an away-side jet modification expected from a medium-induced Mach shock [35] but provides a challenge for models that incorporate large angle gluon radiation [31,32], Cherenkov gluon radiation [34], or deflected jets [23,29].

For relatively large values of $p_T^a \otimes p_T^b$, Figs. 6(e)–6(h) (also Fig. 36) show that the away-side jet shape for Au+Au gradually becomes peaked as for $p + p$, albeit suppressed. This "reappearance" of the away-side peak seems to be due to a reduction of the yield centered at $\Delta\phi \sim \pi \pm 1.1$ relative to that at $\Delta\phi \sim \pi$, rather than a merging of the peaks centered at $\Delta\phi \sim \pi \pm 1.1$. This is consistent with the dominance of dijet fragmentation at large $p_T^a \otimes p_T^b$, possibly due to jets that "punch through" the medium [14] or those emitted tangentially to the medium's surface [69].

The evolution pattern of the away-side jet shape with p_T suggests separate contributions from a medium-induced component at $\Delta\phi \sim \pi \pm 1.1$ and a fragmentation component centered at $\Delta\phi \sim \pi$. A model independent study of these contributions can be made by dividing the away-side jet function into equal-sized "head" ($|\Delta\phi - \pi| < \pi/6$, HR) and "shoulder" ($\pi/6 < |\Delta\phi - \pi| < \pi/2$, SR) regions, as indicated in Fig. 6(c).

TABLE IV. Centrality dependence of $R_{\rm HS}$ for $2 < p_T^a, p_T^b < 3$ GeV/c (Fig. 8).

Figure 6 also shows significant modifications of the near-side $\Delta\phi$ distributions. For the $p_T^a \otimes p_T^b$ bins where the away-side has a concave shape, the near-side jet also shows a clear enhancement in the yield and a modification of the width relative to $p+p$. To facilitate a more detailed investigation, we define a near-side region ($|\Delta\phi| < \pi/3$, NR) as indicated in Fig. 6(c). In the following, we focus on the jet-induced pairs in these three $\Delta\phi$ regions, and discuss in detail the p_T and centrality dependence of their shapes and yields.

B. Medium modification of away-side jets

1. Away-side jet shape

We characterize the relative importance of the jet yields in the HR and SR by the ratio $R_{\rm HS}$,

$$R_{\rm HS} = \frac{\int_{\Delta\phi\in{\rm HR}} d\Delta\phi Y_{\rm jet_ind}(\Delta\phi)}{\int_{\Delta\phi\in{\rm HR}} d\Delta\phi} \Big/ \frac{\int_{\Delta\phi\in{\rm SR}} d\Delta\phi Y_{\rm jet_ind}(\Delta\phi)}{\int_{\Delta\phi\in{\rm SR}} d\Delta\phi}, \tag{23}$$

i.e., it is a ratio of area-normalized jet yields in the HR and the SR. This ratio reflects the away-side jet shape and is symmetric with respect to p_T^a and p_T^b, i.e., $R_{\rm HS}(p_T^a, p_T^b) = R_{\rm HS}(p_T^b, p_T^a)$. For concave and convex shapes, one expects $R_{\rm HS} < 1$ and $R_{\rm HS} > 1$, respectively; for a flat distribution, $R_{\rm HS} = 1$.

Figure 7 shows the p_T^b dependence of $R_{\rm HS}$ for both $p+p$ and central Au+Au collisions for four p_T^a bins. The uncertainty for efficiency corrections drops out in the ratio; the v_2 errors (shaded bars) and ZYAM errors (brackets) are correlated in the two regions, thus they partially cancel.

The $R_{\rm HS}$ values for $p+p$ are always above unity and increase with p_T^b. This reflects the narrowing of a peaked away-side jet shape with increasing p_T^b. In contrast, the ratios for Au+Au show a nonmonotonic dependence on $p_T^{a,b}$. They evolve from $R_{\rm HS} \sim 1$ for p_T^a or $p_T^b \lesssim 1$ GeV/c, through $R_{\rm HS} < 1$ for $1 \lesssim p_T^{a,b} \lesssim 4$ GeV/c, followed by $R_{\rm HS} > 1$ for $p_T^{a,b} \gtrsim 5$ GeV/c. These trends reflect the competition between medium-induced modification and jet fragmentation in determining the away-side jet shape, and they suggest that the latter dominates for $p_T^{a,b} \gtrsim 5$ GeV/c.

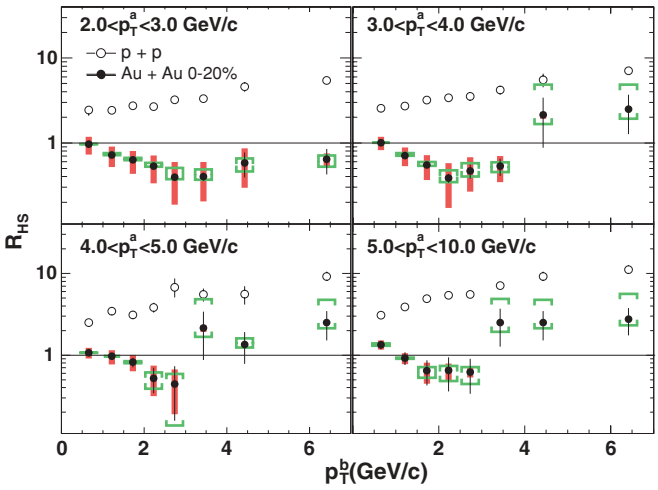

FIG. 7. (Color online) $R_{\rm HS}$ vs p_T^b for $p+p$ (open) and Au+Au (filled) collisions for four trigger selections. Shaded bars (brackets) represent p_T-correlated uncertainties due to elliptic flow (ZYAM procedure).

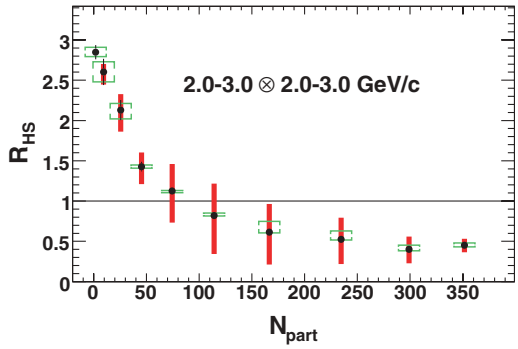

FIG. 8. (Color online) $R_{\rm HS}$ vs $N_{\rm part}$ for 2–3 $\otimes$ 2–3 GeV/c. Shaded bars (brackets) represent p_T-correlated uncertainties due to elliptic flow (ZYAM procedure). The left-most point is from $p+p$.

$R_{\rm HS}$ values for Au+Au are smaller than those for $p+p$ even at the highest p_T. This difference could be due to some medium modification of the punch-through jets. However, the HR yield dominates the SR yield ($R_{\rm HS} \gg 1$) in this p_T region, and the values for $R_{\rm HS}$ become very sensitive to the SR yield. For instance, a small enhancement of the SR yield can significantly reduce the value of $R_{\rm HS}$, without significantly affecting the overall away-side feature.

$R_{\rm HS}$ values reach their minimum around 2–3 GeV/c. Additional information can be obtained from their centrality dependence, as shown in Fig. 8 for the 2–3 $\otimes$ 2–3 GeV/c bin. $R_{\rm HS}$ starts at around 3 for $p+p$ collisions but quickly drops and crosses 1 at $N_{\rm part} \sim 80$. It then slowly decreases with $N_{\rm part}$ to a level of about 0.5 in central collisions. This trend implies a quick change of the HR and/or SR yield in relatively peripheral collisions. The saturation of the $R_{\rm HS}$ for $N_{\rm part} > 200$ may suggest that the HR yield is dominated by the feed-in of the SR yield (see further discussion in Sec. IV B2).

Although the p_T and centrality dependence of $R_{\rm HS}$ suggests that the away-side yield contains separate contributions from a fragmentation component (in the HR) and a medium-induced component (in the SR), $R_{\rm HS}$ does not constrain the shape of the two components directly. An alternative approach for quantifying the away-side shape is to assume a specific functional form for these two components and carry out a model-dependent fit. Such a fit was performed with the following two functional forms:

$$Y^{\rm FIT1}_{\rm jet_ind}(\Delta\phi) = G_1(\Delta\phi) + G_2(\Delta\phi - \pi + D) + G_2(\Delta\phi - \pi - D) + \kappa, \tag{24}$$

$$Y^{\rm FIT2}_{\rm jet_ind}(\Delta\phi) = G_1(\Delta\phi) + G_2(\Delta\phi - \pi + D) + G_2(\Delta\phi - \pi - D) + G_3(\Delta\phi - \pi) + \kappa. \tag{25}$$

The first (FIT1) assumes two Gaussian shoulder components located symmetrically about π, each separated by the distance D from π. The second (FIT2) assumes the same shoulder components but also includes an additional Gaussian component centered at π; the latter represents the

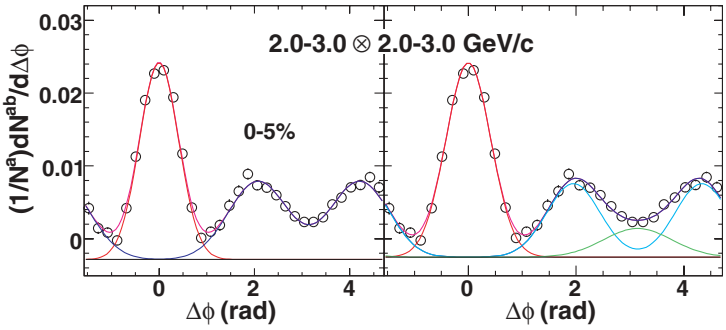

FIG. 9. (Color online) Per-trigger yield $\Delta\phi$ distribution and corresponding fits for 2–3 $\otimes$ 2–3 GeV/c in 0–5% Au+Au collisions. FIT1 (FIT2) is shown in the left panel (right panel). The total fit function and individual components are shown relative to the κ level indicated by the horizontal line.

jet fragmentation contribution and is parametrized to have the same width as that for the $p + p$ away-side jet. FIT1 has six free parameters: background level κ, near-side peak integral and width, and shoulder peak location D, integral, and width. In addition to the parameters of FIT1, FIT2 has a parameter that controls the integral of the fragmentation component.

The separate contributions of FIT1 and FIT2 are illustrated for a typical $p_T^a \otimes p_T^b$ in Fig. 9.

The two fits treat the region around $\Delta\phi = \pi$ differently. FIT2 tends to assign the yield around π to the center Gaussian, while FIT1 tends to split that yield into the two shoulder Gaussians. Note, however, that a single Gaussian centered at π can be treated as two shoulder Gaussians with $D = 0$. Thus FIT1 does a good job at low p_T and high p_T, where the away-side is dominated by shoulder and head components, respectively. It does not work as well for intermediate p_T, where both components are important. The center Gaussian and shoulder Gaussians used in FIT2 are strongly anticorrelated. That is, a small shoulder yield implies a large head yield and vice versa. In addition, the center Gaussian tends to "push" the shoulder Gaussians away from π, and this results in larger D values than obtained with FIT1.

Figure 10(a) shows the D values obtained from the two fitting methods as a function of centrality for the p_T selection 2–3 $\otimes$ 2–3 GeV/c. The systematic errors from v_2 are shown as brackets (shaded bars) for FIT1 (FIT2). The values of D for FIT1 are consistent with zero in peripheral collisions, but grow rapidly to $\sim$1 for $N_{\text{part}} \sim 100$, approaching $\sim$1.05 in the most central collisions. The D values obtained from FIT2 are slightly larger ($\sim$1.2 rad) in the most central collisions. They are also relatively stable to variations of v_2 because most of the yield variation is "absorbed" by the center Gaussian [cf. Fig. 10(b)]. Thus, the associated systematic errors are also smaller than those for FIT1.

For $N_{\text{part}} < 100$, the centrality dependence of D is also quite different for FIT1 and FIT2. As seen in Fig. 10, the D values for FIT2 are above 1. However, the away-side yield in the SR, associated with these D values, are rather small, and the away-side distribution is essentially a single peak centered around π. For such cases, the values of D are prone to fluctuations and non-Gaussian tails. The deviation between the D values obtained with FIT1 and FIT2 for $N_{\text{part}} < 100$ simply reflects the weak constraint of the data on D in peripheral collisions.

Figure 11 shows the p_T dependence of D in 0–20% central Au+Au collisions. The values from FIT2 are basically flat with p_T^b. Those from FIT1 show a small increase with p_T^b, but with a larger systematic error. At low p_T, the values from FIT1 are systematically lower than those from FIT2. However, they approach each other at large $p_T^{a,b}$. From FIT1 and FIT2, it appears that the values of D cover the range 1–1.2 rad for p_T^a, $p_T^b \lesssim 4$ GeV/c. This trend ruled out a Cherenkov gluon radiation model [34] (with only transition from scalar bound states), which predicts decreasing D with increasing momentum.

2. *Away-side jet per-trigger yield*

Relative to $p + p$, the Au+Au yield is suppressed in the HR but is enhanced in the SR (cf. Fig. 6). A more detailed mapping of this modification pattern is obtained by comparing the jet yields in the HR and SR as a function of partner p_T. Such a comparison is given in Fig. 12 for central Au+Au and for $p + p$ collisions. The figure shows that relative to $p + p$,

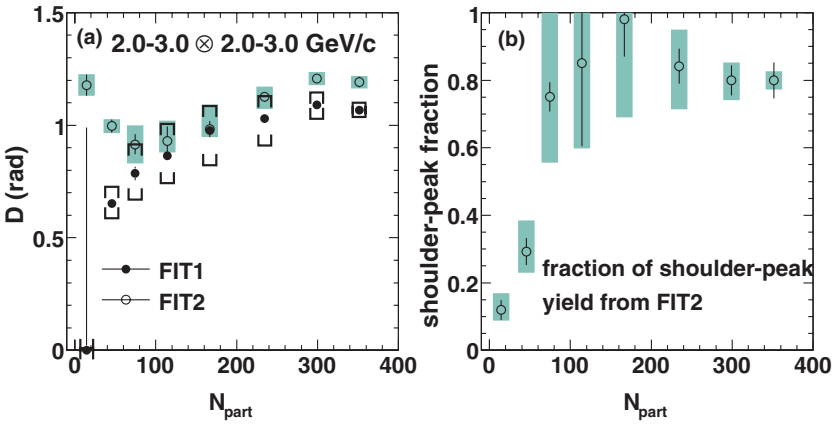

FIG. 10. (Color online) (a) D vs N_{part} from FIT1 (solid circles) and FIT2 (open circles) for 2–3 $\otimes$ 2–3 GeV/c bin. The error bars are the statistical errors; shaded bars and brackets are the systematic errors due to v_2. (b) Fraction of the shoulder Gaussian yield relative to the total away-side yield as function of N_{part} determined from FIT2.

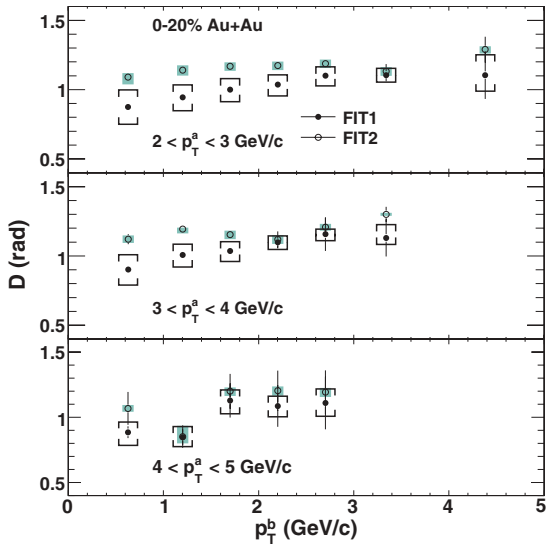

FIG. 11. (Color online) Values of D determined from FIT1 (solid circles) and FIT2 (open circles) as function of partner p_T for three trigger p_T ranges in 0–20% Au+Au collisions. The error bars are the statistical errors. The shaded bars and brackets are the systematic errors due to elliptic flow.

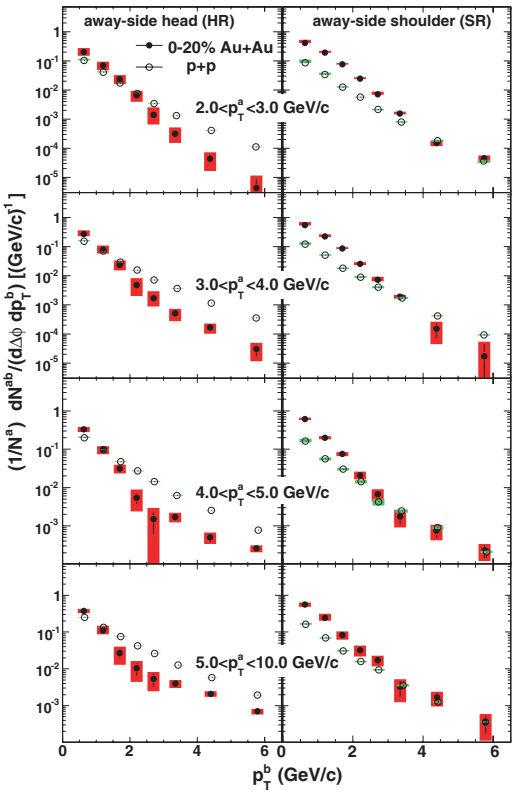

FIG. 12. (Color online) Per-trigger yield as function of partner p_T for the HR (left panels) and the SR region (right panels). Filled (open) circles represent the 0–20% Au+Au ($p + p$) collisions. Results for four trigger p_T in 2–3, 3–4, 4–5, 5–10 GeV/c are shown. The shaded bars represent the total systematic uncertainties.

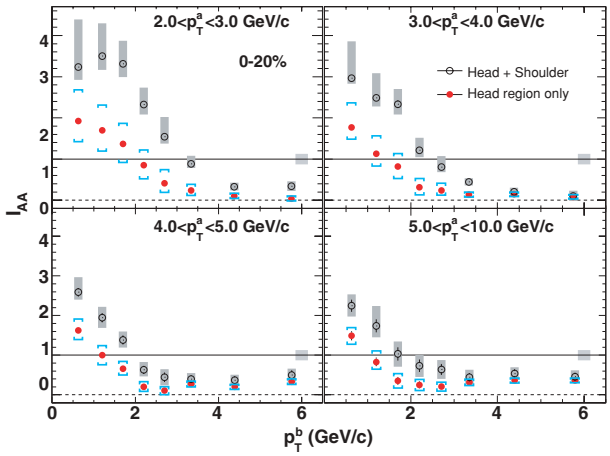

FIG. 13. (Color online) I_{AA} vs p_T^b for four trigger p_T bins in HR+SR ($|\Delta\phi - \pi| < \pi/2$) and HR ($|\Delta\phi - \pi| < \pi/6$) in 0–20% Au+Au collisions. The shaded bars and brackets represent the total systematic errors in the two regions. They are strongly correlated. Grey bands around $I_{AA} = 1$ represent 12% combined uncertainty on the single particle efficiency in Au+Au and $p + p$.

the Au+Au data are enhanced in the SR for low p_T, and suppressed in the HR for high p_T. The shape of the Au+Au spectra in the HR is also quite different from that for $p + p$. For $p_T^{a,b} \lesssim 4$ GeV/c, the spectra for Au+Au are steeper than those for $p + p$. For higher p_T, both spectra have the same shape (parallel to each other), but the yield for Au+Au is clearly suppressed.

To quantify this suppression/enhancement, we use the per-trigger yield ratio I_{AA}, the ratio of per-trigger yield for Au+Au collisions to that for $p + p$ collisions [cf. Eq. (5)]. Such ratios for the HR and the HR+SR are shown as a function of p_T^b for four different p_T^a selections in Fig. 13. For triggers of $2 < p_T^a < 3$ GeV/c, I_{AA} for HR+SR exceeds unity at low p_T^b, but falls with p_T^b and crosses unity around 3.5 GeV/c. A similar trend is observed for the higher p_T triggers, but the enhancement for low p_T^b is smaller, and the suppression for

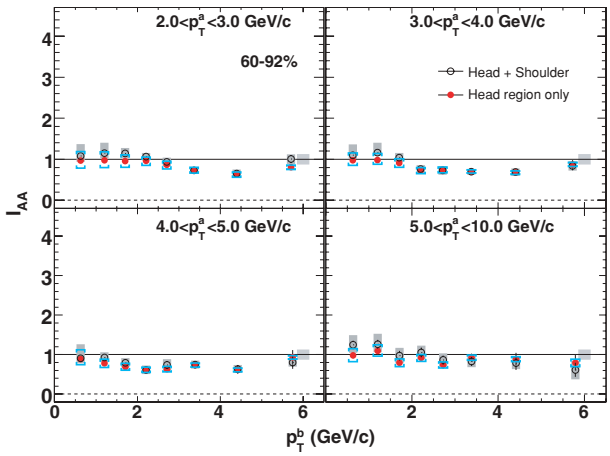

FIG. 14. (Color online) Same as Fig. 13, but for 60–92% Au+Au collisions.

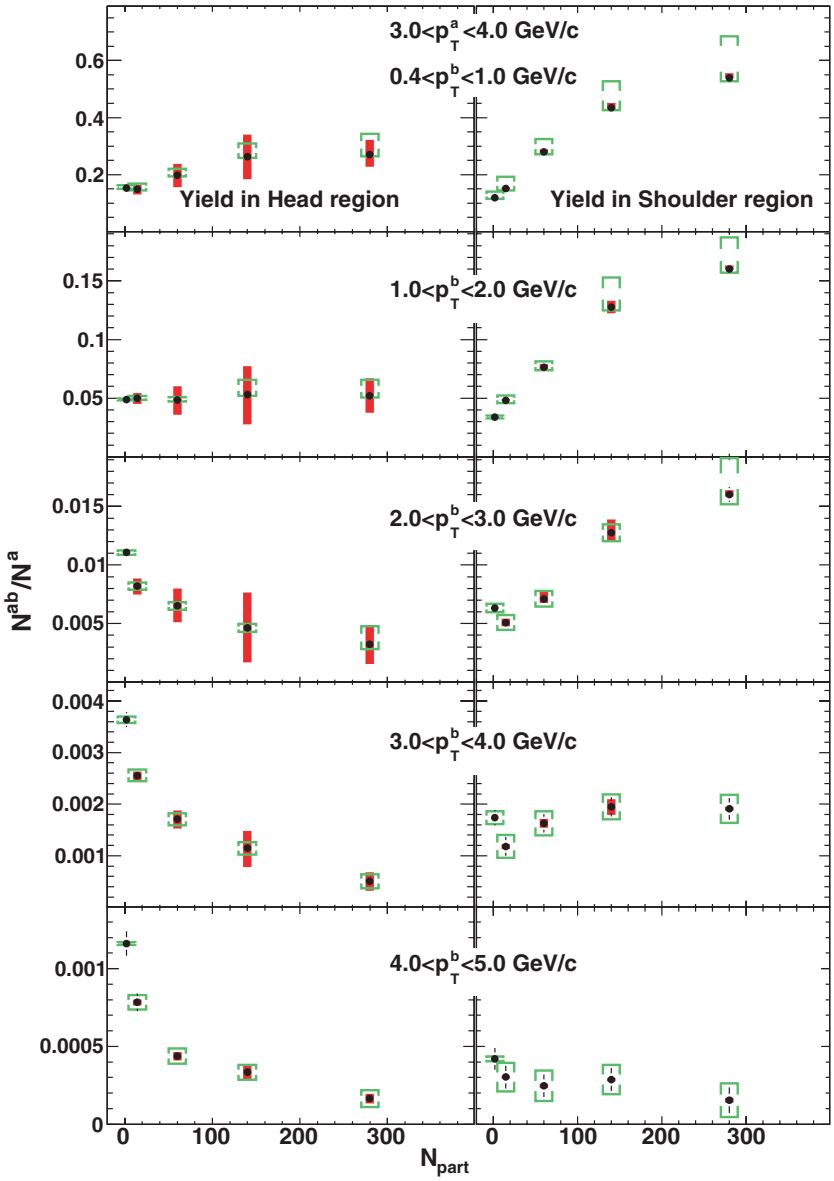

FIG. 15. (Color online) Per-trigger yield vs $N_{\rm part}$ in the HR (left panels) and the SR (right panels) for partner p_T in 0.4–1, 1–2, 2–3, 3–4, 4–5 GeV/c and fixed trigger in 3–4 GeV/c. The left-most points are from $p + p$ collisions. The shaded bars (brackets) represent uncertainties due to elliptic flow (ZYAM procedure).

high p_T^b is stronger. The I_{AA} values in the HR are also lower relative to HR+SR, for all $p_T^{a,b}$. For the low-p_T triggers, the HR suppression sets in for $1 \lesssim p_T^b \lesssim 3$ GeV/c, followed by a fall-off for $p_T^b \gtrsim 4$ GeV/c. For the higher p_T triggers, a constant level ∼0.2–0.3 is observed above ∼2 GeV/c, similar to the suppression level of inclusive hadrons [6].

For comparison, Fig. 14 shows the I_{AA} for peripheral collisions. They indicate that in contrast to the values for central collisions, there is only a small suppression in both the HR and the HR+SR for low-p_T triggers at large p_T^b. Moreover, the overall modifications are much smaller than observed for the more central Au+Au collisions.

A more detailed view of the enhancement/suppression patterns in the SR/HR can be provided by investigating their centrality dependence. Figure 15 shows the per-trigger yield in the SR and HR as a function of $N_{\rm part}$ for trigger p_T of 3–4 GeV/c and five partner p_T bins ranging from 0.4 to 5 GeV/c. With increasing partner p_T, both the SR and HR yields show a characteristic evolution with $N_{\rm part}$. That is, they first show an increase, followed by an essentially flat dependence, followed by a decrease (in the HR only). However, the value of p_T^b at which the centrality dependence becomes flat is quite different for the SR and the HR ($p_T^b \sim 4$ for the SR and $p_T^b \sim$ 1–2 GeV/c for the HR).

Figures 13 and 15 provide clear evidence that in central Au+Au collisions, there is significant yield suppression in the HR and an enhancement in the SR. The suppression for the HR is consistent with a jet-quenching scenario in which the HR yield at high p_T is dominated by radiated gluons and jets which survive passage through the medium. The enhancement for the SR could reflect the dissipative processes that redistribute the energy lost in the medium.

Several previous jet correlation measurements were carried out for an intermediate range of $p_T^a \otimes p_T^b$ [7,17–19,68,70] and/or in a limited away-side integration window roughly equal to the HR [7,12,68,70]. However, Fig. 15 shows that

away-side yield modifications are sensitive to both p_T and the $\Delta\phi$ integration range. By choosing a certain p_T and $\Delta\phi$ range, the combined effect of SR enhancement and HR suppression can result in away-side yields that are almost independent of centrality, while their shapes still vary with centrality. Thus a detailed survey of the jet yield in a broad p_T and a more differential study in $\Delta\phi$ for the away-side are important to obtaining the full picture.

C. Medium modification of near-side jets

In this section, we map out the p_T and centrality dependence of the shape and yields of the near-side jets.

1. Near-side jet shape

We characterize the near-side shape in $\Delta\phi$ by the Gaussian fit functions FIT1 and FIT2 described in Sec. IV B1. The systematic uncertainties include the differences between FIT1 and FIT2 and the uncertainties associated with the elliptic flow subtraction. To account for a possible influence from feed-in of the shoulder component, we also performed fits to the near-side distribution with a single Gaussian function in $\pm 1\sigma$, $\pm 2\sigma$, and $\pm 3\sigma$ windows, where σ is the width of the near-side peak obtained with FIT2. Deviations from σ were added in quadrature to the total systematic errors. For $p + p$, a simple fit with a near- and an away-side Gaussian plus a constant background was used.

Figure 16 compares the near-side Gaussian widths obtained for $p + p$ and 0–20% central Au+Au collisions. The results are shown as a function of partner p_T for four trigger p_T bins as indicated. The $p + p$ widths show the expected decrease with partner p_T for all trigger bins, as expected from a narrowing of the jet cone as p_T^b increases. The Au+Au widths also decrease with partner p_T except at low $p_T^{a,b}$. For low-p_T triggers of

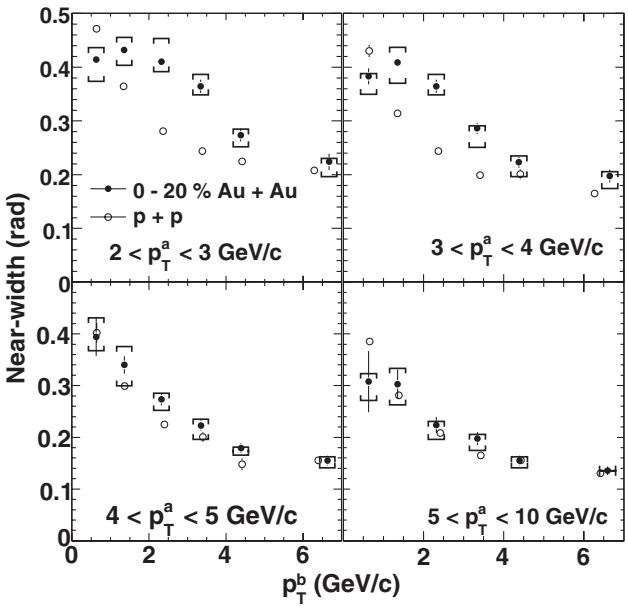

FIG. 16. Near-side Gaussian widths vs partner p_T for four trigger p_T ranges compared between 0–20% Au+Au (solid circles) and $p + p$ (open circles).

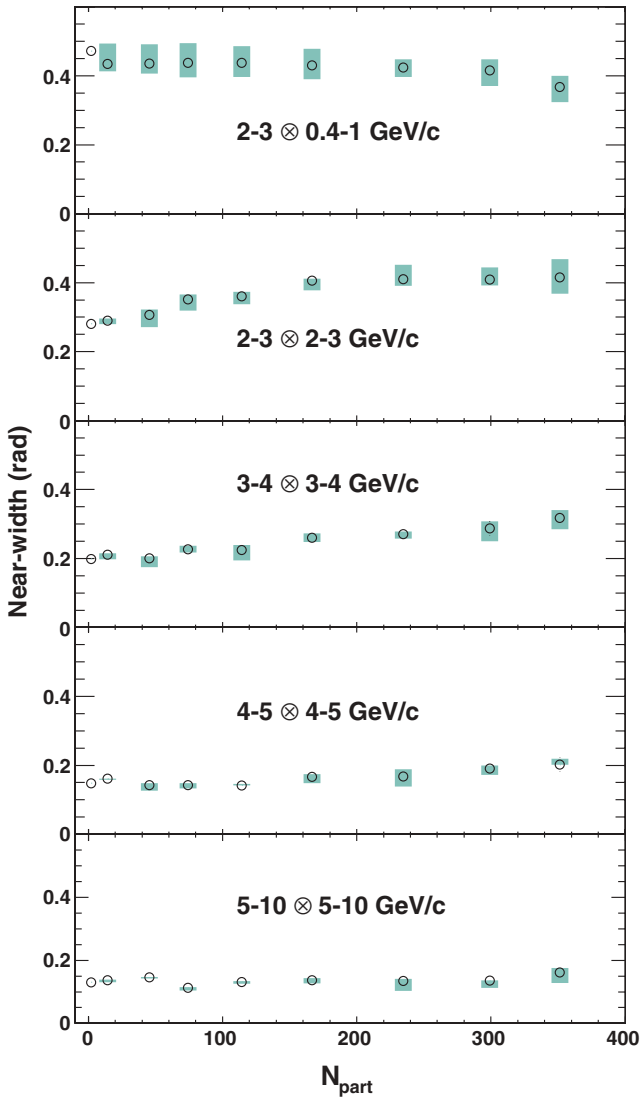

FIG. 17. (Color online) Near-side Gaussian widths vs $N_{\rm part}$ for five successively increasing $p_T^a \otimes p_T^b$. The left-most point in each panel represents the value from $p + p$.

$2 < p_T^a < 3$ and $3 < p_T^a < 4$ GeV/c, the values for the widths are slightly below those for $p + p$ for $p_T^b < 1$ GeV/c; they are, however, significantly broader for $1 \lesssim p_T^b \lesssim 4$ GeV/c. For higher trigger p_T, the extracted widths are similar for Au+Au and $p + p$.

Figure 17 shows the centrality dependence of the near-side widths for successively higher $p_T^a \otimes p_T^b$. For the lowest p_T bin of 2–3 $\otimes$ 0.4–1 GeV/c, the width decreases slightly with $N_{\rm part}$ and approaches a value of 0.4 rad in central collisions. A similar trend has been reported for measurements at low p_T [16]. For the 2–3 $\otimes$ 2–3 GeV/c selection, the near-side width grows with $N_{\rm part}$ and approaches a value about 40% larger than the $p + p$ value for $N_{\rm part} > 200$. For higher $p_T^a \otimes p_T^b$ bins, the near-side widths are narrower, and their centrality dependence is flatter. For the 5–10 $\otimes$ 5–10 GeV/c bin, the near-side widths ($\sim$0.14 rad) are essentially independent of $N_{\rm part}$, as might be expected if the near-side correlations are dominated by jet fragmentation.

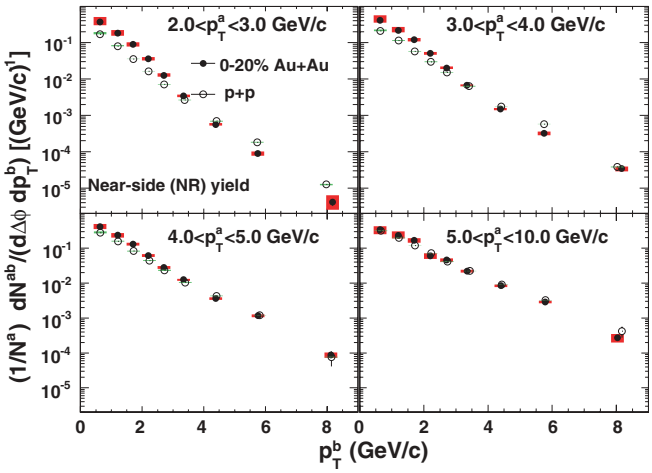

FIG. 18. (Color online) Near-side yield in $|\Delta\phi| < \pi/3$ vs partner p_T for four trigger p_T selections. The filled and open circles are for 0–20% Au+Au and $p + p$, respectively.

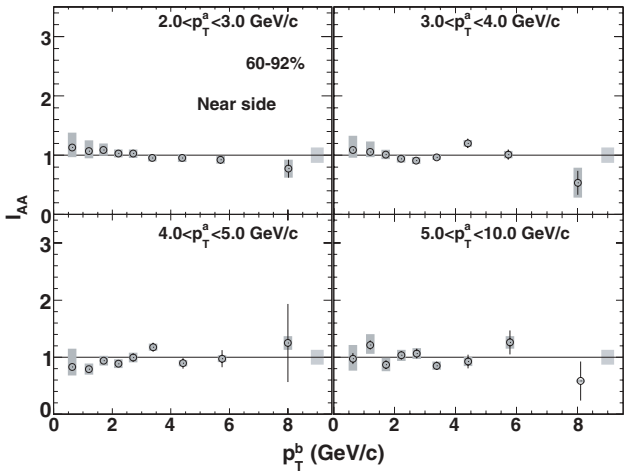

FIG. 20. Near-side I_{AA} in 60–92% Au+Au vs partner p_T for four trigger p_T bins. The shaded bars around the data points are the total systematic errors. Grey bands around $I_{AA} = 1$ represent 12% combined uncertainty on the single particle efficiency in Au+Au and $p + p$.

2. *Near-side jet per-trigger yield*

The near-side yield in $|\Delta\phi| < \pi/3$ (NR) as a function of partner p_T is shown in Fig. 18 for $p + p$ and Au+Au collisions, for four trigger p_T bins. The corresponding results for the modification factor I_{AA} are shown in Fig. 19. For triggers of 2–3 GeV/c, I_{AA} is enhanced by more than a factor of 2 for $p_T^b < 2$ GeV/c, followed by a falloff below unity for $p_T^b \gtrsim 4$ GeV/c. The overall deviation from $I_{AA} = 1$ decreases with increasing trigger p_T. For the highest p_T trigger, the near-side yield is close to that for $p + p$ over the full range of p_T^b. As a comparison, the I_{AA} values for the 60–92% centrality bin, shown in Fig. 20, are close to 1 for all $p_T^{a,b}$, suggesting a rather weak medium modification of the near-side yield in peripheral collisions.

The patterns of the near-side jet shape and yields in Figs. 16–20 suggest an influence from both medium modification and jet fragmentation at intermediate p_T. The influence of the medium has also been linked to a long-range correlation component in $\Delta\eta$ [16,17,20]. This so-called η ridge has been shown to be flat up to $|\Delta\eta| \sim 2$. The PHENIX $\Delta\eta$ acceptance is limited to $|\Delta\eta| < 0.7$. However, if contributions from the ridge are significant, they should show up in $\Delta\eta$ distributions.

The left panel of Fig. 21 shows a two-dimensional $\Delta\eta$-$\Delta\phi$ correlation function for 2–3 $\otimes$ 2–3 GeV/c in 0–20% central Au+Au collisions. The $\Delta\eta$ range is displayed for $|\Delta\eta| < 0.5$ to suppress the relatively large statistical fluctuations at the edge of $\Delta\eta$ acceptance. The correlation function peaks along $\Delta\phi \sim 0$ and π, largely because of the elliptic flow modulation of the combinatoric pairs. To subtract the flow term, we assume that ξ and v_2 are identical to those used in our one-dimensional $\Delta\phi$ correlation analysis and constant for $|\eta| < 0.35$. The distribution after v_2 subtraction is shown in the right panel of Fig. 21. One can clearly see one near-side and two shoulder

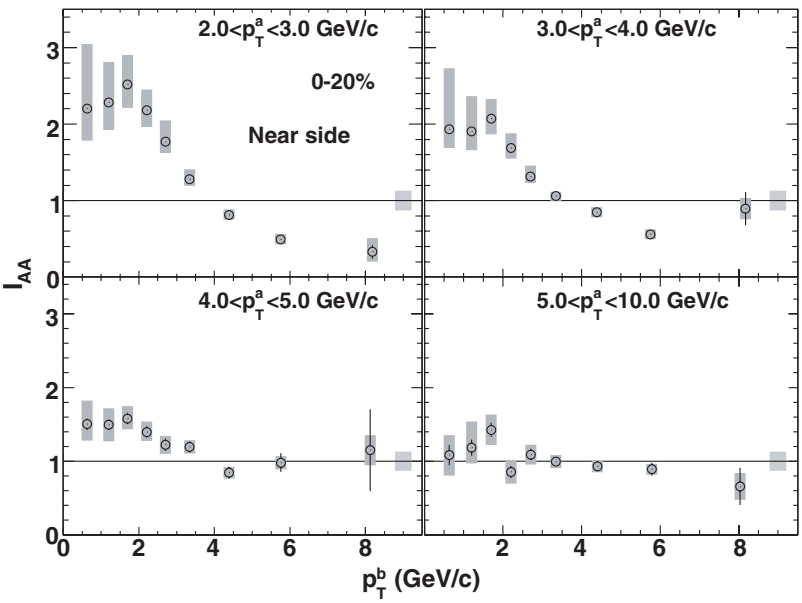

FIG. 19. Near-side I_{AA} in 0–20% Au+Au vs partner p_T for four trigger p_T bins. The shaded bars around the data points are the total systematic errors. Grey bands around $I_{AA} = 1$ represent 12% combined uncertainty on the single particle efficiency in Au+Au and $p + p$.

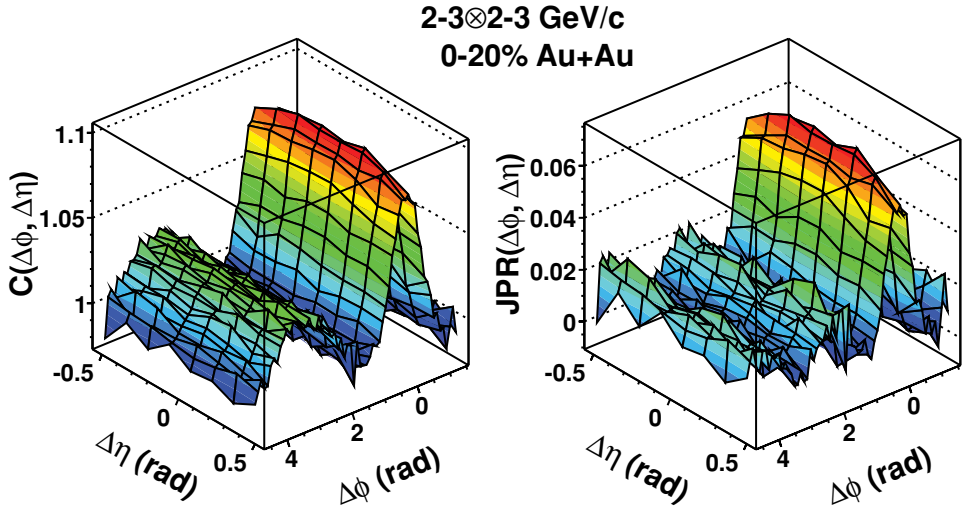

FIG. 21. (Color online) Correlation function [left panel, Eq. (8)] and background subtracted hadron-pair ratio [right panel, Eq. (13)] in $\Delta\eta$ and $\Delta\phi$ space for 2–3 $\otimes$ 2–3 GeV/c in 0–20% Au+Au collisions.

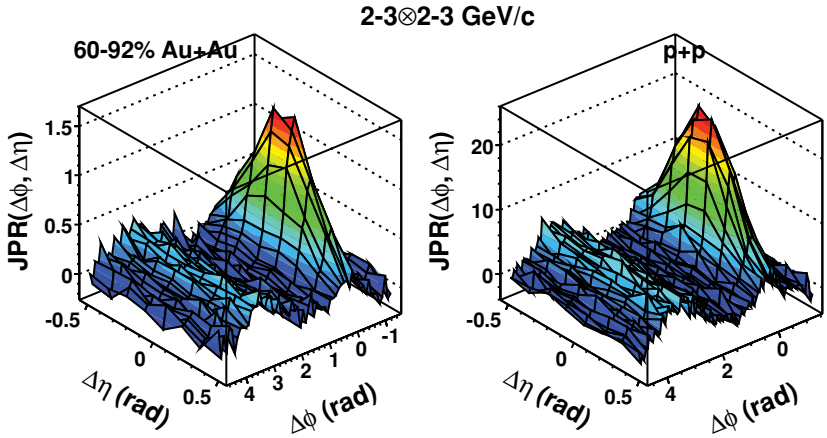

FIG. 22. (Color online) Background subtracted hadron-pair ratio [via Eq. (13)] for 2–3 $\otimes$ 2–3 GeV/c in 60–92% Au+Au (left panel) and $p + p$ (right panel) collisions.

peaks (in $\Delta\phi$), which extend over the full range of $\Delta\eta$. However, both $p + p$ and peripheral Au+Au collisions for the same p_T selections (Fig. 22) show one near-side peak centered around $\Delta\eta \sim 0$ and one away-side peak elongated over $\Delta\eta$. These features are expected for fragmentation of back-to-back dijets in vacuum.

To facilitate further detailed investigation, we focus on a near-side region defined by $|\Delta\phi| < 0.7$ and $|\Delta\eta| < 0.7$ and study the projected distributions in $\Delta\phi$ and $\Delta\eta$. Figure 23 compares the the $\Delta\eta$ distributions for $p + p$ and 0–20% central Au+Au collisions. The $p + p$ data indicate a relatively narrow jet-like peak for all four p_T selections. For the 2–3 $\otimes$ 2–3 GeV/c bin, the Au+Au data are enhanced and broadened relative to $p + p$. However, these differences gradually decrease toward higher p_T and essentially disappear for the 5–10 $\otimes$ 5–10 GeV/c bin. This possibly suggests that the ridge component at high p_T either disappears or becomes overwhelmed by the jet fragmentation component.[1]

Figure 24 compares the projected distributions in $\Delta\eta$ and $\Delta\phi$ for 0–20% central Au+Au collisions. By construction, the integrals of the two distributions are the same. For the 2–3 $\otimes$ 2–3 and 2–3 $\otimes$ 3–4 GeV/c bins, the distributions in $\Delta\eta$ are broader than in $\Delta\phi$. For the 3–4 $\otimes$ 3–5 and 5–10 $\otimes$ 5–10 GeV/c bins, the distributions become similar between $\Delta\phi$ and $\Delta\eta$. These observations suggest that the medium modifications are limited to $p_T^{a,b} \lesssim 4$ GeV/c, a similar p_T range in which the away-side is also strongly modified.

The evolution of the enhancement and broadening with the $p_T^{a,b}$ reflects the competition between contributions from the medium response and jet fragmentation. The former is important at $p_T^{a,b} \lesssim 4$ GeV/c and manifests itself as an enhanced and broadened distribution in $\Delta\eta$ and $\Delta\phi$. The latter dominates at higher p_T, reflected by $I_{AA} \approx 1$ and a near-side width similar to $p + p$. The strong modifications at intermediate p_T may reflect the remnants of those jets that interact with the medium, appearing as low-p_T hadron pairs with modified width and multiplicity. Possible physics mechanisms for this parton-medium interaction include jet interaction with a longitudinal flowing medium [22,23,27], position-momentum correlations induced by radial flow [21], correlation between radial flow boosted beam jet and medium suppressed transverse jet [26], plasma instability [24,25], or

[1]Note that the pseudorapidity coverage of PHENIX is smaller than that used in STAR, thus the amount of ridge yield seen in PHENIX is also smaller. The projected near-side jet shape in $\Delta\phi$ may also depend on the pseudorapidity coverage.

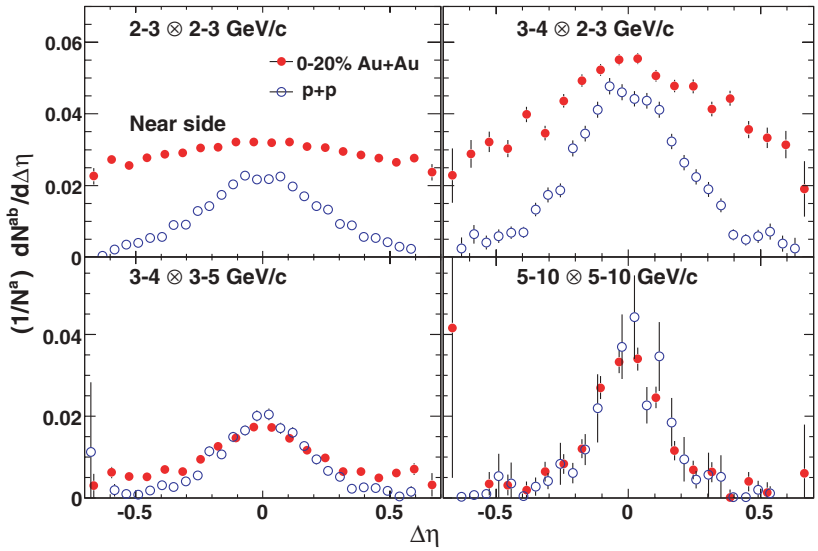

FIG. 23. (Color online) Per-trigger yield vs $\Delta\eta$ for $p + p$ (open symbols) and 0–20% central Au+Au (filled symbols) collisions. Results are shown for four $p_T^a \otimes p_T^b$ selections as indicated.

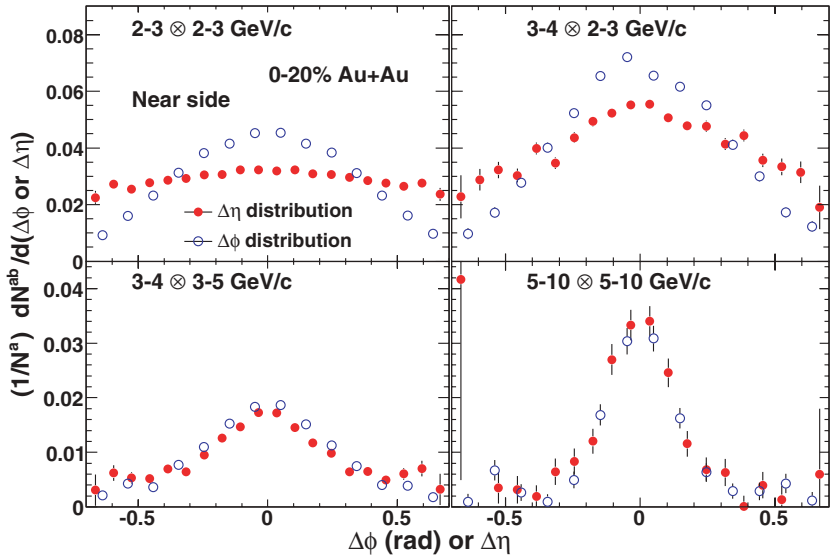

FIG. 24. (Color online) Projection of two-dimensional per-trigger yield in $|\Delta\eta| < 0.7 \otimes |\Delta\phi| < 0.7$ and 0–20% central Au+Au collisions onto $\Delta\phi$ (open symbols) and $\Delta\eta$ (filled symbols) for four $p_T^a \otimes p_T^b$ selections.

back-splash caused by the quenched jets [28]. However, the modification mechanisms for the near- and away-side may be related: both near- and away-side distributions show enhancement and broadening in the lower range $p_T < 4$ GeV/c, above which the jet characteristics qualitatively approach the jet fragmentation.

D. Away- and near-side spectral slopes

To further explore the differences between the NR, HR, and SR, we compare the shapes of the partner p_T spectra in these three $\Delta\phi$ regions. To do this, we characterize the local inverse slope of the spectra via a truncated mean p_T in a given p_T range,

$$\langle p_T' \rangle \equiv \langle p_T^b \rangle_{p_T^{\min} < p_T^b < p_T^{\max}} - p_T^{\min}. \quad (26)$$

where $\langle p_T' \rangle$ is calculated from the jet yields shown in Figs. 12 and 18. For an exponential spectrum with an inverse slope of T and $T \ll p_T^{\max} - p_T^{\min}$, $\langle p_T' \rangle \approx T$.

First, we focus on an intermediate p_T region, $1 < p_T^b < 5$ GeV/c, where the medium-induced contributions are important for the near- and away-side yields. Figure 25 shows values of $\langle p_T' \rangle$ for the HR, SR, and NR as a function of N_{part}. For all trigger p_T bins, the values for the NR drop slightly with centrality to a lower level relative to $p + p$. This can be understood from the shape difference in Fig. 19, where the Au+Au spectra drop faster with increasing p_T^b. For $3 < p_T^a < 4$ GeV/c, a factor of 2 decrease in 1–5 GeV/c amounts to a reduction of ~0.1 GeV/c in $\langle p_T' \rangle$.

Despite the small decrease with N_{part}, the overall average level of $\langle p_T' \rangle$ for the NR for $N_{\text{part}} > 100$ increases with trigger p_T. They are $0.533 + 0.024 - 0.016$, $0.605 + 0.033 - 0.023$, $0.698 + 0.03 - 0.04$, and $0.797 + 0.052 - 0.042$ GeV/c for triggers in 2–3, 3–4, 4–5, and 5–10 GeV/c, respectively. This trend is consistent with the dominance of jet fragmentation on the near-side, i.e., a harder spectrum for partner hadrons is expected for higher p_T trigger hadrons.

Values for the SR also show an almost flat centrality dependence for $N_{\text{part}} \gtrsim 100$. In this case, the values for $\langle p_T' \rangle$

TABLE V. Truncated mean p_T, $\langle p'_T \rangle$, calculated for $1 < p_T^b < 5$ GeV/c and averaged for $N_{\rm part} > 100$ in the NR and SR for various bins of trigger p_T.

p_T^a range (GeV/c)	NR $\langle p'_T \rangle$ (GeV/c)	SR $\langle p'_T \rangle$ (GeV/c)
2–3	0.533+0.024−0.016	0.445+0.013−0.007
3–4	0.605+0.033−0.023	0.443+0.018−0.018
4–5	0.698+0.030−0.040	0.461+0.031−0.051
5–10	0.797+0.052−0.042	0.478+0.079−0.139

are lower (≈0.45 GeV/c, see Table V), and they do not depend on the trigger p_T. They are, however, larger than the values obtained for inclusive charged hadrons (0.36 GeV/c as indicated by the solid lines) [6]. The relatively sharp change in $\langle p'_T \rangle$ for $N_{\rm part} \lesssim 100$ may reflect the dominance of jet fragmentation contribution in peripheral collisions.

The values of $\langle p'_T \rangle$ for the HR show a gradual decrease with $N_{\rm part}$. They start at a level close to the values for the near-side

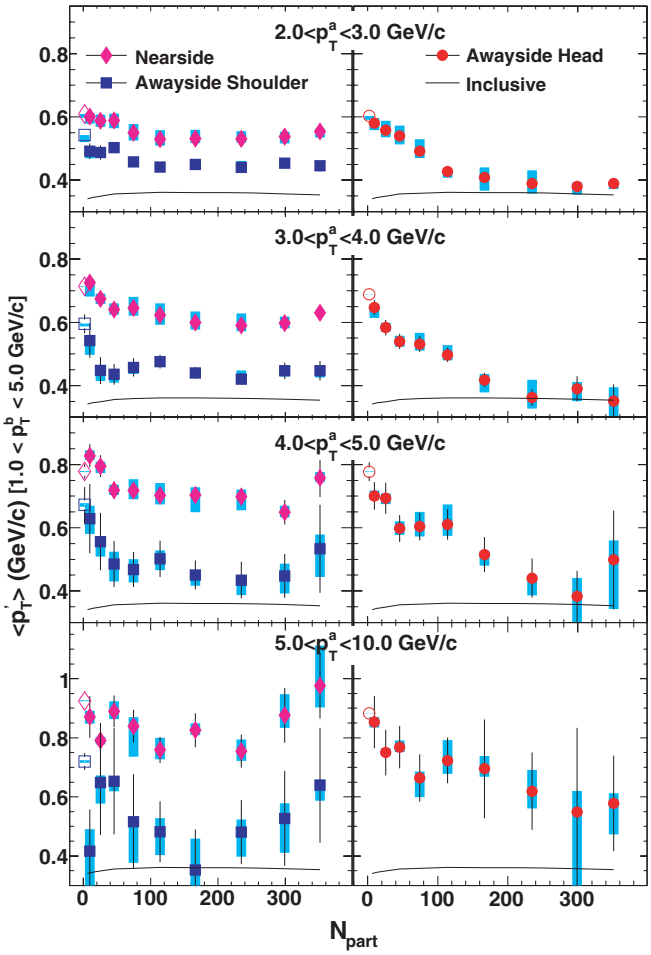

FIG. 25. (Color online) Truncated mean p_T, $\langle p'_T \rangle$, in $1 < p_T^b < 5$ GeV/c vs $N_{\rm part}$ for the near-side (diamonds), away-side shoulder (squares), and head (circles) regions for Au+Au (filled) and $p+p$ (open) for four trigger p_T bins. Solid lines represent values for inclusive charged hadrons (∼0.36 GeV/c) [6]. Error bars represent the statistical errors. Shaded bars represent the sum of $N_{\rm part}$-correlated elliptic flow and ZYAM error.

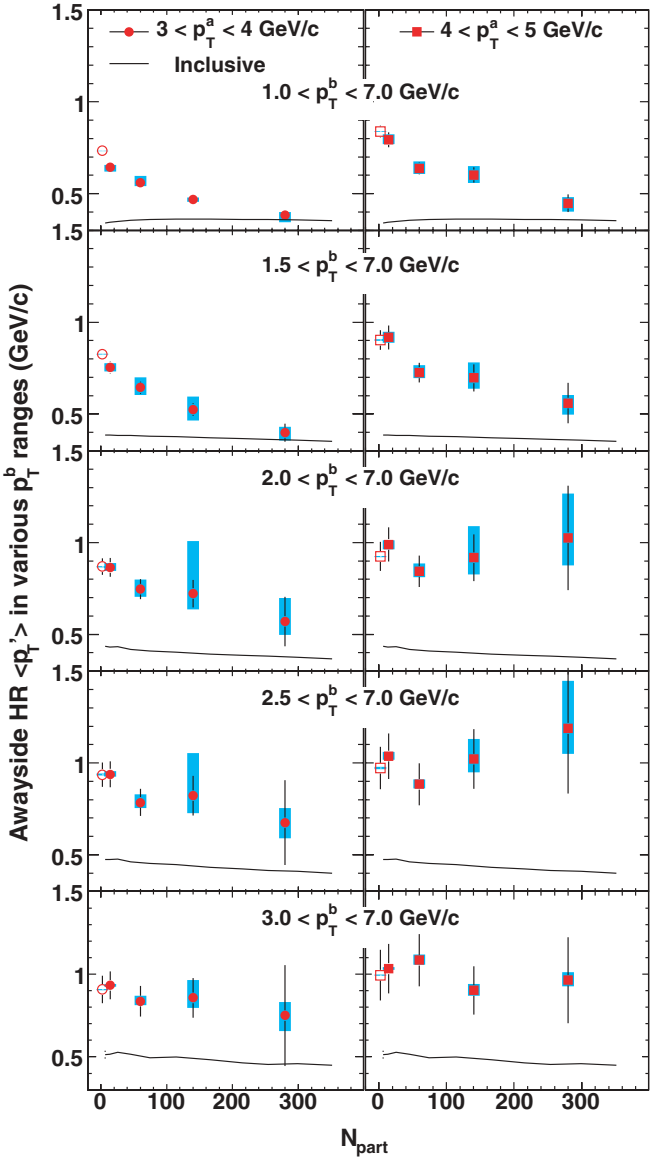

FIG. 26. (Color online) Truncated mean p_T, $\langle p'_T \rangle$, calculated for five partner-p_T ranges (from top to bottom) in the HR. The left panels (right panels) show the results for triggers in 3–4 (4–5) GeV/c. Solid lines represent values for inclusive charged hadrons. Error bars represent the statistical errors. Shaded bars represent the sum of $N_{\rm part}$-correlated elliptic flow and ZYAM error.

and gradually decrease with increasing $N_{\rm part}$, consistent with a softening of the partner spectrum in central collisions. For 2–3 and 3–4 GeV/c trigger bins, the values of $\langle p'_T \rangle$ for $N_{\rm part} \gtrsim 150$ approach those for inclusive spectra. For higher trigger p_T bins, the drop with $N_{\rm part}$ is less dramatic, possibly because of the punch-through jet fragmentation contribution at high p_T.

To further investigate the onset of jet fragmentation in the HR, we study the dependence of $\langle p'_T \rangle$ on partner momentum. Figure 26 shows the centrality dependence of $\langle p'_T \rangle$ calculated in various ranges of p_T^b for triggers in 3–4 GeV/c (left panels) and 4–5 GeV/c (right panels). These results are compared with values for inclusive hadron spectra calculated in the same p_T^b ranges. For $1 < p_T^b < 7$ GeV/c bin, $\langle p'_T \rangle$ decreases with

$N_{\rm part}$. As the p_T^b range shifts upward, the centrality dependence becomes flatter. $\langle p_T' \rangle$ for $3 < p_T^b < 7$ GeV/c is essentially constant with $N_{\rm part}$. The flattening of the spectral slope with $N_{\rm part}$ starts at a lower p_T^b for $4 < p_T^a < 5$ GeV/c than that for $3 < p_T^a < 4$ GeV/c. This implies (1) a similar spectra shape for Au+Au and $p + p$ at high $p_T^{a,b}$, and (2) the jet fragmentation contribution dominates the HR yield at large $p_T^{a,b}$.

The different patterns observed for the yields in the HR and SR suggest a different origin for these yields. The suppression of the HR yield and the softening of its spectrum are consistent with jet quenching. The observed HR yield could be comprised of contributions from punch-through jets, radiated gluons, and feed-in from the SR. By contrast, the enhancement of the SR yield for $p_T^{a,b} \lesssim 4$ GeV/c suggests a remnant of the lost energy from quenched jets. The very weak dependence on p_T and centrality (for $N_{\rm part} \gtrsim 100$) for its peak location and mean p_T may reflect an intrinsic response of the medium to the lost energy. These observations are challenging for simple deflected jet scenarios [23,29], since both the deflection angle and jet spectral slope would depend on p_T^a or p_T^b. On the other hand, they are consistent with expectations for Mach shock in a near-ideal hydrodynamic medium [35,71], and thus they can be used to constrain the medium transport properties such as speed of sound and viscosity-to-entropy ratio within these models.

E. Medium modification of hadron pair yield

In $p + p$ collisions at 200 GeV, it is generally believed that hadrons for $p_T > 2$ GeV/c are dominated by jet fragmentation [72]. By contrast, particle production in heavy-ion collisions is complicated by final state medium effects. Because of strong jet quenching, the jet fragmentation contribution only dominates for $p_T \gtrsim 5$–7 GeV/c [6,11]. The bulk of hadrons, i.e., those at $p_T \lesssim 4$ GeV/c, are dominated by soft processes such as the hydrodynamic flow of locally thermalized partonic medium [37,73,74] which subsequently hadronizes via the coalescence of constituent quarks [38–41]. The p_T of $4 \lesssim p_T \lesssim 7$ GeV/c is a transition region where both soft and hard processes contribute.

Dihadron correlations provide new tools for separating the hard and soft contributions at low and intermediate p_T, albeit for hadron pair production instead of single hadron production. If jets are quenched by the medium, and their energy is transported to lower p_T, a significant fraction of the low- and intermediate-p_T hadron pairs may retain some correlation with the original jet [42]. Consequently, they can contribute to a dihadron correlation analysis. However, such pairs can also be influenced by soft processes which dominate the inclusive hadron production in the same p_T region. For instance, they may couple with hydrodynamic flow at the partonic stage [23] or reflect the effects of the coalescence between shower parton and thermal partons during hadronization [39].

Thus far, we have quantified the jet modifications via per-trigger yields. While sensitive to modifications of jet-induced pairs, these yields are also sensitive to modifications in the number of triggers. For high-p_T triggers, however, the per-trigger yield is roughly equal to the per-jet yield, because most jets fragment into at most one trigger hadron due to the steeply falling jet spectra [44]. For intermediate- and low-p_T triggers, a large fraction of triggers may come from soft processes and hence "dilute" the per-trigger yield.

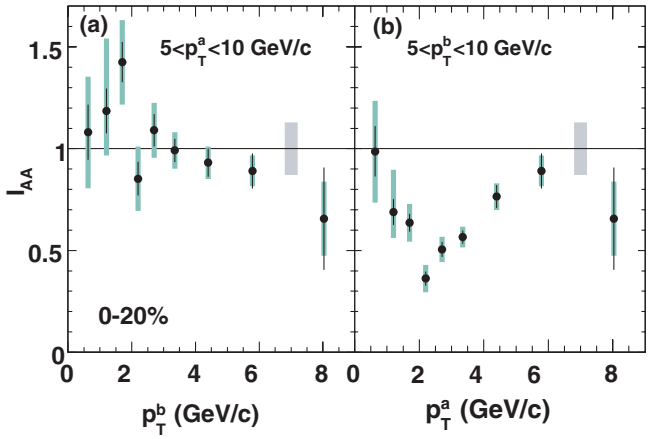

FIG. 27. (Color online) (a) I_{AA} vs partner p_T when 5–10 GeV/c hadrons are designated triggers. (b) I_{AA} vs trigger p_T when 5–10 GeV/c hadrons are used as partners.

To illustrate this dilution effect, we focus on the near-side jet-induced pairs in which the first hadron is fixed in the 5–10 GeV/c p_T range, and the second hadron is varied in p_T from 0.4 to 7 GeV/c. We note here that the requirement of a high-p_T hadron ensures that most of the near-side pairs come from fragmentation of partons. Figure 27(a) shows the per-trigger yield modification factor I_{AA} when hadrons in the 5–10 GeV/c p_T range are designated triggers; Fig. 27(b) shows the corresponding I_{AA} when the lower p_T hadrons are designated as triggers, which is calculated according to Eq. (7).

Figure 27(a) shows that I_{AA} is near unity for all p_T^b for the 5–10 GeV/c hadron triggers. This is consistent with each high-p_T trigger coming from one jet. On the other hand, when low-p_T hadrons are used as triggers, Fig. 27(b) shows that I_{AA} has a nontrivial dependence on p_T^a. That is, there is a strong suppression of I_{AA} in the 2–4 GeV/c p_T range, which reflects an excess of trigger hadrons at low p_T with weaker jet correlation strength. This dilution effect is also reflected in the near-side I_{AA} values in Fig. 19 and for the away-side I_{AA} values in Fig. 13 (also reflected in Fig. 36 for low p_T^a and high p_T^b). The former shows a suppression at large p_T^b for soft triggers ($2 < p_T^a < 3$ and $3 < p_T^a < 4$ GeV/c). The latter shows a stronger suppression for low-p_T triggers ($2 < p_T^a < 3$ and $3 < p_T^a < 4$ GeV/c) than for high-p_T triggers ($4 < p_T^a < 5$ and $5 < p_T^a < 10$ GeV/c). This dilution effect might be the result of the following two scenarios: (1) a large fraction of low-p_T hadrons are from soft processes such as coalescence of flow-boosted thermal quarks related to the anomalous proton/pion ratio [6,11], or (2) jets are quenched, and these hadrons are the remnants of the quenched jets and thus lack associated hadrons at high p_T.

To gain more insight into intermediate-p_T correlations, we focus on the pair suppression factor J_{AA} defined in Eq. (4). We recall here that J_{AA} quantifies the modification of jet-induced

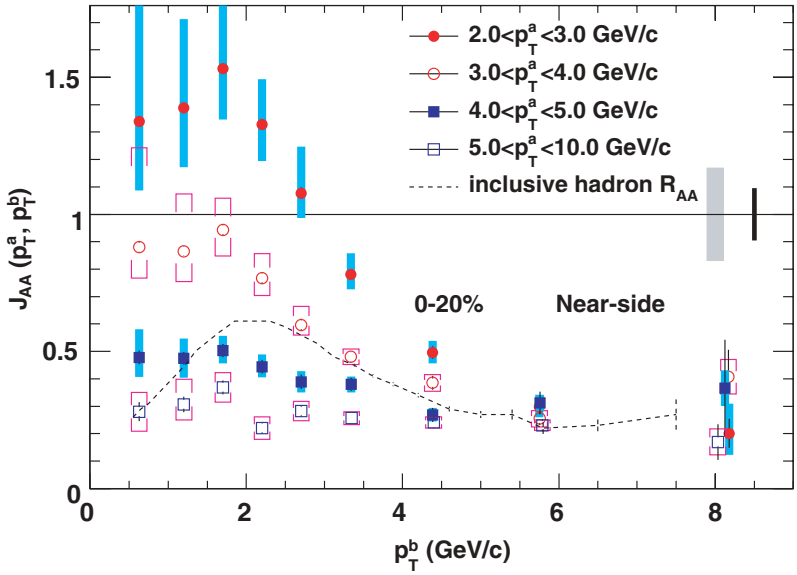

FIG. 28. (Color online) Near-side pair suppression factor J_{AA} in 0–20% Au+Au collisions as function of p_T^b for various ranges of p_T^a. The dashed line indicates the charged hadron R_{AA}. The grey band around unity is the systematic error due to the 20% combined single particle efficiency of the triggers and partners in Au+Au and $p+p$. The dark line around unity indicates the uncertainty on the $N_{\rm coll}$.

pairs in Au+Au relative to that in $p+p$ normalized by $N_{\rm coll}$. It is symmetric with respect to the interchange of p_T^a and p_T^b and equals unity in the absence of medium effects. Figure 28 shows the near-side J_{AA} as function of p_T^b for 0–20% central Au+Au collisions and for four different p_T^a bins. Values of J_{AA} are above unity for $p_T^{a,b} < 2$ GeV/c. However, they decrease with increasing $p_T^{a,b}$ and drop below unity. For high $p_T^{a,b}$, J_{AA} reaches a constant value of ∼0.2–0.3, which is similar to the high-p_T single particle suppression factor R_{AA}.

To interpret these observations, we note that each high-p_T pair at the near-side comes from the same jet. Thus J_{AA} reflects the modification of single jets, which at high p_T should be the same as the leading hadron R_{AA}. Since the values of R_{AA} are constant at high p_T, we expect high-p_T J_{AA} to be constant and equal to R_{AA}.

Furthermore, if each high-p_T near-side pair comes from the same jet, then the sum of their transverse momentum, $p_T^{\rm sum} = p_T^a + p_T^b$, should serve as a better proxy for the original jet energy. With this in mind, we replot in Fig. 29 the near-side J_{AA} values as a function of this "pair proxy energy" $p_T^{\rm sum}$. Interestingly, the pair modification factors roughly follow a single curve in $p_T^{\rm sum}$. It is above unity below 5 GeV/c, followed by a decrease with $p_T^{\rm sum}$, and reaches a constant for $p_T^{\rm sum} >$ 8 GeV/c. The approximate scaling behavior breaks when the p_T of one hadron is $\lesssim$2 GeV/c, where J_{AA} is systematically below the overall trend.

The fact that $J_{AA} > 1$ for $p_T^{\rm sum} < 5$ GeV/c implies that the total jet-induced pair yield is enhanced relative to the $N_{\rm coll}$ scaled $p+p$ collisions. This enhancement may reflect the energy of the quenched jets being transported to low p_T. J_{AA} is almost a factor of 6–7 larger than its high $p_T^{\rm sum}$ limit. By contrast, the enhancement shown for I_{AA} in Fig. 19 is only a factor of 2.5 at low $p_T^{a,b}$. This difference can be attributed to the dilution effect on the triggers. For completeness, Fig. 30 shows the values of J_{AA} vs p_T^b (left panels) and vs $p_T^{\rm sum}$ (right panels) for 20–40%, 40–60%, and 60–92% centrality

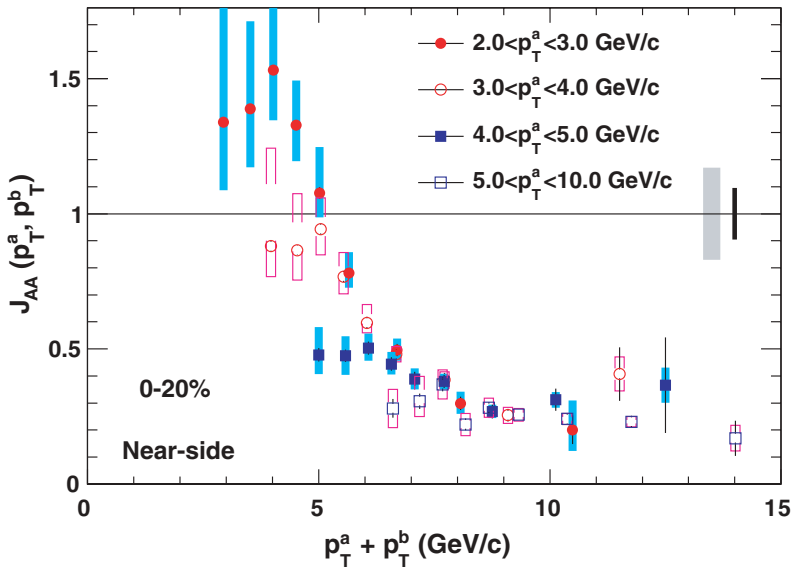

FIG. 29. (Color online) Near-side pair suppression factor J_{AA} as function of pair transverse momentum, $p_T^{\rm sum} = p_T^a + p_T^b$ in 0–20% Au+Au collisions. bins. J_{AA} vs $p_T^{\rm sum}$ shows an approximate scaling behavior for all centralities, i.e, J_{AA} for large $p_T^{\rm sum}$ approaches a constant level roughly equal to that for the high-p_T R_{AA} values.

In Fig. 31, we show the J_{AA} for the away-side HR as a function of p_T^b in various centrality bins. In central collisions, a possible enhancement at low $p_T^{a,b}$ and a strong suppression at large $p_T^{a,b}$ can be seen. This is consistent with the feedback of lost energy to lower p_T on the away-side. The modifications decrease for peripheral collisions, as expected for a weaker medium effect. However, the suppression level seems to approach a constant value for high p_T^b for all centralities. This is expected since $I_{AA} \approx R_{AA}$ at high p_T for the away-side HR. This implies that $J_{AA} = I_{AA} R_{AA} \approx R_{AA}^2$ when one of the hadrons is at high p_T, as indicated by the dashed line.

To quantify this high-p_T scaling behavior, we calculate the ratio $\frac{J_{AA}}{R_{AA}^2}$ for the away-side head region for $4 < p_T^b < 7$ GeV/c and various p_T^a selections. The values for the four centrality ranges used in Fig. 31 are summarized in Table VI. Although the uncertainties are quite substantial, the HR J_{AA} approximately equals R_{AA}^2, suggesting a similar suppression factor for inclusive hadrons and the away-side jet at high p_T. This, as pointed out in Refs. [75,76], could be a canceling effect between a stronger energy loss, which increases the suppression, and harder away-side hadron spectra associated with high-p_T triggers, which decrease the suppression.

V. DISCUSSION

A. Insights from identified particle and energy dependent correlations

To elucidate the underlying physics of the medium-induced component, we focus on intermediate p_T where the SR dominates, and we study the particle composition of the yield in the SR. PHENIX has published results on correlations of a trigger hadron, at intermediate transverse momentum ($2.5 < p_T^a < 4$ GeV/c), with identified partner mesons or baryons at lower p_T [43]. The away-side shape was found to be similar for partner baryons and mesons; namely, the pairs peak at $\Delta\phi \sim \pi \pm 1.1$ with a local minimum at $\Delta\phi \sim \pi$. The particle composition in the away-side jet, as reflected by the baryon-to-meson ratio, was also found to grow with increasing

TABLE VI. Average ratio J_{AA}/R_{AA}^2 for the away-side HR for $4 < p_T^b < 7$ GeV/c (see Fig. 31).

Centrality	J_{AA}/R_{AA}^2 for HR ($\pm$Stat.+Sys.$-$Sys.)
0–20%	$0.81 \pm 0.07 + 0.44 - 0.41$
20–40%	$0.89 \pm 0.05 + 0.37 - 0.35$
40–60%	$0.80 \pm 0.03 + 0.26 - 0.23$
60–92%	$0.90 \pm 0.03 + 0.25 - 0.23$

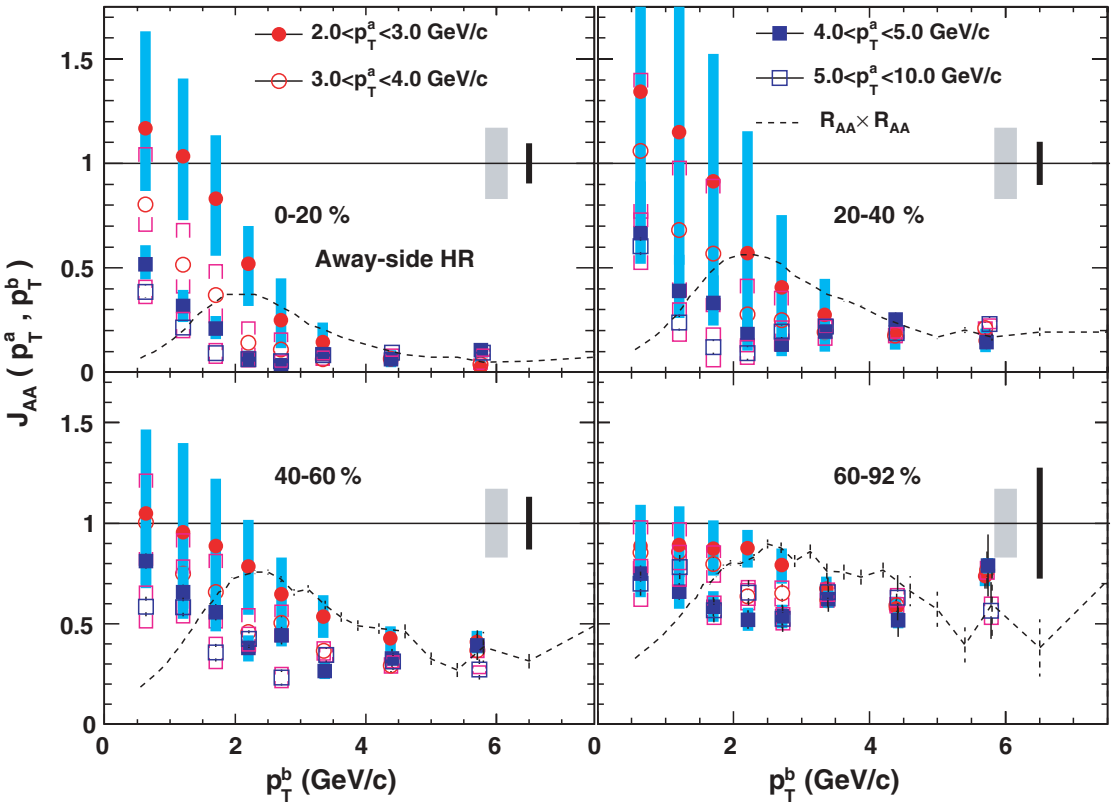

FIG. 31. (Color online) Pair suppression factor J_{AA} for the away-side HR in Au+Au collisions as function of p_T^b for various ranges of p_T^a. The dashed lines indicate the square of the charged hadron R_{AA}. The grey bands around unity are the systematic errors due to the combined single particle efficiency of the two particles in Au+Au and $p+p$. The dark lines around unity indicate the uncertainty on the $N_{\rm coll}$.

partner p_T. The trend is similar to that observed for inclusive hadron production. These observations for intermediate-p_T correlations are consistent with strong parton-medium interactions which induce correlations between soft partons, followed by coalescence at hadronization.

Further insight into the physics underlying the SR yield can be obtained by studying its energy dependence. In particular, it is interesting to see whether the two-component picture applies at much lower collision energy. Figure 32 compares the per-trigger yield at $\sqrt{s_{NN}} = 200$ and 62.4 GeV for $1 < p_T^b < 2.5 < p_T^a < 4$ GeV/c. They are the yields associated with the jet functions previously published in Ref. [19]. The away-side shapes are strongly non-Gaussian in both cases. The 62.4 GeV data seem to be somewhat flatter, however, their relatively large statistical uncertainties do not allow a definite statement to be made.

The CERES Collaboration recently released their high-statistics preliminary results of per-trigger yields in 0–5% and 5–10% Pb+Au collisions for $1 < p_T^b < 2.5 < p_T^a < 4$ GeV/c [77]. This measurement was carried out at $\sqrt{s_{NN}} = 17.2$ GeV at the CERN Super Proton Synchrotron (SPS), for $0.1 < \eta < 0.7$ in the center-of-mass (c.m.) frame. The equivalent pseudorapidity window of 0.6 is close to the PHENIX value of 0.7. Thus, the jet yields from both experiments can be compared after applying the correction of $0.7/0.6 = 1.17$. In contrast to the PHENIX results, the CERES data show an essentially flat away-side jet shape. The maximum of SR is about half that of the PHENIX value, whereas the yield at the HR is close to the PHENIX value. The former might suggest a weaker medium effect at lower energy; the latter could be a combination of a lower jet multiplicity and a weaker jet quenching at SPS energy. However, it is conceivable that other nuclear effects, especially the Cronin effect [78], may also broaden the away-side jet shape. Further detailed

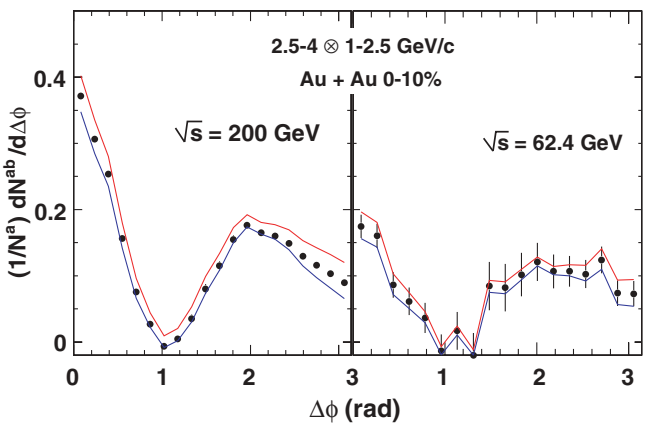

FIG. 32. (Color online) Per-trigger yield in 0–10% central Au+Au collisions from PHENIX at (a) $\sqrt{s_{NN}} = 200$ GeV and (b) $\sqrt{s_{NN}} = 62.4$ GeV. The histograms show the combined uncertainty of the elliptic flow and ZYAM errors.

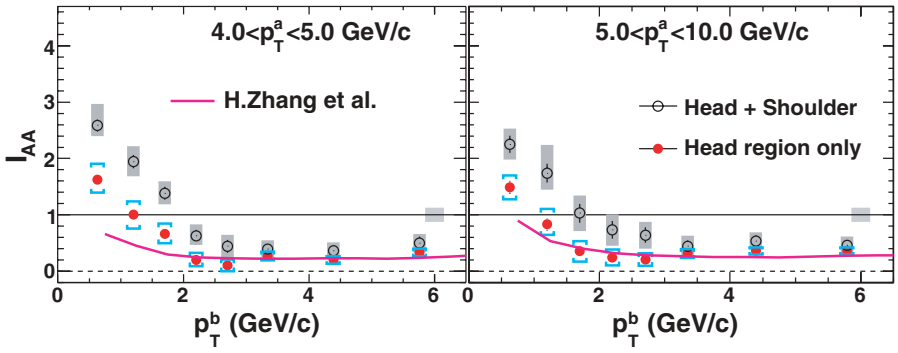

FIG. 33. (Color online) Comparison of I_{AA} with energy loss calculation from Ref. [76].

study of the collision energy dependence of the HR and SR components might elucidate the onset of jet quenching and medium response.

B. Comparison with models

If jets are generated close to the surface, they exit and subsequently fragment outside the medium. Otherwise, they lose energy by radiating gluons. These shower gluons may be emitted at large angles relative to the original partons [31,32] and fragment into hadrons, or they can be deflected to large angles by interactions with medium. Examples of the latter include medium deflection in the azimuthal [23,29] and the beam directions [25] or excitation of collective Mach shock [35,36].

Several calculations for radiative energy loss have been carried out [14,31,76] to describe dihadron production at high p_T. They all describe the data fairly well. As an example, Fig. 33 shows a comparison of data for the 4–5 and 5–10 GeV/c triggers with recent calculations from Ref. [76]. For $p_T^a > 2$ GeV/c, the calculated I_{AA} is approximately constant and agrees well with the data. According to this calculation, both tangential and punch-through jet emission are important, accounting for 3/4 and 1/4 of the away-side high-p_T pairs, respectively.

To extend the calculation to low and intermediate p_T, contributions from radiated gluons have to be taken into account. Early energy loss model calculations suggested that these radiated gluons are almost collinear with the jet axis [79]. However, recent calculations [31] favor large-angle gluon emission due to destructive interference that suppresses collinear emission. By including gluon feedback, the calculation can reproduce away-side per-trigger yields at low partner p_T, but the gluon emission angle is too small to reproduce the away-side jet shape.

In an improved calculation that includes the Sudakov form factors [32], the authors can qualitatively describe the away-side jet shape and its centrality dependence at intermediate p_T, when the leading parton is assumed to split into two semihard gluons which then fragment into hadrons. This model assumes a transport coefficient of $\hat{q} \sim 5$–10 GeV^2/fm. A smaller $\hat{q}$, for instance, would substantially reduce the predicted split angle.

The away-side broadening may also arise from Cherenkov gluon radiation [34]. It could occur when the gluon is scattered by colored bound states in such a way that the permittivity for in-medium gluons becomes space-like. A first calculation that includes only scalar bound states suggests that the peak angle D should gradually decrease to zero with increasing momentum; this trend seems to be ruled out by the present data. More sophisticated calculations including other bound states are needed in future studies.

It has been suggested that shower partons could couple with the longitudinal and transverse flow and are broadened or deflected in $\Delta\eta$ [21–23,27] and/or $\Delta\phi$ [23,29] directions. The longitudinal deflection was argued to be responsible for the $\Delta\eta$ ridge structure at the near-side. The transverse deflection can lead to broadening in $\Delta\phi$. It was argued in Ref. [29] that a random multiple scattering of the leading parton, combined with energy loss, can result in the double peaked structure of the away-side. However, in general, the deflection angle decreases with the hadron momentum. This is not compatible with the observation of p_T-independent D values and universal spectral slopes of the SR.

Finally, it has been proposed that the lost energy can be absorbed by the medium and converted into collective Mach shock [35,36]. In this picture, the fluid elements are boosted along the Mach angle [71] and then hadronize via coalescence. The Mach angle depends only on the sound speed of the medium thus is independent of p_T and consistent with the data. The boost effect also produces a harder slope for the partners, qualitatively consistent with experimental observations. Our results on the PID dependence of the correlation pattern [43] are consistent with the above picture. The propagation of the shock wave requires hydrodynamic behavior of the medium with small viscosity. If the Mach shock is the underlying physics, the observation can be used to constrain the value of η/s.

Many of the models discussed in this section are quite qualitative in nature. These models typically focus on either jet shape or jet yield, near-side or away-side, high p_T or low p_T. The fact that both near- and away-side distributions are enhanced and broadened at low p_T and that the modifications are limited to $p_T \lesssim 4$ GeV/c, above which the jet characteristics qualitatively approach jet fragmentation, may suggest that the modification mechanisms for the near- and away-side are related. A model framework that includes both jet quenching and medium response and can describe the full p_T evolution of the jet shape and yield at both near- and away-side is required to understand the parton-medium interactions. Our data provide valuable guidance for such future model developments.

VI. SUMMARY AND CONCLUSIONS

We have analyzed dihadron azimuthal correlations for $0.4 < p_T < 10$ GeV/c unidentified charged hadrons in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The results are presented as functions of trigger p_T, partner p_T, and centrality and are compared with correlations of identified hadrons as well as results from lower energies. The evolution of the jet shape and yield with p_T seems to suggest four distinct contributions to jet-induced pairs: (1) a jet fragmentation component around $\Delta\phi \sim 0$, (2) a punch-through jet fragmentation component around $\Delta\phi \sim \pi$, (3) a medium-induced component around $\Delta\phi \sim 0$, and (4) a medium-induced component around $\Delta\phi \sim \pi \pm 1.1$.

The jet fragmentation components arise from jets that suffer small energy loss due to the surface or punch-through jet emissions. They dominate the near- and away-side pairs at large p_T. The near-side pair suppression factor J_{AA} follows an approximate scaling with the pair proxy energy $p_T^{\rm sum}$. It reaches a constant for $p_T^{\rm sum} > 8$ GeV/c, at a level similar to the suppression for single jets at high p_T. In this p_T region, the yield of both the single jets (near-side pairs) and back-to-back jets (away-side pairs) are consistent with energy loss calculations.

By contrast, the enhancement of medium-induced components may reflect a remnant of the lost energy from quenched jets. This enhancement is limited to $p_T^{a,b} \lesssim 4$ GeV/c. The near-side medium-induced component is responsible for broadening in $\Delta\phi$ and significant elongation in $\Delta\eta$, and is related to the ridge structure [16,17,20]. The away-side medium-induced component exhibits p_T- and centrality-independent shape and mean p_T and a bulk medium-like particle composition [43], possibly reflecting an intrinsic property of the medium response to energetic jets.

We have also investigated the contribution of medium-induced components to single particle production at intermediate p_T, where soft processes such as hydrodynamic flow and coalescence are important. The yields of jet-induced hadron pairs (via J_{AA}) are not suppressed at low pair proxy energy $p_T^{\rm sum} = p_T^a + p_T^b$. However, pair yields divided by the yield of soft triggers show an apparent dilution effect at large partner p_T. This suggests that these soft hadrons either come from soft processes such as from coalescence of thermal partons, or they are the remnant of quenched jets, and thus lack high-p_T jet partners.

APPENDIX A: DIHADRON CORRELATION METHOD

This section demonstrates that the shape of the $\Delta\phi$ correlation function, constructed as the ratio of same to mixed events, reproduces the shape of the true-pair distribution in $\Delta\phi$. We demonstrate this is generally true for a nonuniform experimental acceptance such as in the PHENIX experiment. Our argument is not original with our analysis but has been used numerous times before in correlation analyses in heavy-ion experiments.

We start by giving notation for the true distributions of type a and type b particles. They are

$$\frac{d^2N_0^{ab}}{d\phi^a d\phi^b}, \quad \frac{dN_0^a}{d\phi^a}, \quad \frac{dN_0^b}{d\phi^b}, \tag{A1}$$

for the true azimuthal distributions for ab pairs and a and b singles produced for PHENIX pseudorapidity acceptance and for events in one centrality bin. We use subscript 0 to indicate the true distributions. The *true* distributions are for particles in PHENIX η range, but with full azimuthal coverage.

The PHENIX beam-beam counter (BBC) and zero-degree calorimeter (ZDC), which trigger on events and determine their centrality, are uniform in azimuth. Therefore the *true* singles distributions are uniform, and the *true* pair distribution depends only on the difference between the two angles:

$$\frac{d^2N_0^{ab}}{d\phi^a\, d\phi^b} = f(\phi^a - \phi^b), \quad \frac{dN_0^a}{d\phi^a} = \text{const}, \quad \frac{dN_0^b}{d\phi^b} = \text{const}. \tag{A2}$$

To study the pair distribution as a function of $\Delta\phi$, we define the difference and average of ϕ^a and ϕ^b as new orthogonal variables:

$$\Delta\phi \equiv \phi^a - \phi^b, \quad \bar{\Phi} \equiv (\phi^a + \phi^b)/2. \tag{A3}$$

We integrate the true pairs over $\bar{\Phi}$ to obtain the projection onto $\Delta\phi$. This is equivalent to binning the data in $\Delta\phi$.

$$\frac{dN_0^{ab}}{d(\Delta\phi)} = \int \frac{d^2N_0^{ab}}{d\phi^a\, d\phi^b}\, d\bar{\Phi} = \int f(\Delta\phi)\, d\bar{\Phi} = f(\Delta\phi) \int d\bar{\Phi} \propto f(\Delta\phi), \tag{A4}$$

The measured distributions (without superscript) are related to the true distributions through the experimental acceptance/efficiency (here just "acceptance" for short):

$$\frac{d^2N^{ab}}{d\phi^a\, d\phi^b} = \varepsilon^{ab}(\phi^a, \phi^b)\, \frac{d^2N_0^{ab}}{d\phi^a\, d\phi^b}, \qquad \frac{dN^a}{d\phi^a} = \varepsilon^a(\phi^a)\, \frac{dN_0^a}{d\phi^a}, \quad \frac{dN^b}{d\phi^b} = \varepsilon^b(\phi^b)\, \frac{dN_0^b}{d\phi^b}, \tag{A5}$$

where ε^{ab}, ε^a, and ε^b describe the experimental acceptances for pairs and singles. The pair acceptance is, to a very good approximation, equal to the product of the singles acceptances:

$$\varepsilon^{ab}(\phi^a, \phi^b) = \varepsilon^a(\phi^a)\, \varepsilon^b(\phi^b), \tag{A6}$$

i.e., the experimental acceptance for a particles is not influenced by the presence or absence of b particles in any particular event, and vice versa.[2]

The numerator of the correlation function is the measured pair distribution projected onto $\Delta\phi$

$$N^{\text{same}}(\Delta\phi) = \int \frac{d^2N_0^{ab}}{d\phi^a\, d\phi^b}\, d\bar{\Phi} = f(\Delta\phi) \int \varepsilon^{ab}(\phi^a, \phi^b)\, d\bar{\Phi}. \tag{A7}$$

Mixed-event pairs are constructed by combining a particle at ϕ^a from one event with particles at ϕ^b from other, unrelated events. The mixed-event pairs over (ϕ^a, ϕ^b) factorize and have the form

$$\frac{d^2N_{\text{mixed}}^{ab}}{d\phi^a\, d\phi^b} \propto \frac{dN^a}{d\phi^a}\frac{dN^b}{d\phi^b}. \tag{A8}$$

The denominator of the correlation function is the projection of the measured mixed-event pairs:

$$N^{\text{mixed}}(\Delta\phi) = \int \frac{d^2N_{\text{mixed}}^{ab}}{d\phi^a\, d\phi^b}\, d\bar{\Phi} \propto \int \frac{dN^a}{d\phi^a}\frac{dN^b}{d\phi^b}\, d\bar{\Phi} \propto \int \varepsilon^a(\phi^a)\varepsilon^b(\phi^b)\, d\bar{\Phi}. \tag{A9}$$

Writing the correlation function with Eqs. (A7) and (A9), and applying Eqs. (A6) and (A4) yields

$$C(\Delta\phi) \equiv \frac{N^{\text{same}}(\Delta\phi)}{N^{\text{mixed}}(\Delta\phi)} \propto \frac{f(\Delta\phi) \int \varepsilon^{ab}(\phi^a, \phi^b)\, d\bar{\Phi}}{\int \varepsilon^a(\phi^a)\varepsilon^b(\phi^b)\, d\bar{\Phi}} \tag{A10}$$

$$\propto f(\Delta\phi) \propto \frac{dN_0^{ab}}{d(\Delta\phi)}. \tag{A11}$$

This shows that the shape of the true-pair distribution is recovered in the correlation function.

APPENDIX B: ROLE OF THE REACTION PLANE

No mention, explicit or implicit, was made of the reaction plane in the preceding proof; this is not surprising, since its validity holds for *any* source of correlation, whether from flow, jets, or other. We show that Eq. (A11) holds for limited detector acceptance with the reaction plane included explicitly.

For events with reaction plane direction Ψ, we define the conditional probabilities of finding an a or b particle, including the effects of acceptance, as

$$P^a(\phi^a|\Psi) = \varepsilon^a(\phi^a)\, \frac{dN^a}{d(\phi^a - \Psi)}, \qquad P^b(\phi^b|\Psi) = \varepsilon^b(\phi^b)\, \frac{dN^b}{d(\phi^b - \Psi)}. \tag{B1}$$

We can write the acceptances, and the *true* singles distributions with respect to Ψ, into their Fourier expansions:

$$\varepsilon^a(\phi) = \sum_{p=-\infty}^{p=+\infty} a_p e^{ip\phi}, \qquad \varepsilon^b(\phi) = \sum_{q=-\infty}^{q=+\infty} b_q e^{iq\phi}, \tag{B2}$$

where $a_{-p} = a_p^*$, $b_{-q} = b_q^*$, and

$$\frac{dN^a}{d(\phi^a - \Psi)} = \frac{1}{2\pi} \sum_{n=-\infty}^{n=+\infty} v_n^a\, e^{in(\phi^a - \Psi)} = \frac{1}{2\pi}\left(1 + \sum_{n=1}^{+\infty} 2v_n^a \cos n(\phi^a - \Psi)\right), \qquad \frac{dN^b}{d(\phi^b - \Psi)} = \frac{1}{2\pi} \sum_{m=-\infty}^{m=+\infty} v_m^b\, e^{im(\phi^b - \Psi)} = \frac{1}{2\pi}\left(1 + \sum_{m=1}^{+\infty} 2v_m^b \cos m(\phi^b - \Psi)\right). \tag{B3}$$

In the case that ab correlations are due to particle correlation with respect to the same reaction plane, as would be true of background pairs, then the *measured* same-event pair

[2] The condition of Eq. (A6) can be violated by some experimental effects, such as ghost-pair tracking artifacts at small angles. We recover the result of Eq. (A6) by applying pair cuts to remove such artifacts identically to same-event and mixed-event pairs. Pair cuts affect the integrands in the numerator and denominator of Eq. (A10) equally and so leave the end result of Eq. (A11) intact.

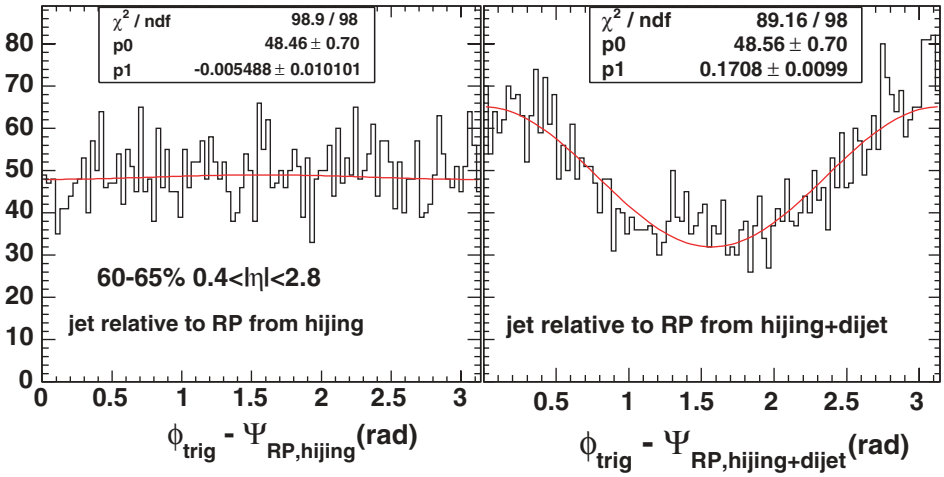

FIG. 34. (Color online) Distribution of the leading particle from the dijets relative to the event plane calculated from HIJING only (left) and event plane from the embedded event (right).

distribution can be written as

$$N^{\text{same}}(\Delta\phi) = \int \frac{d\phi^a}{2\pi}\frac{d\Psi}{2\pi} P^a(\phi^a|\Psi)P^b[(\phi^a - \Delta\phi)|\Psi]$$

$$= \sum_{p=-\infty}^{p=+\infty}\sum_{n=-\infty}^{n=+\infty} a_p\, b_p^*\, v_n^a v_n^b e^{i(p+n)\Delta\phi}. \quad \text{(B4)}$$

Similarly, the *measured* mixed-event pair distribution is

$$N^{\text{mixed}}(\Delta\phi) = \int \frac{d\phi^a d\Psi^a d\Psi^b}{8\pi^3} P^a(\phi^a|\Psi^a)P^b[(\phi^a - \Delta\phi)|\Psi^b]$$

$$= \sum_{p=-\infty}^{p=+\infty} a_p\, b_p^*\, e^{ip\Delta\phi}. \quad \text{(B5)}$$

Using these to construct the correlation function, we find

$$C(\Delta\phi) \equiv \frac{N^{\text{same}}(\Delta\phi)}{N^{\text{mixed}}(\Delta\phi)} = \sum_{n=-\infty}^{n=+\infty} v_n^a v_n^b e^{in\Delta\phi}. \quad \text{(B6)}$$

It is clear that the dependence upon the reaction plane angle is integrated out when forming the correlation function. It is also clear that the quadruple modulation strength of the correlation function $v_2^a v_2^b$ for background pairs is exactly the product of the *true* modulation strengths of the *true* singles distributions v_2^a and v_2^b.

APPENDIX C: SIMULATION STUDY OF THE NONFLOW EFFECT FROM JETS

The elliptic flow of the triggers and partners, which are used to estimate the background contribution in the correlation function of Eq. (15), are provided by the BBC reaction plane method. In this section, we show that the large rapidity separation of $|\Delta\eta| > 2.75$ between the PHENIX BBC and central arm greatly suppresses the bias due to jets and dijets to the reaction plane determination. More details can be also be found in Ref. [80].

The intrajet correlation is typically limited by the size of the jet cone, which is much smaller than the $\Delta\eta$ separation between the BBC and central arm. However, due to their broad distribution of parton x values, the away-side jets have a very broad distribution in $\Delta\eta$. Hence the interjet correlations can potentially bias the BBC reaction plane determination. We study the biases by embedding back-to-back jet pairs into HIJING events. The HIJING events serve as the underlying Au+Au events and were checked to reproduce the charged hadron multiplicity in η from PHOBOS [81]. Elliptic flow is implemented by applying a track-by-track weight in each HIJING event:

$$w(\mathbf{b}, p_T, \eta) = 1 + 2v_2(\mathbf{b}, p_T, \eta)\cos 2(\phi - \Psi),$$

where Ψ is the direction of the impact parameter $\mathbf{b}$. The centrality and p_T dependence of the v_2 is tuned according to the PHENIX measurement [82]. The η dependence of v_2 is obtained from PHOBOS [60] minimum bias events. The v_2 shape vs η is assumed to be independent of centrality selections. This gives an overall $\mathbf{b}$, p_T, and η dependence by a single function,

$$v_2(p_T, \mathbf{b}, \eta) = 0.02834\ \mathbf{b}\ e^{-0.5(\eta/3.92)^2}\left(1 - \frac{2.1}{1 + e^{1.357 p_T}}\right).$$

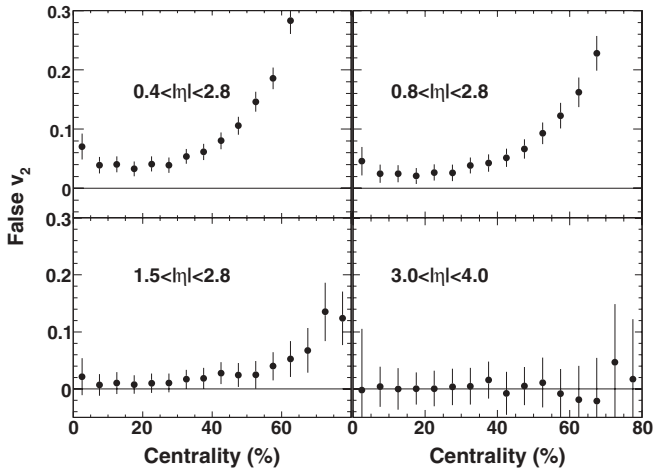

FIG. 35. False reaction plane v_2 of the leading hadron from the embedded dijet as function of centrality. The η range used to determine the event plane is indicated in each panel. The embedded dijet is required to have a trigger hadron above 6 GeV/c with a midrapidity window of $|\eta| < 0.35$.

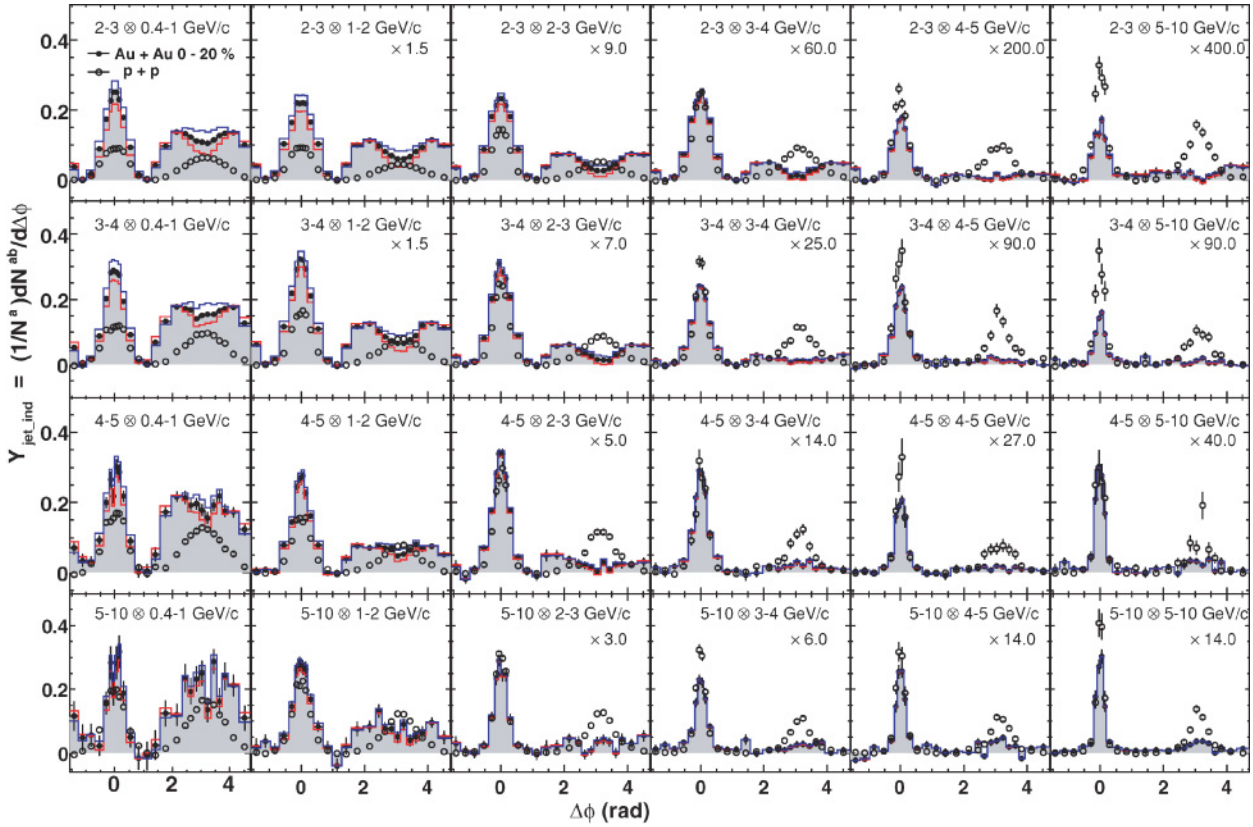

FIG. 36. (Color online) Per-trigger yield vs $\Delta\phi$ for successively increasing trigger and partner p_T ($p_T^a \otimes p_T^b$) in $p + p$ (open circles) and 0–20% Au+Au (filled circles) collisions. Data are scaled to the vertical axes of the four left panels. Histograms indicate elliptic flow uncertainties for Au+Au collisions.

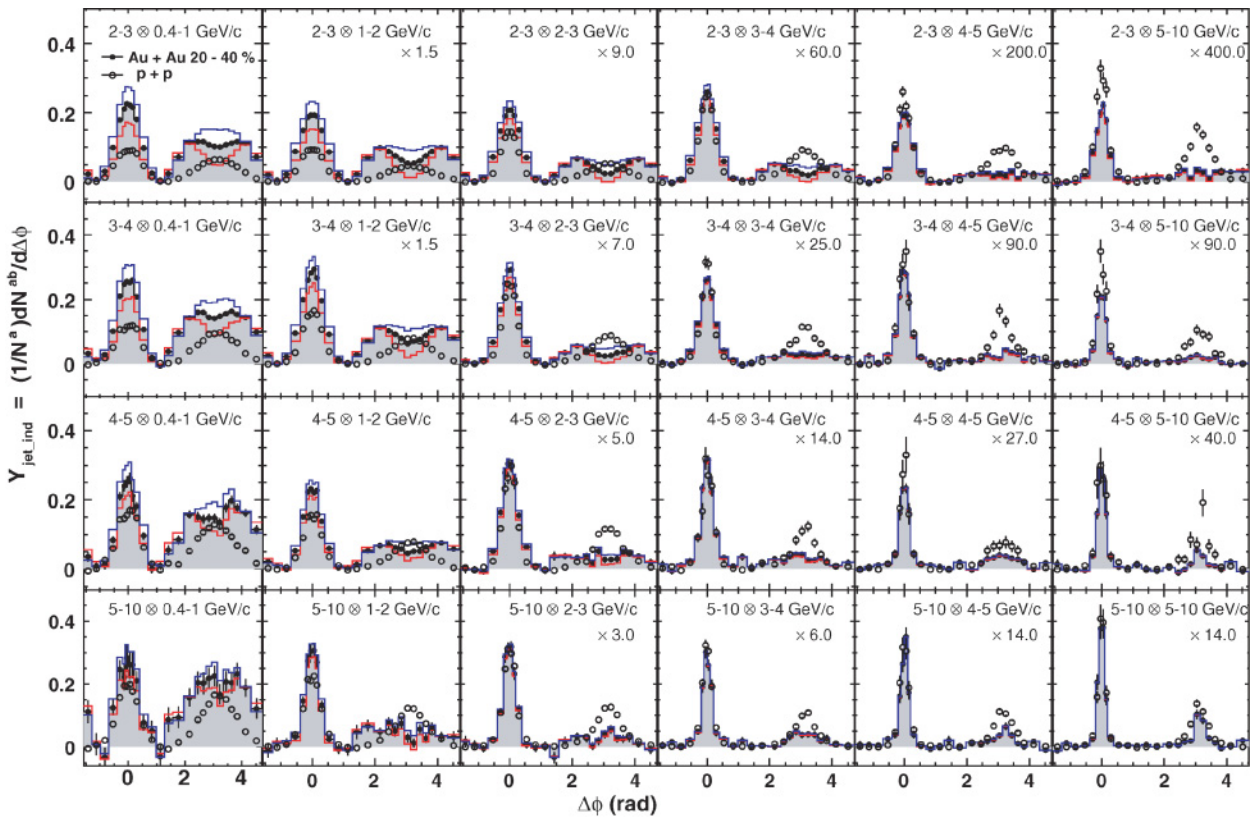

FIG. 37. (Color online) Same as Fig. 36, but for 20–40% Au+Au collisions.

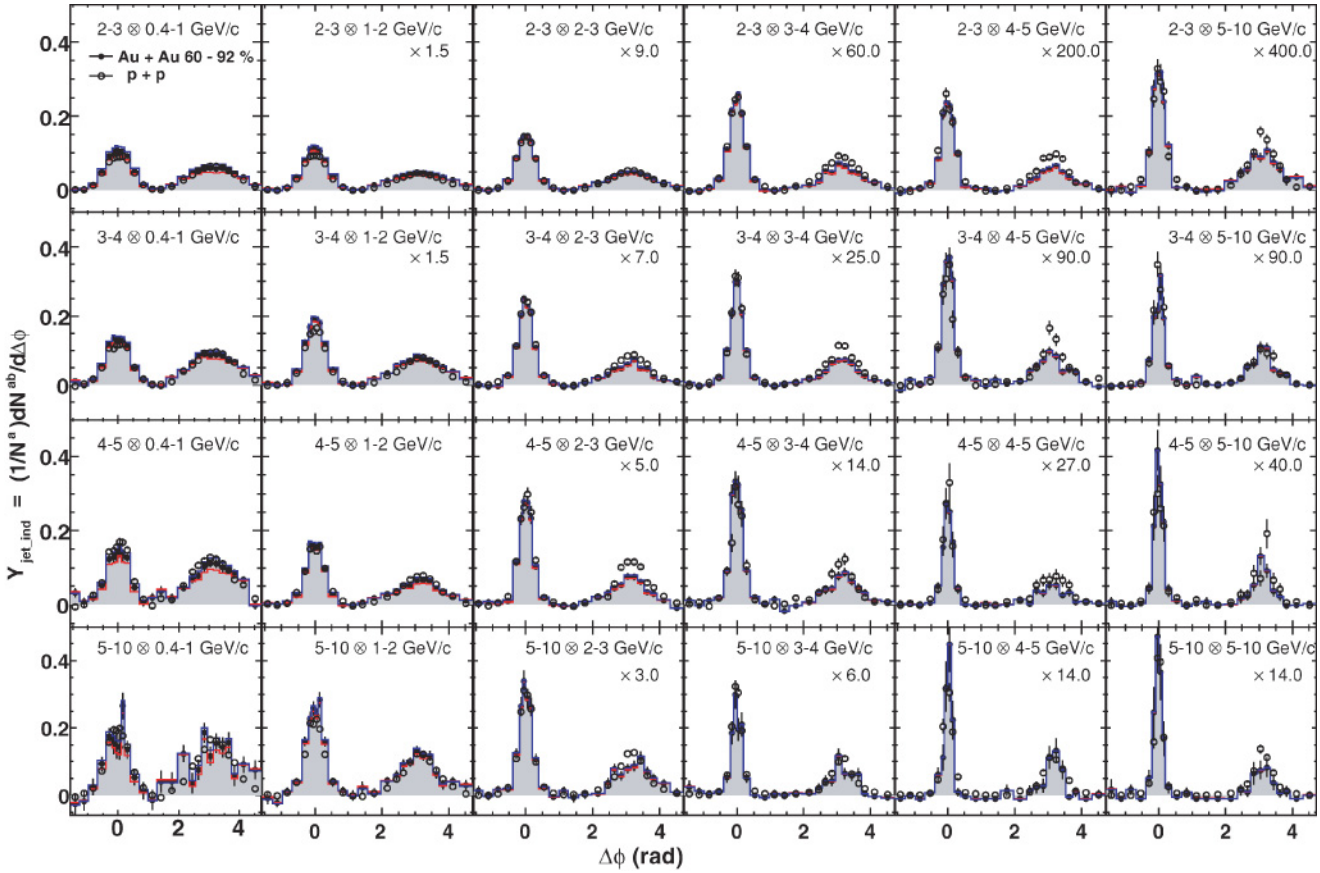

FIG. 38. (Color online) Same as Fig. 36, but for 60–92% Au+Au collisions.

We then generate back-to-back jet pairs from the PYTHIA event generator, requiring a leading particle above 6 GeV/c at midrapidity ($|\eta| < 0.35$). Assuming the fractional momentum of the leading hadron is $\langle z \rangle \approx 0.7$ [44], this corresponds to a typical jet energy of $6/\langle z \rangle \approx 9$ GeV/c.

We evaluate the dijet bias by comparing the event plane before and after the embedding. Dijets tend to bias the event plane toward the dijet direction, resulting in a false v_2 for the jet particles. Figure 34 shows the relative azimuth distribution between the jet leading hadrons and the event plane (EP) from the HIJING event (left panel) or the combined event (right panel). The dijets clearly become correlated with the EP determined from the combined event, leading to a false v_2 for the leading hadrons. However, since we embed one such dijet pair for every event, the bias shown in Fig. 34 should be interpreted as the bias for those events containing a high-p_T dijet. Thus it sets an upper limit for the bias effect.

To understand the impact of the false v_2, we have to determine their magnitudes in the same way as the real data analysis, i.e., according to

$$v_2 = \frac{v_{2,\mathrm{raw}}}{c_{v_2}} = \frac{\langle\langle \cos 2(\phi - \Phi_{\mathrm{EP}})\rangle\rangle}{\langle \cos 2(\Phi_{\mathrm{EP}} - \Phi_{\mathrm{RP}})\rangle}.$$

We obtain the raw v_2 by fitting the embedded trigger distribution (such as in Fig. 34) for each individual centrality bin. The raw v_2 is then divided by the corresponding reaction plane resolution, which can be calculated as $c_{v_2} = \langle \cos 2(\Phi_{\mathrm{EP}} - \Phi_{\mathrm{RP}})\rangle$.

The magnitude of the false v_2 depends on the rapidity separation between the trigger and the subevent used to determine the EP. Because of away-side jet swing, this bias could persist to large rapidity regions. Figure 35 shows the centrality dependence of false trigger v_2 for events containing high-p_T dijets for various rapidity windows used for EP determination. The false v_2 decreases as the subevent used to determine the EP moves toward large η. When the subevent is in the BBC acceptance ($3 < |\eta| < 4$), the false v_2 becomes negligible.

APPENDIX D: COMPREHENSIVE DATA PLOTS AND DATA TABLES

Figures 36–38 show the comprehensive array of results, covering the momentum range of 0.4–10 GeV/c from which the representative subset shown in Fig. 6 was derived. These results are described in Secs. III and IV.

Tables VII to XIX show numerical values of the plotted data. The corresponding figures are indicated in the table captions.

(Received 25 January 2008; published 3 December 2008)

For Au + Au collisions at 200 GeV, we measure neutral pion production with good statistics for transverse momentum, p_T, up to 20 GeV/c. A fivefold suppression is found, which is essentially constant for $5 < p_T < 20$ GeV/c. Experimental uncertainties are small enough to constrain any model-dependent parametrization for the transport coefficient of the medium, e.g., $\langle \hat{q} \rangle$ in the parton quenching model. The spectral shape is similar for all collision classes, and the suppression does not saturate in Au + Au collisions.

DOI: 10.1103/PhysRevLett.101.232301 PACS numbers: 25.75.Dw

Large transverse momentum (p_T) hadrons originate primarily from the fragmentation of hard scattered quarks or gluons. In high energy $p + p$ collisions, this is well described in the framework of perturbative QCD [1]. In ultrarelativistic heavy ion collisions, such hard scatterings occur in the early phase of the reaction, and the transiting partons serve as probes of the strongly interacting medium produced in the collisions. Lattice QCD predicts a phase transition to a plasma of deconfined quarks and gluons, which induces gluon radiation from the scattered parton and depletes hadron production at high p_T (''jet quenching'') [2,3]. The measurements in Au + Au collisions at Relativistic Heavy Ion Collider (RHIC) showed suppressed hadron yields in central collisions [4] as predicted [5,6], and motivated advanced theoretical studies of radiative energy loss.

All energy loss models must incorporate the space-time evolution of the medium, as it is not static, and the initial distribution of the partons throughout the medium. Models generally also include an input parameter for the medium density and/or the coupling. Different assumptions in the various models lead to similar descriptions of the π^0 suppression with different model-dependent parameters [7,8]. For instance, the Parton Quenching model (PQM) is a Monte Carlo program using the quenching weights from Baier-Dokshitzer-Mueller-Peigne-Schiff (BDMPS) [5] that combines the coupling strength with the color-charge density to create a single transport coefficient, often referred to as $\langle \hat{q} \rangle$ [9,10], which gives the $\langle p_T^2 \rangle$ transferred from the medium to the parton per mean free path.

Establishing the magnitude, p_T and centrality dependence of the suppression pattern up to the highest possible p_T is crucial to constrain the theoretical models and separate contributions of initial and final state effects from the energy loss mechanism. As neutral pions can be identified up to very high p_T, their suppression and its centrality (average pathlength) dependence puts important constraints on the energy loss. Whereas di-hadron suppression at high p_T may be somewhat more sensitive to medium opacity [11] than single hadron suppression, such improvement is contingent upon theoretical and experimental, statistical and systematic uncertainties.

This Letter reports on the measurement of π^0s up to $p_T = 20$ GeV/c in Au + Au collisions at $\sqrt{s_{NN}} =$ 200 GeV at RHIC, using the high statistics data taken in 2004. The results are used to extract the $\langle \hat{q} \rangle$ parameter of the PQM model for the most central collisions.

The analysis used 1.03×10^9 minimum bias events taken by the PHENIX experiment [12]. Collision centrality was determined from the correlation between the number of charged particles detected in the Beam-Beam Counters (BBC, $3.0 < |\eta| < 3.9$) and the energy measured in the Zero Degree Calorimeters (ZDC). A Glauber model Monte Carlo program with a simulation of the BBC and ZDC responses was used to estimate the average number of participating nucleons ($\langle N_{\mathrm{part}} \rangle$) and binary nucleon-nucleon collisions ($\langle N_{\mathrm{coll}} \rangle$) for each centrality bin [13].

Neutral pions were measured in the $\pi^0 \to \gamma\gamma$ decay channel with the photons reconstructed in the Electromagnetic Calorimeter (EMCal) located in the two central arms of PHENIX ($|\eta| \leq 0.35$). The EMCal [14] consists of two subsystems: six sectors of lead-scintillator sandwich calorimeter (PbSc) and two sectors of lead-glass Čerenkov calorimeter (PbGl) at the radial distance of about 5 m. The fine segmentation of the EMCal ($\delta\phi \times \delta\eta \sim 0.01 \times 0.01$ for PbSc and $\sim 0.008 \times 0.008$ for PbGl) ensures that the two photons from a $\pi^0 \to \gamma\gamma$ decay are well resolved up to $p_T^{\pi^0} \approx 12$ (PbSc) and 16 (PbGl) GeV/c. Data from the two subsystems were analyzed separately, and the fully corrected results were combined.

Details of the analysis including extraction of the raw π^0 yield, correction for acceptance, detector response, reconstruction efficiency have been described elsewhere [15,16]. In this analysis, the higher p_T range required an additional

TABLE I. Summary of the systematic uncertainties on the π^0 yield extracted independently with the PbSc (PbGl) electromagnetic calorimeters. The last row is the total systematic uncertainty on the combined spectra.

p_T (GeV/c)	2	6	10	16
uncertainty source	PbSc (PbGl)			
yield extraction (%)	3.0 (4.1)	3.0 (4.1)	3.0 (4.1)	3.0 (4.1)
PID efficiency (%)	3.5 (3.9)	3.5 (3.5)	3.5 (3.7)	3.5 (3.9)
Energy scale (%)	6.7 (9.0)	8.0 (9.2)	8.0 (8.2)	8.0 (12.3)
Acceptance (%)	1.5 (4.1)	1.5 (4.1)	1.5 (4.1)	1.5 (4.1)
π^0 merging (%)	$\cdots$ ($\cdots$)	$\cdots$ ($\cdots$)	4.4 ($\cdots$)	28 (4.8)
Conversion (%)	3.0 (2.5)	3.0 (2.5)	3.0 (2.5)	3.0 (2.5)
off-vertex π^0 (%)	1.5 (1.5)	1.5 (1.5)	1.5 (1.5)	1.5 (1.5)
Total (%)	8.7 (12)	9.8 (11)	11 (11)	30 (15)
PbSc and PbGl combined: Total (%)	7.0	7.5	7.6	14

correction for losses in the observed (raw) π^0s due to "cluster merging."

With increasing $p_T^{\pi^0}$, the minimum opening angle of the two photons decreases, and eventually they will be reconstructed as a single cluster. Such "merging" reaches 50% of the total raw yield at $p_T = 14$ GeV/c in the PbSc and at $p_T = 18$ GeV/c in the PbGl. Merged clusters were rejected by various shower profile cuts, and the loss was determined by simulated π^0s embedded into real events and analyzed with the same cuts. The systematic uncertainties were estimated by comparing π^0 yields in the PbSc extracted in bins of asymmetry $|E_{\gamma_1} - E_{\gamma_2}|/(E_{\gamma_1} + E_{\gamma_2})$ and also by comparing yields in the PbSc and PbGl.

We considered two sources of π^0s not coming from the vertex (off-vertex π^0): those produced by hadrons interacting with detector material (instrumental background) and feed-down products from weak decay of higher mass hadrons (physics background). Based upon simulations both types of background were found to be negligible ($< 1\%$ at $p_T > 2.0$ GeV/c) except for π^0s from K^0_S decay ($\approx 3\%$ of π^0 yield for $p_T > 1$ GeV/c), which has been subtracted from the data. Finally, the yields were corrected to the center of the p_T bins using the local slope.

The main sources of systematic uncertainties are yield extraction, efficiency corrections, energy scale, and merging, none of which exhibits a significant centrality dependence. The PbSc and PbGl have quite different systematics with all but one of them (off-vertex π^0) uncorrelated. Therefore, when combining their results, the total error is reduced in the weighted average of the two independent measurements. The final systematic uncertainties (1 standard deviation) on the spectra are shown in Table I.

The top panel of Fig. 1 shows the π^0 invariant yield for all centralities and minimum bias, combined from the independent PbSc and PbGl measurements which now extend to $p_T \sim 20$ GeV/c, 6 GeV/c higher than those published earlier [15]. In the overlap region, the results are consistent with the ones in [15] while the errors are reduced by a factor of 2 to 2.5. The bottom panel shows the consistency of the PbSc and PbGl results. The spectra are similar at all centralities: when fitting $p_T > 5$ GeV/c with a power-law function ($\propto p_T^{-n}$), the exponents vary from $n = 8.00 \pm 0.12$ in 0–5% to $n = 8.06 \pm 0.08$ in the 80–92% (most peripheral) bin. Note that $n = 8.22 \pm 0.09$ in $p + p$ collisions. The errors are combined statistical errors and systematic uncertainties.

To quantify the comparison of spectra in heavy ion and $p + p$ collisions, the nuclear modification factor

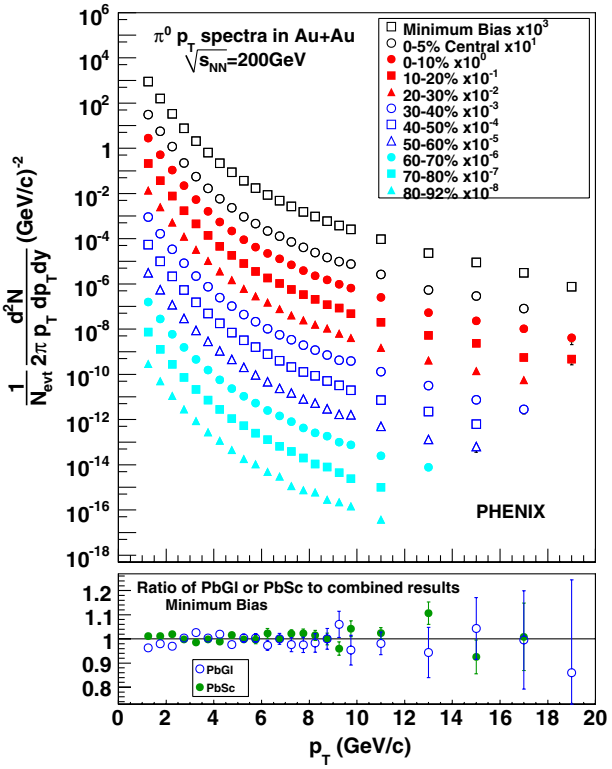

FIG. 1 (color online). Top: π^0 invariant yields for all centralities and minimum bias. Bottom: ratios of the (separately analyzed) PbSc and PbGl yields to the combined minimum bias invariant yield, which is shown in the top panel.

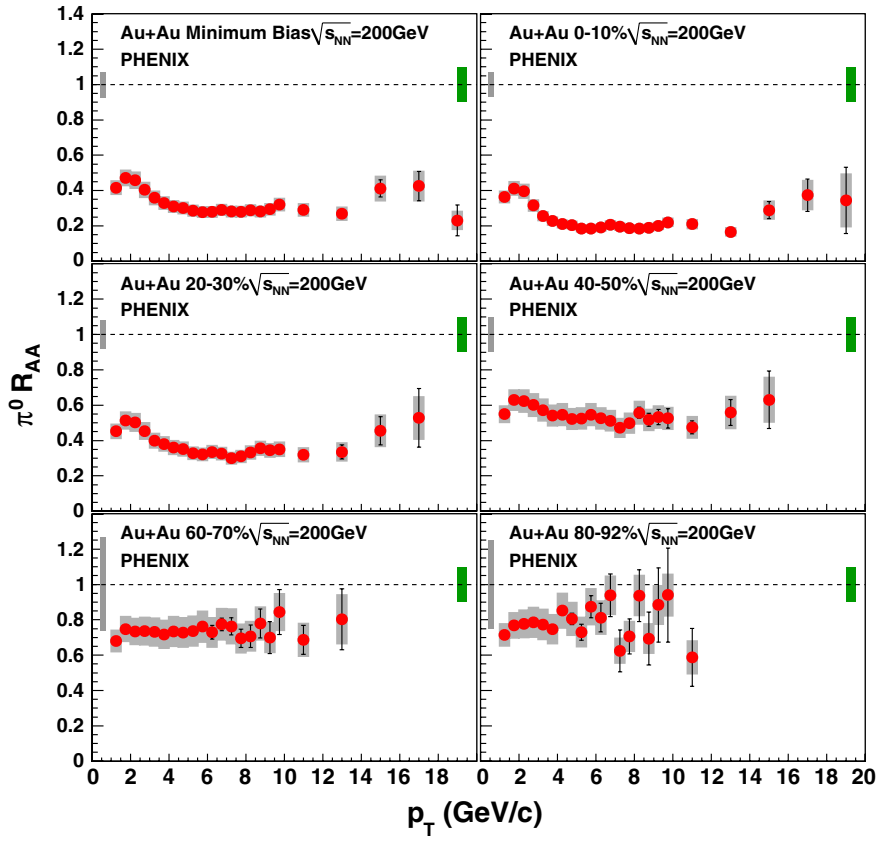

FIG. 2 (color online). Nuclear modification factor (R_{AA}) for π^0s. Error bars are statistical and p_T-uncorrelated errors, boxes around the points indicate p_T-correlated errors. Single box around $R_{AA} = 1$ on the left is the error due to N_{coll}, whereas the single box on the right is the overall normalization error of the $p + p$ reference spectrum.

$$R_{AA} = \frac{1/N_{evt} d^2N/dydp_T}{\langle T_{AB}\rangle d^2\sigma_{pp}/dydp_T} \quad (1)$$

is used, where σ_{pp} is the production cross section of the particle in $p + p$ collisions, and $\langle T_{AB}\rangle$ is the nuclear thickness function averaged over a range of impact parameters for the given centrality, calculated within a Glauber model [13]. Figures 2 and 3 show R_{AA} for π^0 at different centralities. The reference $p + p$ yield was obtained from the 2005 (Run-5) RHIC $p + p$ measurement [17].

R_{AA} reaches ~0.2 in 0–10% centrality at $p_T > 5$ GeV/c with very little (if any) p_T dependence. This trend is compatible with most current energy loss models but not with a semiopaque medium assumption, where R_{AA} would decrease with increasing p_T [7]. While its magnitude changes, the suppression pattern itself is remarkably similar at all centralities suggesting that the bulk R_{AA} (integrated over azimuth) is sensitive only to the N_{part} but not to the specific geometry. Consequently, study of the p_T-integrated R_{AA} vs centrality is instructive.

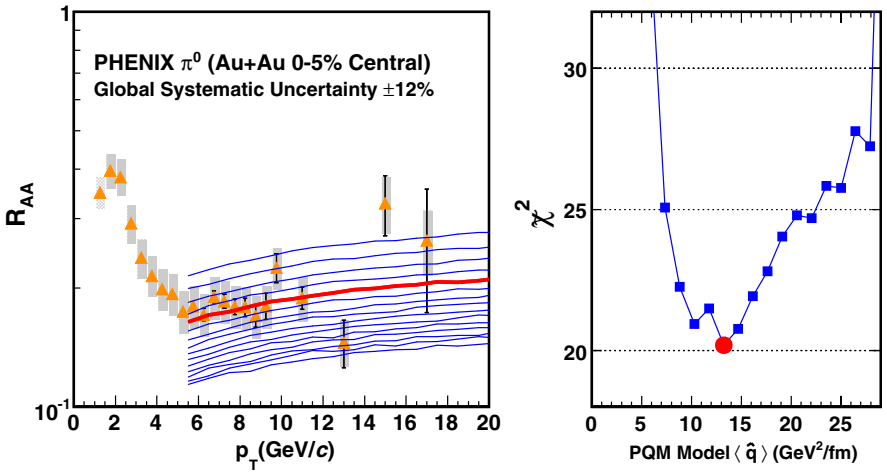

FIG. 3 (color online). Left: π^0 R_{AA} for the most central (0–5%) Au + Au collisions and PQM model calculations for different values of $\langle\hat{q}\rangle$. Right: $\tilde{\chi}^2(\epsilon_b, \epsilon_c, p)$ distribution for the corresponding values of $\langle\hat{q}\rangle$. The bold (red) curve in the left panel and the round (red) point in the right panel are the best fit values.

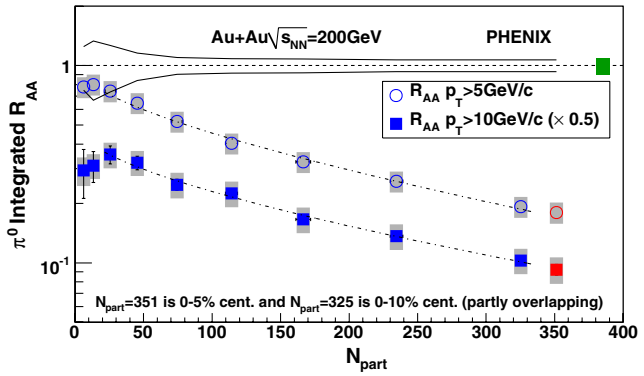

FIG. 4 (color online). Integrated nuclear modification factor (R_{AA}) for π^0 as a function of collision centrality expressed in terms of N_{part}. The error bars/bands are the same as in Fig. 2. The two lines at unity show the errors on $\langle N_{coll}\rangle$. The last two points correspond to partially overlapping centrality bins. The dashed lines show the fit explained in the text.

Figure 4 shows R_{AA} for π^0s integrated above $p_T > 5$ GeV/c, and $p_T > 10$ GeV/c, as a function of centrality. The last two points indicate overlapping 0–10% and 0–5% bins. In both cases, the suppression increases monotonically with N_{part} without any sign of saturation, suggesting that larger colliding systems (such as $U + U$ planned at RHIC) should exhibit even more suppression.

The common power-law behavior ($\propto p_T^{-n}$) in $p + p$ and Au + Au allows the suppression to be reinterpreted as a fractional energy loss $S_{loss} = 1 - R_{AA}^{1/(n-2)}$ where n is the power-law exponent, and we found that $S_{loss} \propto N_{part}^a$ [15,18]. Fitting the integrated R_{AA} with a function $R_{AA} = (1 - S_0 N_{part}^a)^{n-2}$, where n is fixed as 8.1, gives $a = 0.57 \pm 0.13$ for $N_{part} > 20$ for $p_T > 5$ GeV/c, and $a = 0.55 \pm 0.14$ for $p_T > 10$ GeV/c. The fit does not take errors on $p + p$ luminosity into account. The Gyulassy-Levai-Vitev (GLV) [6] and PQM [10] models predict that $a \approx 2/3$, which is consistent with the data. The fitted values of S_0 are $(9.0 \pm 6.1) \times 10^{-3}$ and $(9.4 \pm 7.3) \times 10^{-3}$ for $p_T > 5$ GeV/c and $p_T > 10$ GeV/c, respectively. The fits are shown as dashed lines in Fig. 4.

We use the highest centrality (0–5%) R_{AA} data as shown in Fig. 3 to constrain the PQM model parameter $\langle\hat{q}\rangle$. This must be done with careful consideration of the various, partially coupled error sources, leading to necessary refinement beyond a naive least square analysis. We calculate

$$\tilde{\chi}^2(\epsilon_b, \epsilon_c, p) = \left(\sum_{i=1}^{n} \frac{[y_i + \epsilon_b \sigma_{b_i} + \epsilon_c y_i \sigma_c - \mu_i(p)]^2}{\tilde{\sigma}_i^2}\right) + \epsilon_b^2 + \epsilon_c^2, \quad (2)$$

using theory curves $\mu_i(p)$ with different values of the input parameter p, i.e., $\langle\hat{q}\rangle$ in the PQM model. p_T-uncorrelated, statistical ⊕ systematic errors are σ_i, p_T-correlated errors are σ_{b_i} (boxes on Figs. 2 and 3), while uniform fractional shifts of all points are given by σ_c. All the measured values y_i are allowed to shift by the same fraction, ϵ_b, of their systematic error σ_{b_i} from the nominal values. The ϵ_c is a similar correlated fraction of σ_c, and $\tilde{\sigma}_i = \sigma_i(y_i + \epsilon_b \sigma_{b_i} + \epsilon_c y_i \sigma_c)/y_i$ is the point-to-point random error scaled by the multiplicative shift, so that the fractional error is unchanged by the shift, which is true for the present measurement. The best fit, $\tilde{\chi}^2_{min}$, the minimum of $\tilde{\chi}^2(\epsilon_b, \epsilon_c, p)$ by variation of ϵ_b, ϵ_c, and p, is found by standard methods. Further details are given in [16]. The right panel of Fig. 3 shows the minima of $\tilde{\chi}^2(\epsilon_b, \epsilon_c, p)$ by varying ϵ_b and ϵ_c for a wide range of values of the PQM model transport coefficient, $\langle\hat{q}\rangle$. Our data constrain $\langle\hat{q}\rangle$ as $13.2\ ^{+2.1}_{-3.2}$ and $^{+6.3}_{-5.2}$ GeV^2/fm at the 1 and 2 standard deviation levels. These constraints include only the experimental uncertainties and do not account for the large model-dependent differences in the quenching scenario and description of the medium. Extracting fundamental model-independent properties of the medium from the present data requires resolution of ambiguities and open questions in the models themselves, which also will have to account simultaneously for the p_T and centrality (average path-length) dependence. This work demonstrates the power of data for pion production in constraining the energy loss of partons. The large $\langle\hat{q}\rangle$ suggests that the matter consists of strongly coupled partons.

The $R_{AA}(p_T)$ for 0–5% was fitted with a simple linear function in the entire $p_T > 5$ GeV/c range as well: the slope of the fit is $0.0017\ ^{+0.0035}_{-0.0039}$ and $^{+0.0070}_{-0.0076}$ c/GeV at the 1 and 2 standard deviation levels [16]. The fact that R_{AA} as well as the power (n) for all spectra from $p + p$ to Au + Au are essentially constant proves that the dominant term in energy loss is proportional to p_T.

In summary, PHENIX has measured neutral pions in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV at mid rapidity in the transverse momentum range of $1 < p_T < 20$ GeV/c, analyzing high statistics data taken in 2004. The shape of the spectra is similar for all centralities, as is the shape of $R_{AA}(p_T)$ at $p_T > 5$ GeV/c. In central collisions, the yield is suppressed by a factor of ~5 at 5 GeV/c compared to the binary scaled $p + p$ reference, and the suppression prevails with little or no change up to 20 GeV/c. The integrated R_{AA} vs centrality does not saturate at this nuclear size; also, the predicted $S_{loss} \propto N_{part}^{2/3}$ [6,10] is consistent with our data. In this picture, the energy loss increases with p_T. Using the 0–5% (most central) R_{AA}, we find that the transport coefficient $\langle\hat{q}\rangle$ of the PQM model is constrained to $13.2\ ^{+2.1}_{-3.2}$ ($^{+6.3}_{-5.2}$) GeV^2/fm at the one (two) σ level. The experimental evidence for a high transport coefficient, derived with remarkable accuracy due to high quality data and sophisticated new analysis, as presented here and in [16], reveals a totally nontrivial feature of the dense QCD medium created at RHIC. The shape of the spectra and the suppression pattern

indicate that the dominant term in energy loss is proportional to p_T.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 10 January 2008; published 24 June 2008)

The PHENIX experiment has measured the suppression of semi-inclusive single high-transverse-momentum π^0's in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The present understanding of this suppression is in terms of energy loss of the parent (fragmenting) parton in a dense color-charge medium. We have performed a quantitative comparison between various parton energy-loss models and our experimental data. The statistical point-to-point uncorrelated as well as correlated systematic uncertainties are taken into account in the comparison. We detail this methodology and the resulting constraint on the model parameters, such as the initial color-charge density dN^g/dy, the medium transport coefficient $\langle\hat{q}\rangle$, or the initial energy-loss parameter ϵ_0. We find that high-transverse-momentum π^0 suppression in Au+Au collisions has sufficient precision to constrain these model-dependent parameters at the ±20–25% (one standard deviation) level. These constraints include only the experimental uncertainties, and further studies are needed to compute the corresponding theoretical uncertainties.

I. INTRODUCTION

Heavy-ion collisions at very high energy are of interest due to the formation of a novel partonic medium approximately the size of a large nucleus, but with an energy density exceeding that of normal nuclei by considerably more than an order of magnitude. At such high energy densities, it is believed that quarks and gluons are no longer confined in hadrons but may be constituents of a quark-gluon plasma with characteristics of a near-perfect fluid (for a detailed review see Ref. [1]). Experiments at the Relativistic Heavy Ion Collider (RHIC) have already demonstrated that a very hot and dense, strongly interacting medium is created in Au+Au collisions at $\sqrt{s_{NN}} =$ 200 GeV [2]. The goal is now to quantitatively determine the properties of this medium.

Important properties of the medium include the density of color charges as well as the exchange of transverse momentum between parton probes and the medium. In rare events, in addition to the creation of the medium, there can also be a hard scattering (high-Q^2 process) between the colliding partons that, at leading order, sends two high-energy quark or gluon partons in opposite transverse directions. These high-energy partons can be utilized to probe both the color-charge density of the medium and the coupling strength between the parton and the medium. There are various calculational frameworks for modeling these interactions (for a detailed review see Ref. [3]).

In this article, we consider four specific calculations of parton energy loss (discussed below): the parton quenching model (PQM) [4], the Gyulassy-Levai-Vitev (GLV) model [5], the Wicks-Horowitz-Djordjevic-Gyulassy (WHDG) model [6], and the Zhang-Owens-Wang-Wang (ZOWW) model [7]. We detail a quantitative method of assessing the sensitivity of the latest measurements to the input parameters of these models that characterize the initial parton density or medium transport coefficients.

II. EXPERIMENTAL RESULTS

During the 2004 data-taking period at the Relativistic Heavy Ion Collider, the PHENIX experiment recorded an integrated luminosity of 0.24 nb^{-1} in $\sqrt{s_{NN}} = 200$ GeV Au+Au collisions, which extends the measurement of π^0 to much higher p_T than previous data sets allowed. The results and further details of this measurement are given in Ref. [9]. A brief description is given below.

The PHENIX experiment measures π^0's via the two-photon decay mode with two types of highly segmented ($\Delta\eta \times \Delta\phi \approx 0.01 \times 0.01$) electromagnetic calorimeters (EMCal) located at the radial distance of approximately 5 m from the vertex [8]. One is a lead scintillator sampling calorimeter (PbSc), which covers the geometrical acceptance of $|\eta| < 0.35$ and $\Delta\phi = 3/4\pi$. The other is a lead glass Cerenkov calorimeter (PbGl), whose geometrical coverage is $|\eta| < 0.35$ and $\Delta\phi = \pi/4$. The energy resolution of the PbSc and PbGl calorimeters as determined from test beam measurements are given by $8.1\%/\sqrt{E(\text{GeV})} \oplus 2.1\%$ and $5.9\%/\sqrt{E(\text{GeV})} \oplus 0.8\%$, respectively. The energy calibration of the EMCal modules is based on the measured position of the π^0 mass peak, the deposited energy of minimum ionizing particles that traverse the calorimeter, and the ratio of energy to momentum that is expected to be about 1 for electrons identified by the ring-imaging Cerenkov detector. The systematic uncertainty on the energy scale is ∼1%, which corresponds to ∼7–12% uncertainty on the invariant π^0 yield over the p_T range of the measurement.

Neutral pions were reconstructed in their $\pi^0 \to \gamma\gamma$ decay channel. Photon candidates are identified by applying particle identification cuts based mainly on the shower shape. The invariant mass for all photon-pair combinations within one event that satisfy cuts on the energy asymmetry $|E_{\gamma 1} - E_{\gamma 2}|/|E_{\gamma 1} + E_{\gamma 2}| < 0.8$ were calculated in bins of p_T. The combinatorial background is determined by combining into pairs uncorrelated photons from different events with similar centrality, reaction plane, and vertex location.

The raw π^0 yield was obtained by integrating the mass peak region of the invariant mass distribution after subtracting the combinatorial background. The raw spectra are corrected for the detector response (energy resolution), the reconstruction efficiency, and occupancy effects (e.g., overlapping clusters). These corrections are made by embedding simulated single π^0's from a full GEANT simulation of the PHENIX detector into real events and analyzing the embedded π^0 events with the same analysis cuts as used with real events.

After computing the invariant yields in Au+Au collisions [9], the medium effects are quantified using the nuclear modification factor (R_{AA}). R_{AA} is the ratio between the

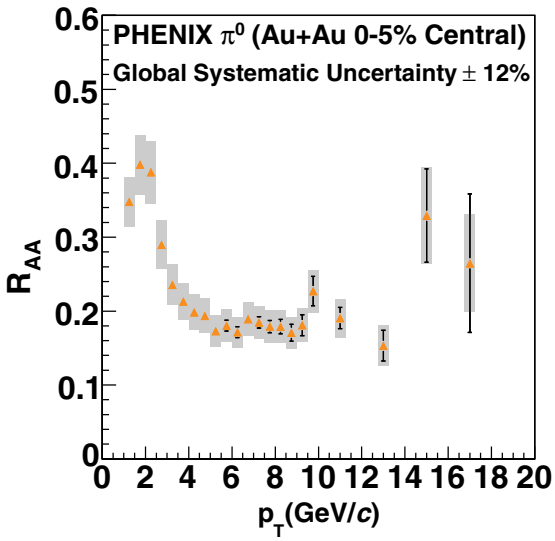

FIG. 1. (Color online) The π^0 nuclear suppression factor $R_{\rm AA}$ as a function of transverse momentum for 0–5% Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Point-to-point uncorrelated statistical and systematic uncertainties are shown as uncertainty bars. Correlated systematic uncertainties are shown as gray boxes around the data points. The global scale factor systematic uncertainty is ±12%.

measured yield and the expected yield for pointlike processes scaled from the $p+p$ result and is defined as:

$$\mathrm{R_{AA}}(p_T) = \frac{\left(1/N_{\rm AA}^{\rm evt}\right) d^2 N_{\rm AA}^{\pi^0}/dp_T dy}{\langle T_{\rm AA}\rangle d^2\sigma_N^{\pi^0}/dp_T dy}, \qquad (1)$$

where $\langle T_{\rm AA}\rangle$ is the average Glauber nuclear overlap function for the Au+Au centrality bin under consideration

$$\langle T_{\rm AA}\rangle \equiv \frac{\int T_{\rm AA}(\mathbf{b}) d\mathbf{b}}{\int \left(1 - e^{-\sigma_{NN}^{\rm inel} T_{\rm AA}(\mathbf{b})}\right) d\mathbf{b}} = \left\langle N_{\rm coll}^{\sigma_{NN}}\right\rangle / \sigma_{NN}^{\rm inel}, \qquad (2)$$

where $\langle N_{\rm coll}^{\sigma_{NN}}\rangle$ is the average number of inelastic nucleon-nucleon collisions for the Au+Au centrality bin under consideration calculated with inelastic nucleon-nucleon cross section $\sigma_{NN}^{\rm inel}$.

The measured nuclear modification factors for 0–5% central Au+Au reactions at $\sqrt{s_{NN}} = 200$ GeV are shown in Fig. 1 and tabulated in Table I with statistical and systematic uncertainties. The systematic uncertainties fall into three categories. We denote type A uncertainties as systematic uncertainties that are uncorrelated from point to point. Type A systematic uncertainties are added in quadrature with statistical uncertainties and are shown as uncertainty bars. Partially correlated point-to-point systematic uncertainties are broken into a 100% correlated component, referred to as type B, and the above mentioned type A. The type B uncertainties are shown as gray boxes. The sources of type B uncertainties are discussed in detail in Ref. [9] and are dominated by energy scale uncertainties but also have contributions from photon shower merging at the highest p_T (≈15–20 GeV/c). There are also global systematic uncertainties, referred to as type C uncertainties, that are globally correlated systematic uncertainties (i.e., where all data points move by the same multiplicative factor). The type C uncertainties are ±12% and derive from uncertainties in the calculated nuclear thickness function and from the $p+p$ absolute normalization.

TABLE I. The π^0 nuclear suppression factor $R_{\rm AA}$ as a function of transverse momentum for 0-5% Au+Au collisions at $\sqrt{s_{NN}} =$ 200 GeV. The type A, B, and C uncertainties are tabulated for each point.

III. THEORETICAL CALCULATIONS

The parton quenching model (PQM) [4] encodes the dissipative properties of the system in terms of a single transport coefficient, often referred to as $\hat{q}$, obtained as the product of the parton-medium cross section times the color-charge density. The average $\hat{q}$ quantifies the average squared transverse momentum transferred from the medium to the parton per mean free path. The PQM model is a Monte Carlo program constructed using the quenching weights from BDMPS [10,11]. BDMPS is a perturbative calculation explicitly including only coherent radiative energy loss for the parton via gluon bremsstrahlung. The PQM model incorporates a realistic transverse collision geometry, though with a static medium. It is also notable that the PQM model does not include initial state multiple scattering or modified nuclear parton distribution functions (PDF's).

The Gyulassy-Levai-Vitev (GLV) [5] model is a formalism developed to calculate in-medium gluon bremsstrahlung. An analytic expression is derived for the single gluon emission spectrum to all orders in opacity, assuming an infrared cutoff given by the plasmon frequency. Thus, within this framework, one can extract the local color-charge density. The color-charge density is written simply as dN^g/dy, assuming a completely

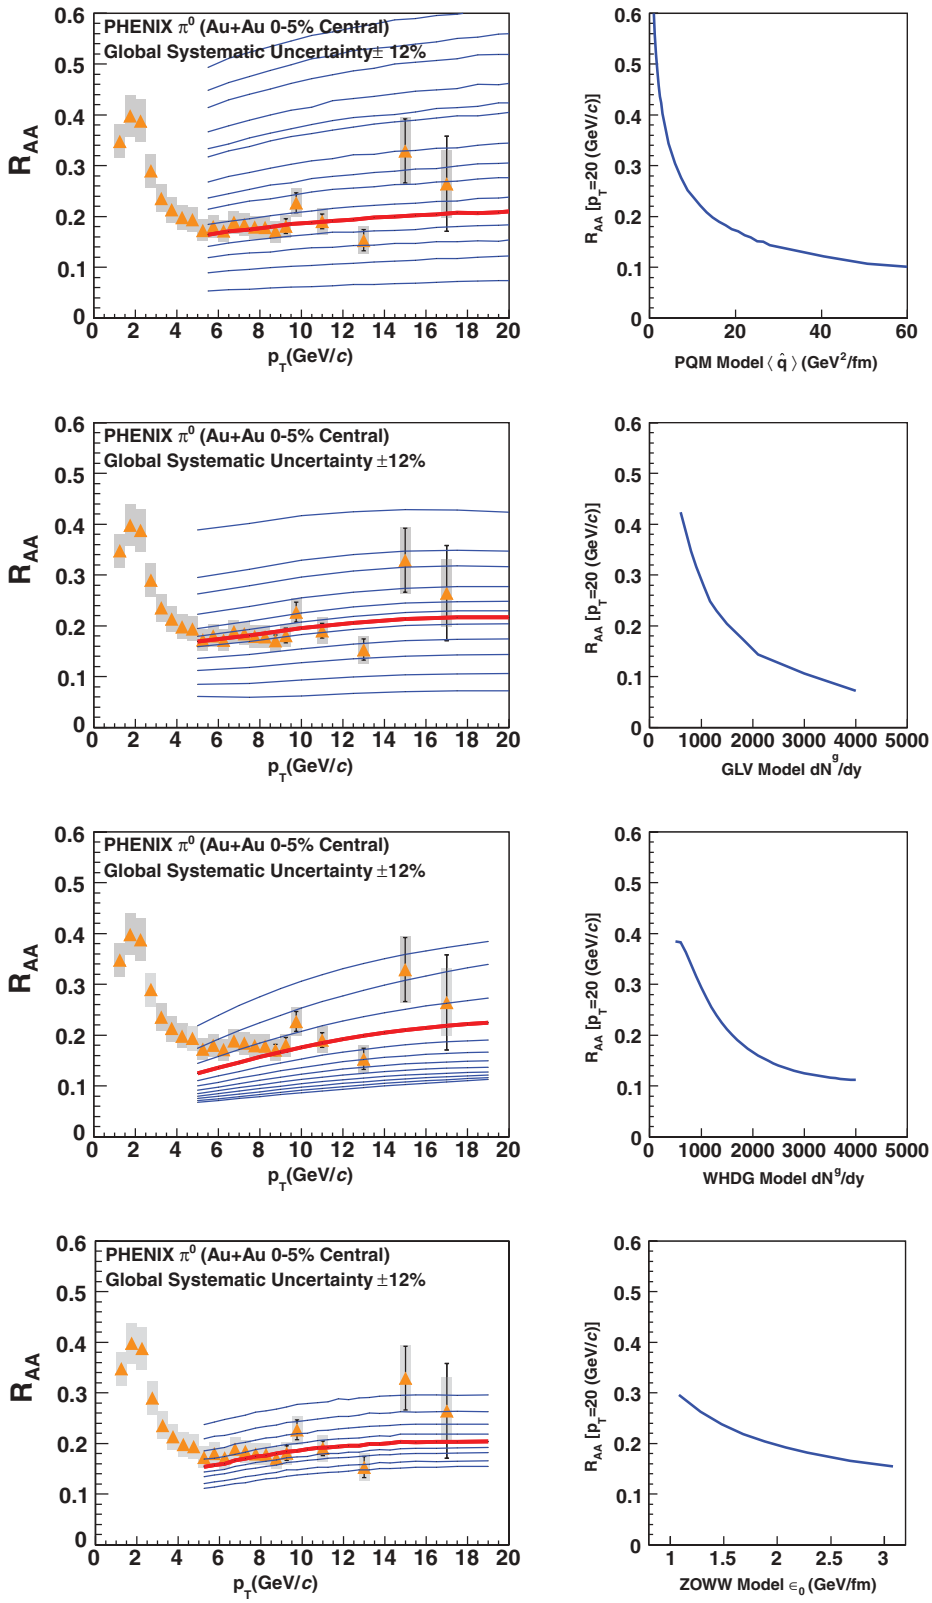

FIG. 2. (Color online) Left panels show π^0 $R_{\rm AA}$ for 0–5% Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV and predictions from PQM [4], GLV [12], WHDG [6], and ZOWW [7] models with (from top to bottom) $\langle \hat{q} \rangle$ values of 0.3, 0.9, 1.2, 1.5, 2.1, 2.9, 4.4, 5.9, 7.4, 10.3, 13.2, 17.7, 25.0, 40.5, 101.4 GeV^2/fm; dN^g/dy values of 600, 800, 900, 1050, 1175, 1300, 1400, 1500, 1800, 2100, 3000, 4000; dN^g/dy values of 500, 800, 1100, 1400, 1700, 2000, 2300, 2600, 2900, 3200, 3500, 3800; and ϵ_0 values of 1.08, 1.28, 1.48, 1.68, 1.88, 2.08, 2.28, 2.68, 3.08 GeV/fm. Red lines indicate the best fit cases of (top) $\langle \hat{q} \rangle = 13.2$, (upper middle) $dN^g/dy = 1400$, (lower middle) $dN^g/dy = 1400$, and (bottom) $\epsilon_0 = 1.88$ GeV/fm. Right panels show $R_{\rm AA}$ at $p_{\rm T} = 20$ GeV/c.

gluonic medium, or an equivalent $dN^{q,g}/dy$ for a mixture of quarks and gluons. In Ref. [12], using a realistic transverse collision geometry, the authors calculate *a priori*, without energy loss, the single fixed geometrical average path length from the production point to the medium edge, $\langle L \rangle_{\rm prod}$, and use it to calculate the parton energy loss in a Bjorken expanding medium [13]. The calculation also incorporates initial-state multiple scattering effects and modified nuclear PDF's.

The Wicks-Horowitz-Djordjevic-Gyulassy (WHDG) [6] model utilizes the generalized GLV formalism [15] for

radiative energy loss described above. In addition, their calculation includes a convolution of radiative energy loss and collisional energy-loss mechanisms. A realistic transverse collision geometry with a Bjorken time expansion is utilized, and then a full distribution of parton paths through the medium is calculated. The WHDG model does not yet include initial-state multiple scattering or modified PDF's.

The Zhang-Owens-Wang-Wang (ZOWW) [7] calculations incorporate a next-to-leading-order perturbative QCD parton model with modified jet fragmentation functions. The calculation explicitly includes only radiative energy loss. A hard-sphere transverse collision geometry with a one-dimensional expanding medium is utilized. The calculation also incorporates initial-state multiple scattering effects and modified nuclear PDF's.

The top left panel of Fig. 2 shows a comparison of the experimental data with calculated results from the PQM energy-loss model (as described in Ref. [4]) corresponding to different $\langle\hat{q}\rangle$ values [16]. Note that only a subset of all the calculations corresponding to different $\langle\hat{q}\rangle$ values are shown in the figure for clarity. The upper right panel shows the π^0 suppression factor predicted at $p_T = 20$ GeV/c from the PQM model as a function of the $\langle\hat{q}\rangle$ value. One can see that as the $\langle\hat{q}\rangle$ increases, the additional suppression becomes smaller (i.e., saturates). This saturation effect was noted in Ref. [14], and interpreted as a result of the dominance of preferential surface emission.

The other panels of Fig. 2 show similar comparisons of the experimental data with calculated results utilizing the GLV numerical calculation framework (as described in Ref. [12]) corresponding to different dN^g/dy values [17]; the WHDG calculational framework (as described in Ref. [6]) corresponding to different dN^g/dy values [18]; and the ZOWW calculational framework (as detailed in Ref. [7]) corresponding to different ϵ_0 values [19]. Note that all calculations are shown only for $p_T > 5$ GeV/c as that is where the calculations are considered applicable.

In Fig. 3, the same π^0 suppression factor predicted at $p_T = 20$ GeV/c from the PQM model as a function of the $\langle\hat{q}\rangle$ value is shown, but in this case with a log-x and log-y scale. The $R_{\rm AA} \approx 0.75/\sqrt{\langle\hat{q}\rangle}$ with $\langle\hat{q}\rangle$ in units of GeV^2/fm over the range $5 < \langle\hat{q}\rangle < 100$. This means that over this range for a given fractional change in $\langle\hat{q}\rangle$ there is always the same fractional change in $R_{\rm AA}$ (i.e., $\Delta\langle\hat{q}\rangle/\langle\hat{q}\rangle \approx 2.0 \times \Delta R_{\rm AA}/R_{\rm AA}$).

IV. COMBINED RESULTS

The task is now to detail how the experimental uncertainties (statistical and systematic) constrain the model parameters that are reflected in the suppression factors. As described previously, the uncertainties of the measured points are separated into type A (p_T-uncorrelated, statistical $\oplus$ systematic, σ_i), type B (p_T-correlated, σ_{b_i}, boxes on Fig. 1), type C (normalization, uniform fractional shift for all points, σ_c), where the σ's represent the standard deviations of the assumed Gaussian distributed uncertainties. With the predicted theory value $\mu_i(p)$ for each data point calculated for different values of the input parameter p, we perform a least-squares fit the to the theory

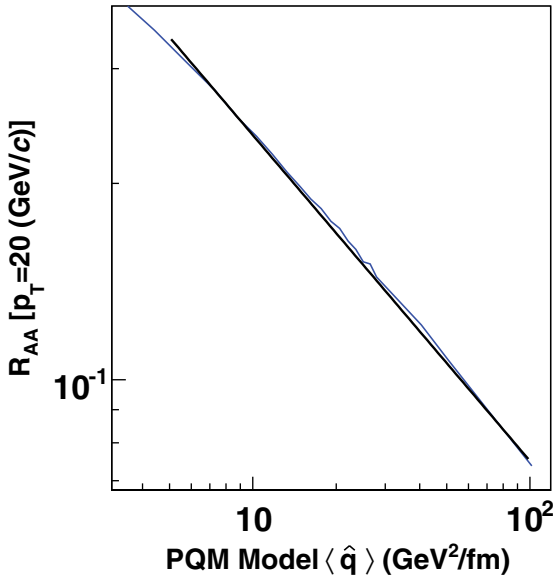

FIG. 3. (Color online) The nuclear suppression factors at $p_T = 20$ GeV/c for PQM as a function of $\langle\hat{q}\rangle$ are shown as a blue line with a log-x and log-y display. Also shown is the functional form $\Delta\langle\hat{q}\rangle/\langle\hat{q}\rangle \approx 2.0 \times \Delta R_{\rm AA}/R_{\rm AA}$) over the range $5 < \langle\hat{q}\rangle < 100$ GeV^2/fm.

by finding the values of $p, \epsilon_b, \epsilon_c$, that minimize:

$$\tilde{\chi}^2(\epsilon_b, \epsilon_c, p) = \left\{ \sum_{i=1}^{n} \frac{[y_i + \epsilon_b \sigma_{b_i} + \epsilon_c y_i \sigma_c - \mu_i(p)]^2}{\tilde{\sigma}_i^2} + \epsilon_b^2 + \epsilon_c^2 \right\}, \quad (3)$$

where ϵ_b and ϵ_c are the fractions of the type B and C systematic uncertainties that all points are displaced together and where $\tilde{\sigma}_i = \sigma_i(y_i + \epsilon_b \sigma_{b_i} + \epsilon_c y_i \sigma_c)/y_i$ is the point-to-point random uncertainty scaled by the multiplicative shift in y_i such that the fractional uncertainty is unchanged under systematic shifts, which is true for the present measurement. For clarity of presentation, the derivation of Eq. (3) (above) is given in Appendix A.

For any fixed values of ϵ_b, ϵ_c, Eq. (3) follows the χ^2 distribution with $n+2$ degrees of freedom, for testing the theoretical predictions $\mu_i(p)$, because it is the sum of $n+2$ Gaussian distributed random variables. The best fit, $\tilde{\chi}^2_{\rm min}$, the minimum of $\tilde{\chi}^2(\epsilon_b, \epsilon_c, p)$ by variation of ϵ_b, ϵ_c, and p, is found by standard methods (for example, using a MINUIT type minimization algorithm) and should follow the χ^2 distribution with $n-1$ degrees of freedom. The correlated uncertainties of the best fit parameters are estimated in the Gaussian approximation by $\tilde{\chi}^2(\epsilon_b, \epsilon_c, p) = \tilde{\chi}^2_{\rm min} + N^2$ for N standard deviation (σ) uncertainties.

The present experimental type B uncertainties have point-to-point correlations whose exact correlation matrix is difficult to evaluate precisely. Thus, we consider two limiting correlation cases. The first is where the type B uncertainties are 100% correlated, i.e., all points move in the same direction by the same fraction of their respective type B uncertainty. The second is where the type B uncertainties are correlated such that the

low p_T and high p_T points may shift with opposite sign (and linearly scaled in between), thus tilting the R_{AA} either upward or downward as a function of p_T. The minimum $\tilde{\chi}^2$ of the two cases is used for each constraint.

We take as a first example the resulting theory predictions from the PQM model. For each calculation characterized by the $\langle\hat{q}\rangle$, we calculate $\tilde{\chi}^2$. We determine this value by varying ϵ_b and ϵ_c (the systematic offsets) until we obtain the minimum $\tilde{\chi}^2$. These values are shown in Fig. 4 in the top panel. One can see that the overall lowest $\tilde{\chi}^2$ value corresponds to $\langle\hat{q}\rangle \approx 13$ GeV^2/fm.

We then calculate the p value for the $\tilde{\chi}^2$ [the minimum of Eq. (3)], where the p value is defined as:

$$p\text{ value} = \int_{\tilde{\chi}^2}^{\infty} \chi^2_{(n_d)}(z)dz, \tag{4}$$

where $\chi^2_{(n_d)}$ is the chi-square distribution with the appropriate number of degrees of freedom, n_d [20]. This calculation is valid because the goodness-of-fit statistic $\tilde{\chi}^2$ follows a standard χ^2 distribution. Note that p value is the probability, under the assumption that the hypothesis is correct, of randomly obtaining data with a worse fit to the hypothesis than the experimental data under test [20]. These p value s are shown in the middle panel of Fig. 4.

We find the overall minimum (or best) $\tilde{\chi}^2$ and then compute which $\langle\hat{q}\rangle$ scenarios are 1 and 2 standard deviations away from this minimum. The PQM transport coefficient $\langle\hat{q}\rangle$ is constrained by the experimental data as $13.2^{+2.1}_{-3.2}$ and $^{+6.3}_{-5.2}$ GeV^2/fm at the 1 and 2 standard deviation levels, respectively. The two standard deviation constraints correspond to the 95% confidence intervals. We note that this range of large $\langle\hat{q}\rangle$ values is currently under intense theoretical debate (see, for example, Ref. [21]). Thus, the quoted $\langle\hat{q}\rangle$ constraint is for the model-dependent parameter of the specific PQM implementation, and relating this parameter to the fundamental value of the mean transverse momentum squared exchange per unit length traversed may substantially lower the value.

We apply the identical procedure to the GLV, WHDG, and ZOWW calculations and show those results in Figs. 5, 6, and 7. For the GLV calculations this results in a constraint of $dN^g/dy = 1400^{+270}_{-150}$ and $^{+510}_{-290}$ at the 1 and 2 standard deviation levels, respectively. All of these constraint results are summarized in Table II. Constraints for the WHDG model are $dN^g/dy = 1400^{+200}_{-375}$ and $^{+600}_{-540}$ at the 1 and 2 standard deviation levels, respectively. Constraints for the ZOWW model are $\epsilon_0 = 1.9^{+0.2}_{-0.5}$ and $^{+0.7}_{-0.6}$ at the 1 and 2 standard deviation levels, respectively.

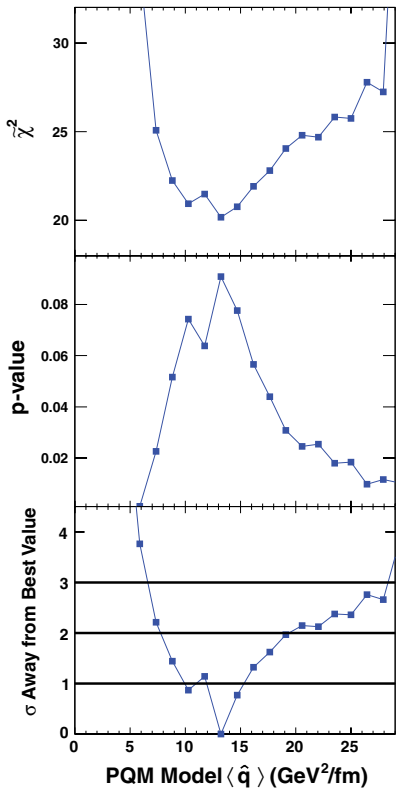

FIG. 4. (Color online) The statistical analysis results from the comparison of the PQM model with the π^0 $R_{AA}(p_T)$ experimental data. The top panel shows the modified $\tilde{\chi}^2$ for different values of the PQM $\langle\hat{q}\rangle$. The middle panel shows the computed p value directly from the modified $\tilde{\chi}^2$ as shown above. The bottom panel shows the number of standard deviations (σ) away from the minimum (best) $\langle\hat{q}\rangle$ parameter value for the PQM model calculations.

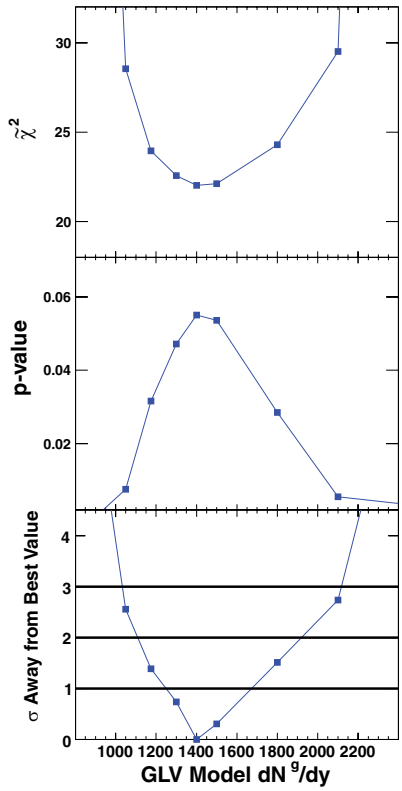

FIG. 5. (Color online) The statistical analysis results from the comparison of the GLV model with the $\pi^0 R_{AA}(p_T)$ experimental data. The top panel shows the modified $\tilde{\chi}^2$ for different values of the GLV dN^g/dy. The middle panel shows the computed p value directly from the modified $\tilde{\chi}^2$ as shown above. The bottom panel shows the number of standard deviations (σ) away from the minimum (best) dN^g/dy parameter value for the GLV model calculations.

TABLE II. Quantitative constraints on the model parameters from the PQM, GLV, WHDG, and ZOWW models and a linear functional form fit.

Model name	Model parameter	1 standard deviation uncertainty	2 standard deviation uncertainty	Maximum p value (%)
PQM	$\langle\hat{q}\rangle = 13.2$ GeV^2/fm	$+2.1 - 3.2$	$+6.3 - 5.2$	9.0
GLV	$dN^g/dy = 1400$	$+270 - 150$	$+510 - 290$	5.5
WHDG	$dN^g/dy = 1400$	$+200 - 375$	$+600 - 540$	1.3
ZOWW	$\epsilon_0 = 1.9$ GeV/fm	$+0.2 - 0.5$	$+0.7 - 0.6$	7.8
Linear	b (intercept) $= 0.168$	$+0.033 - 0.032$	$+0.065 - 0.066$	11.6
	m (slope) $= 0.0017$ (c/GeV)	$+0.0035 - 0.0039$	$+0.0070 - 0.0076$	

For each of the above fits, there is a best fit value of ϵ_b and ϵ_c corresponding to the parameters in Eq. (3). For completeness, these values are for PQM, GLV, WHDG, and ZOWW, $\epsilon_b = 0.6$ and $\epsilon_c = -0.3$, $\epsilon_b = 0.7$ and $\epsilon_c = -0.0$, $\epsilon_b = 2.1$ and $\epsilon_c = -1.5$, and $\epsilon_b = 1.1$ and $\epsilon_c = -0.6$, respectively. All of the models considered here have a steeper p_T dependence of R_{AA} than the experimental data. Thus, the best fit is obtained within the type B uncertainties by tilting the $R_{\rm AA}$.

It is notable that although there is a well-defined overall minimum in the modified $\tilde{\chi}^2$ for all four models, the maximum p value in each case is different. In the PQM, GLV, and ZOWW models the maximum p value s are approximately 9.0%, 5.5%, and 7.8%, respectively. However, in the WHDG model the maximum p value is substantially smaller at 1.3%. This is due to the fact that the WHDG model has a steeper p_T dependence of the nuclear modification factor $R_{\rm AA}$ (regardless of parameter input) than the other models and also steeper than the experimental data points.

The identical best value of dN^g/dy for the GLV and WHDG calculations is interesting, because the inclusion of important collisional energy loss in WHDG leads to the naive expectation that a smaller color-charge density would

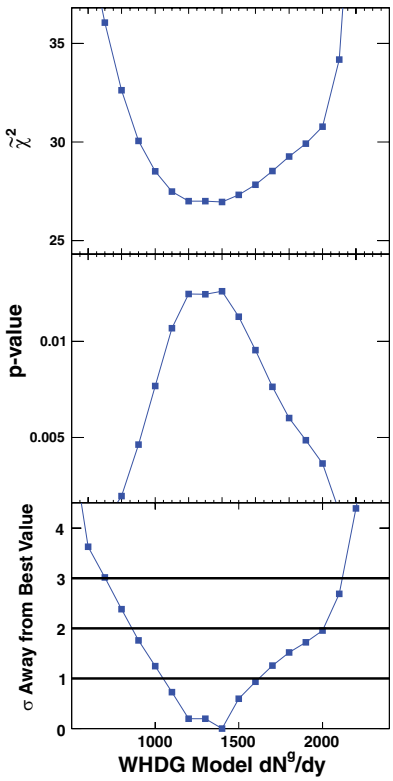

FIG. 6. (Color online) The statistical analysis results from the comparison of the WHDG model with the $\pi^0 R_{\rm AA}(p_T)$ experimental data. The top panel shows the modified $\tilde{\chi}^2$ for different values of the WHDG dN^g/dy. The middle panel shows the computed p value directly from the modified $\tilde{\chi}^2$ as shown above. The bottom panel shows the number of standard deviations (σ) away from the minimum (best) dN^g/dy parameter value for the WHDG model calculations.

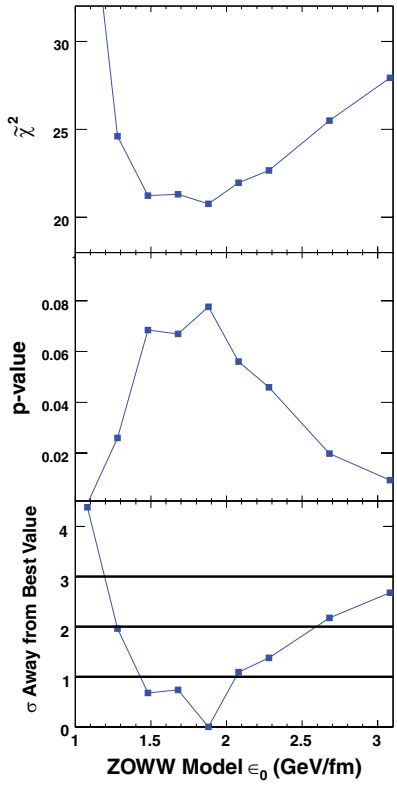

FIG. 7. (Color online) The statistical analysis results from the comparison of the ZOWW model with the $\pi^0 R_{\rm AA}(p_T)$ experimental data. The top panel shows the modified $\tilde{\chi}^2$ for different values of the ZOWW ϵ_0. The middle panel shows the computed p value directly from the modified $\tilde{\chi}^2$ as shown above. The bottom panel shows the number of standard deviations (σ) away from the minimum (best) ϵ_0 parameter value for the ZOWW model calculations.

be needed for a similar suppression. However, the different treatments of the distribution of paths through the medium may be compensating for this effect. Further theoretical studies are needed to disentangle the physics implications of the shape differences and the similar best dN^g/dy from GLV and WHDG. For all the models considered, the relevant parameter constraint is approximately a ±20–25% uncertainty at the 1 standard deviation level.

It is also interesting to inquire what simple linear fit function best describes the experimental data for $p_T >$ 5 GeV/c. The identical procedure to that described above is applied to the function $R_{AA}(p_T) = \mathrm{b} + \mathrm{m} \times p_T$ to determine the best values for the two parameters. The best fit line and the envelope of lines with 1 standard deviation uncertainties are shown in Fig. 8. The results including all types of uncertainties are $b(\text{intercept}) = 0.168^{+0.033}_{-0.032}$ and $\mathrm{m(slope)} = 0.0017^{+0.0035}_{-0.0039}$ (GeV/c). The uncertainties on these parameters are correlated as shown by the 1, 2, and 3 standard deviation contours in Fig. 9.

Thus the data are consistent with a completely flat p_T dependence of R_{AA} for $p_T >$5 GeV/c (i.e., $m = 0$) within 1 standard deviation uncertainties. The maximum p value for this simple linear function fit is 11.6%.

The p value s for all models considered are less than 12%. It is notable that the five highest p_T points ($p_T > 9.5$ GeV/c) contribute over 70% to the total $\tilde{\chi}^2$. As a check on the influence of these points on the extracted parameter values, we have repeated the above procedure to the restricted range $5 < p_T < 9.5$ GeV/c. We find the following new constraints: PQM model

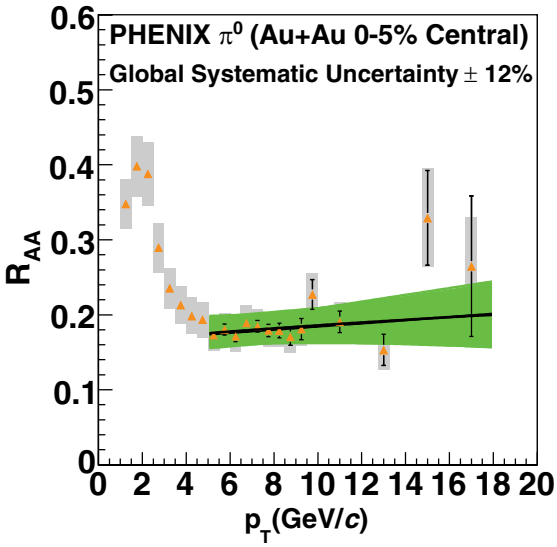

FIG. 8. (Color online) The π^0 nuclear suppression factor R_{AA} as a function of transverse momentum for 0–5% Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Point-to-point uncorrelated statistical and systematic uncertainties are shown as uncertainty bars. Correlated systematic uncertainties are shown as gray boxes around the data points. The global scale factor systematic uncertainty is quoted as text. Also shown are the best fit and the envelope of lines with one standard deviation uncertainty for a simple linear fit function constrained by the statistical and systematic uncertainties.

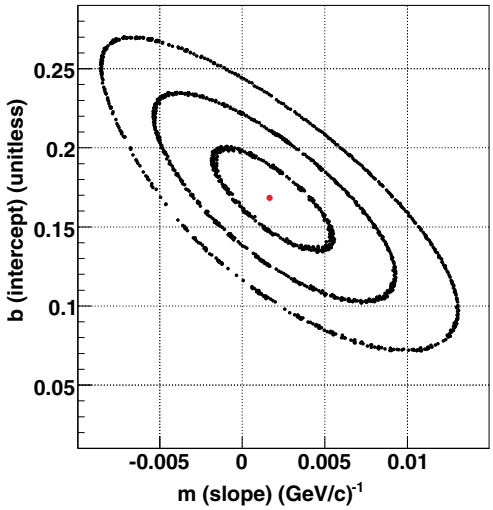

FIG. 9. (Color online) Shown are the best fit values for m(slope) and b(intercept) as constrained by the experimental data. Also shown are the 1, 2, and 3 standard deviation uncertainty contours.

$\langle\hat{q}\rangle = 13.2^{+1.8}_{-4.2}$ GeV^2/fm; GLV model $dN^g/dy = 1400^{+200}_{-210}$; WHDG model $dN^g/dy = 1000^{+300}_{-170}$; ZOWW model $\epsilon_0 = 1.5^{+0.5}_{-0.2}$ GeV/fm; simple linear fit $b(\text{intercept}) = 0.170^{+0.034}_{-0.034}$ and $\mathrm{m(slope)} = 0.0013^{+0.0047}_{-0.0051}$ (GeV/c). We find that the resulting new constraints are within the 1 standard deviation uncertainties of those quoted for the full p_T range. However, with the restricted range, the p value s increase to 55, 36, 17, 62, and 75% for the PQM model, GLV model, WHDG model, ZOWW model, and the simple linear fit, respectively. Improvements in the data for $p_T > 9.5$ GeV/c expected from future measurements will be crucial in determining whether any of the models discussed provide a statistically valid description of the data over the full range $5 \leqslant p_T \leqslant 20$ GeV/c.

V. SUMMARY AND CONCLUSIONS

In this article, we compared model predictions of parton energy loss with experimental data of semi-inclusive single high-transverse-momentum π^0 suppression in central Au+Au reactions at $\sqrt{s_{NN}} = 200$ GeV. In the comparison, statistical and systematic uncertainties were taken into account. We obtained experimental constraints on model parameters of the color-charge density of the medium or its transport coefficient. These values indicate a large medium density. It is crucial to note that the quoted constraints on these parameters do not include any systematic uncertainties in the models but rather give the limits assuming a "perfect theory" with one unknown parameter, for example, the color-charge density, constrained by the measurements, including the experimental statistical and systematic uncertainties. Additional theoretical systematic uncertainties from the time evolution, energy-loss approximations, and calculation details need further investigation.

APPENDIX: CONSTRAINT FORMALISM

In the case of only point-to-point uncorrelated uncertainties (statistical and/or systematic), if one assumes they are Gaussian distributed and characterized by σ, the root-mean-square (rms), calculating the best-parameter fit is straightforward via a log-likelihood or least-squares χ^2 method [20].

The likelihood function $\mathcal{L}$ is defined as the *a priori* probability of a given outcome. Let $y_1, y_2, \ldots y_n$ be n samples from a population with normalized probability density function $f(y, \vec{p})$, where $\vec{p}$ represents a vector of k parameters. For instance, y_i could represent a measurement of a cross section at transverse momentum $(p_T)_i$, where the probability density of the measurement is Gaussian distributed about the expectation value $\mu = \langle y \rangle$:

$$f(y, \vec{p}) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp - \left[\frac{(y-\mu)^2}{2\sigma^2} \right]. \tag{A1}$$

If the samples are independent, then the likelihood function is:

$$\mathcal{L} = \prod_i f(y_i, \vec{p}) = \frac{1}{\sigma_1 \sigma_2 \ldots \sigma_n} \frac{1}{\sqrt{2\pi}^n} \exp - \left\{ \sum_{i=1}^{n} \frac{[y_i - \mu_i(\vec{p})]^2}{2\sigma_i^2} \right\}. \tag{A2}$$

However, if the samples are correlated, for example, via correlated systematic uncertainties, then the full covariance matrix must be used

$$V_{ij} = \langle [y_i - \mu_i(\vec{p})][y_j - \mu_j(\vec{p})] \rangle. \tag{A3}$$

Then the likelihood function takes the more general form:

$$\mathcal{L} = \frac{1}{\sqrt{|V|}} \frac{1}{\sqrt{2\pi}^n} \exp - \left\{ \sum_{i=1}^{n} \sum_{j=1}^{n} \frac{[y_i - \mu_i(\vec{p})] V_{ij}^{-1} [y_j - \mu_j(\vec{p})]}{2} \right\}, \tag{A4}$$

where $|V|$ is the determinant of the covariance matrix V. Note that Eq. (A4) reduces to Eq. (A2) if the correlations vanish so that the covariances are zero and V_{ij} is diagonal

$$\begin{aligned} V_{ij} &= \langle [y_i - \mu_i(\vec{p})][y_j - \mu_j(\vec{p})] \rangle \\ &= \delta_{ij} \langle [y_i - \mu_i(\vec{p})]^2 \rangle = \delta_{ij} \sigma_i^2. \end{aligned} \tag{A5}$$

Because Gaussian probability distributions are inevitable (as a consequence of the central limit theorem) and because there is also an important theorem regarding likelihood ratios for composite hypotheses, it is convenient to use the logarithm of the likelihood

$$\begin{aligned} -2 \ln \mathcal{L} = \ln |V| + n \log 2\pi \\ + \sum_{i=1}^{n} \sum_{j=1}^{n} [y_i - \mu_i(\vec{p})] V_{ij}^{-1} [y_j - \mu_j(\vec{p})]. \end{aligned} \tag{A6}$$

We separate the uncertainties into four classes: type A (point-to-point uncorrelated systematic uncertainties); type B (correlated systematic uncertainties, for which the point-to-point correlation is 100% by construction, because the uncorrelated part has been separated out and included in uncertainty A); type C [overall systematic uncertainties by

which all the points move by the same fraction (i.e., normalization uncertainties)]; and type D (statistical). Categories A and D are simply added in quadrature and represent the total point-to-point uncorrelated uncertainties, denoted σ_i below.

We model a correlated systematic uncertainty as if there were an underlying uncertainty, e.g., absolute momentum scale, which may cause correlated systematic variations Δy_i of the set of measurements, y_i, around their nominal value, that can be represented as a random variable, z_b. The correlated type B variation of the measurements is represented by the displacement of all points from their nominal values by the correlated amounts

$$\Delta y^b(\mathrm{sys})_i \equiv b_i \Delta z_b \tag{A7}$$

$$\langle \Delta y^b(\mathrm{sys})_i \Delta y^b(\mathrm{sys})_j \rangle = b_i b_j \sigma_b^2 \equiv \sigma_{b_i} \sigma_{b_j}, \tag{A8}$$

where $\Delta z_b \equiv z_b - \langle z_b \rangle = z_b$.

Because $\langle z_b \rangle \equiv 0$, $\langle (\Delta z_b)^2 \rangle = \langle z_b^2 \rangle - \langle z_b \rangle^2 = \sigma_b^2$ and the random variable z_b is the same for all i measurements, whereas b_i is a constant of proportionality that may be different for each i. We define $\sigma_{b_i} \equiv b_i \sigma_b$, where $\pm|\sigma_{b_i}|$ is the systematic uncertainty bar shown on each point (gray box on each data point in Fig. 1) and where b_i may be of either sign, as it is possible that one point could move up while its neighbor moves down. The random variable z_b is assumed to have a Gaussian probability distribution $f(z_b)$, with rms σ_b

$$f(z_b) = \frac{1}{\sigma_b \sqrt{2\pi}} \exp - \left[\frac{(\Delta z_b)^2}{2\sigma_b^2} \right]. \tag{A9}$$

The type C variation is independent of the type B variation. It is similarly assumed to be caused by an underlying random variable z_c that results in a systematic displacement of the measurement by an amount Δy_i^c with

$$\Delta y^c(\mathrm{sys})_i / y_i \equiv \Delta z_c \tag{A10}$$

$$\langle (\Delta y^c(\mathrm{sys})_i / y_i)(\Delta y^c(\mathrm{sys})_j / y_j) \rangle = \sigma_c^2, \tag{A11}$$

where by definition σ_c is the same for all points.

We then assume that the likelihood function factorizes as the product of independent Gaussian probabilities as in Eq. (A2) but that the distributions are correlated through their dependence on the random variables z_b and z_c:

$$\mathcal{L} = \prod_i f(y_i; z_b, z_c, \vec{p}) f(z_b) f(z_c) = \frac{1}{\sigma_1 \sigma_2 \ldots \sigma_n \sigma_b \sigma_c} \frac{1}{\sqrt{2\pi}^{(n+2)}} \exp - \left\{ \sum_{i=1}^{n} \frac{[y_i + b_i \Delta z_b + y_i \Delta z_c - \mu_i(\vec{p})]^2}{2\sigma_i^2} + \frac{(\Delta z_b)^2}{2\sigma_b^2} + \frac{(\Delta z_c)^2}{2\sigma_c^2} \right\}. \tag{A12}$$

To account for the type B systematic uncertainty, we allow any given sample of measurements, y_i, corresponding to theoretical predictions $\mu_i(\vec{p})$ to have a correlated variation from their nominal values by an amount corresponding to a certain fraction ϵ_b of the underlying root-mean-square variation of z_b, i.e., $\Delta z_b = \epsilon_b \sigma_b$, such that each point moves by an amount $\Delta y_i^b = b_i \epsilon_b \sigma_b \equiv \epsilon_b \sigma_{b_i}$, the same fraction ϵ_b of its systematic uncertainty bar, and similarly for the type C uncertainty. Then the likelihood function for any outcome, including the variation of ϵ_b and ϵ_c, would be:

$$\mathcal{L} = \frac{1}{\sigma_1 \sigma_2 \ldots \sigma_n \sigma_b \sigma_c} \frac{1}{\sqrt{2\pi}^{(n+2)}} \exp - \left\{ \sum_{i=1}^{n} \frac{[y_i + \epsilon_b \sigma_{b_i} + \epsilon_c y_i \sigma_c - \mu_i(\vec{p})]^2}{2\sigma_i^2} + \frac{\epsilon_b^2}{2} + \frac{\epsilon_c^2}{2} \right\}, \tag{A13}$$

where the last two terms represent $(\Delta z_b)^2/(2\sigma_b^2) = \epsilon_b^2 \sigma_b^2/(2\sigma_b^2)$ and $(\Delta z_c)^2/(2\sigma_c^2) = \epsilon_c^2 \sigma_c^2/(2\sigma_c^2)$ because we assumed the probability of the systematic displacements $f(z_{b,c})$ to be Gaussian. Other probability distributions for the correlated systematic uncertainty could be used. For instance, if $\pm|\sigma_{b_i}|$ had represented full extent systematic uncertainties, with equal probability for any Δz_b, then the $\epsilon_b^2/2$ term and associated normalization constant $1/\sigma_b\sqrt{2\pi}$ would be absent from Eq. (A13).

Then we use the likelihood ratio test to establish the validity or the confidence interval of the theoretical predictions $\mu_i(\vec{p})$. One can use the modified log likelihood

$$-2 \ln \mathcal{L} = \left\{ \sum_{i=1}^{n} \frac{[y_i + \epsilon_b \sigma_{b_i} + \epsilon_c y_i \sigma_c - \mu_i(\vec{p})]^2}{\sigma_i^2} + \epsilon_b^2 + \epsilon_c^2 \right\} \equiv \chi^2(\epsilon_b, \epsilon_c, \vec{p}) \tag{A14}$$

because we will eventually take the ratio of the likelihood of a given set of parameters $\vec{p}$ to the maximum likelihood when all the parameters ϵ_b, ϵ_c, and $\vec{p}$ are varied [the minimum value of Eq. (A15)] so that the terms preceding the exponential in Eq. (A13) cancel because they are not varied. Equation (A15)

follows the χ^2 distribution with $n+2$ degrees of freedom because it is the sum of $n+2$ independent Gaussian distributed random variables [i.e., in statistical terminology $\chi^2(\epsilon_b, \epsilon_c, \vec{p})$ is $\chi^2_{(n+2)}$]. This establishes Eq. (A15) as the χ^2-distributed quantity that we use for least-squares fit to the theoretical predictions, including the systematic uncertainties. Note that Eq. (A15) agrees with Eq. (8) in Ref. [24] in the discussion of fits with correlated systematics. The specific procedure is described in the next paragraph.

First "fit the theory" to the data by minimizing Eq. (A15) by varying all the parameters to find $\hat{\epsilon}_b, \hat{\epsilon}_c, \hat{\vec{p}}$, the values of the parameters that give the overall minimum $\chi^2_{\rm min}$. If the $\chi^2_{\rm min}$ for this fit is acceptable for the $n+2-(m+2) = n-m$ degrees of freedom, where m are the number of parameters in $\vec{p}$, then the theory is not rejected at this level. A confidence interval is then found for testing any other set of k parameters constrained to specific values, $\vec{p}_0$, by again finding the minimum of Eq. (A15) for the k fixed values of $\vec{p}_0$, by letting all the other parameters, including ϵ_b and ϵ_c, vary. For constant values of σ_i, and large values of n, the "likelihood ratio" $-2\ln[\mathcal{L}(\vec{p}_0)/\mathcal{L}(\hat{\vec{p}})] = -2[\ln\mathcal{L}(\vec{p}_0) - \ln\mathcal{L}(\hat{\vec{p}})]$, i.e., $\chi^2(\vec{p}_0) - \chi^2_{\rm min}$ is χ^2 distributed with k degrees of freedom, from which the confidence interval on the parameters can be evaluated. However, in general, the uncertainty on the parameters is estimated in the Gaussian approximation by $\chi^2(\vec{p}_0) = \chi^2_{\rm min} + N^2$ for N standard deviation uncertainties (for example, using a MINUIT-type fitting algorithm [23]).

For the present data, the statistical and random systematic uncertainties are such that the shift in the measurement y_i due to the correlated systematic uncertainties preserves the fractional uncertainty. In this case the maximum likelihood and least-squares methods no longer coincide and we use a least-squares fit of Eq. (A16) instead of Eq. (A15) to estimate the best fit parameters:

$$\tilde{\chi}^2 = \left\{ \sum_{i=1}^{n} \frac{[y_i + \epsilon_b \sigma_{b_i} + \epsilon_c y_i \sigma_c - \mu_i(\vec{p})]^2}{\tilde{\sigma}_i^2} + \epsilon_b^2 + \epsilon_c^2 \right\}, \tag{A15}$$

where $\tilde{\sigma}_i$ is the uncertainty scaled by the multiplicative shift in y_i such that the fractional uncertainty is unchanged under shifts

$$\tilde{\sigma}_i = \sigma_i \left(\frac{y_i + \epsilon_b \sigma_{b_i} + \epsilon_c y_i \sigma_c}{y_i} \right). \tag{A16}$$

Yields for J/ψ production in Cu + Cu collisions at $\sqrt{s_{NN}} = 200$ GeV have been measured over the rapidity range $|y| < 2.2$ and compared with results in $p + p$ and Au + Au collisions at the same energy. The Cu + Cu data offer greatly improved precision over existing Au + Au data for J/ψ production in collisions with small to intermediate numbers of participants, in the range where the quark-gluon plasma transition threshold is predicted to lie. Cold nuclear matter estimates based on *ad hoc* fits to d + Au data describe the Cu + Cu data up to $N_{\text{part}} \sim 50$, corresponding to a Bjorken energy density of at least 1.5 GeV/fm^3.

DOI: 10.1103/PhysRevLett.101.122301 PACS numbers: 25.75.Dw

High-energy heavy-ion collisions provide the opportunity to study strongly interacting matter at very high-energy densities where quantum chromodynamics (QCD) predicts a transition from normal nuclear matter to a deconfined system of quarks and gluons, the quark-gluon plasma (QGP) [1]. At the Relativistic Heavy Ion Collider (RHIC) the energy density in central Au + Au collisions is well in excess of the critical energy density expected for this transition [2].

Over the past 20 years, there has been intense theoretical and experimental work on J/ψ production. First predicted by Matsui and Satz [3], suppression of quarkonia production in ultrarelativistic heavy-ion collisions was expected to be an unambiguous signature for the formation of a QGP. It is now recognized that in order to interpret J/ψ production as a QGP probe one has to consider cold nuclear matter effects such as initial state energy loss [4] and shadowing [5], as well as charm quark energy loss [6], comover interactions [7], corrections for feed-down from higher mass charmonium states, and secondary production mechanisms, such as recombination of initially uncorrelated $c\bar{c}$ pairs [8].

Experiment NA50 reported suppression of J/ψ production in Pb + Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV [9] that exceeds expectations based on their measurements of cold nuclear matter effects in $p + A$ collisions [10]. NA60 observed similar behavior in In + In collisions at the same energy [11]. The PHENIX experiment [12] at RHIC has characterized effects of the nuclear medium on J/ψ production at $\sqrt{s_{NN}} = 200$ GeV. The basic invariant yield reference is obtained from $p + p$ data [13–15]. Cold nuclear matter effects are studied using d + Au data [14,16]. Cold and hot nuclear matter effects are studied for large numbers of participants (N_{part}) using Au + Au data [17,18], and for smaller N_{part} using Cu + Cu data, the subject of this Letter. The results are presented as a nuclear modification factor, R_{AA}, the ratio of the yield in heavy-ion collisions to the yield in $p + p$ collisions scaled by the number of binary nucleon-nucleon collisions (N_{coll}), which is appropriate for pointlike processes.

Lattice QCD calculations [19] indicate that the threshold energy density for QGP formation is of order 1 GeV/fm^3. At $\sqrt{s_{NN}} = 200$ GeV this is expected to occur below $N_{\text{part}} = 100$ [20], in a region where Au + Au data have limited statistical and systematic precision [18]. High statistics measurements with the intermediate sized system Cu + Cu provide crucial information in that important region.

In this Letter we present results obtained by PHENIX during the 2005 RHIC run on the production of J/ψ in Cu + Cu collisions at $\sqrt{s_{NN}} = 200$ GeV. J/ψ invariant yields were studied via $J/\psi \to e^+e^-$ decays measured at midrapidity with the central arm spectrometers ($|y| \leq 0.35$, $\Delta\phi = 2 \times 90°$), and $J/\psi \to \mu^+\mu^-$ decays measured at forward rapidity with the two muon arm spectrometers ($1.2 < |y| < 2.2$, $\Delta\phi = 360°$). Event centrality and the location of the collision vertex along the beam axis (z_{vtx}) are measured with two Beam-Beam Counters (BBC) located at $3.0 < |\eta| < 3.9$. A Glauber model and a simulation of the BBC response was used to determine N_{part} and N_{coll} and their systematic uncertainties for different collision centrality ranges [21].

Data were recorded using lepton triggers in coincidence with a minimum bias trigger which required a coincidence between the BBC detectors and a valid z_{vtx}. After applying a cut of $|z_{vtx}| < 30$ cm and quality assurance criteria, the data correspond to a sampled luminosity of about 2.1 nb^{-1} (1.3 nb^{-1}) in the e^+e^- ($\mu^+\mu^-$) analysis.

Electron detection at midrapidity used the drift chambers for momentum measurement, the pad chambers for pattern recognition and track location, and the ring imaging Cherenkov (RICH) detector plus electromagnetic calorimeter (EMCal) for electron identification. Charged particle tracks were matched with a RICH ring and an EMCal hit to select electron candidates by requiring at least two RICH phototube hits inside an annulus around the projected ring center, ring quality cuts, track or cluster position matching cuts at the EMCal, and a cut on the ratio of EMCal energy to track momentum, $E/p - \langle E/p \rangle > -2\sigma$.

The $J/\psi \to e^+e^-$ trigger required one signal above a certain energy threshold in the EMCal and a matching RICH hit. Two energy thresholds were used during the run, 1.1 and 0.8 GeV, yielding average J/ψ trigger efficiencies of ~65% and 82%, respectively. The $J/\psi \to e^+e^-$ signal extraction method was very similar to the method used in the recent Au + Au [18] and $p + p$ [15] analyses. The like sign invariant mass spectrum was subtracted from the unlike sign spectrum. The remaining yield in the J/ψ mass region ($2.9 \leq M_{\text{inv}} \leq 3.3$ GeV/c^2) was

corrected for pairs lost to the radiative tail and pairs added by the continuum signal under the peak [15]. The total J/ψ count in the e^+e^- channel was ≈ 2050. The signal to background ratio (S/B) was $\approx 1(6)$ for the most central (peripheral) collisions.

Muon detection at forward and backward rapidities used the muon arms, consisting of cathode strip tracking chambers in a magnetic field (MuTr) and Iarocci tube planes interleaved with thick steel absorbers (MuID). Muon candidates were identified by penetration to the last MuID gap, and their momenta were measured by their bend through the MuTr.

The dimuon trigger required two candidate tracks to penetrate the MuID, point back to the event vertex, and pass an opening angle cut ($\theta > 19°$). The dimuon combinatorial background was estimated using the product of the like sign counts, $2\sqrt{N^{++}N^{--}}$, and was subtracted from the unlike sign spectra. The residual background (notably from the open charm pairs and Drell-Yan processes) was evaluated using an exponential form. The $J/\psi \to \mu^+\mu^-$ signal was estimated by direct counting of the remaining pairs above the exponential fit in the mass range $2.6 \leq M_{\rm inv} \leq 3.6$ GeV/c^2 and also by using two fits with different parameterizations (single and double Gaussian) of the J/ψ line shapes, as described in [15,18]. The average of the results gave the signal count and the variation gave the systematic error. The total J/ψ yield was ≈ 9000. The S/B was $\approx 0.3(1.0)$ for the most central(peripheral) collisions.

The J/ψ invariant yield in the appropriate centrality, rapidity, and transverse momentum bin is given by

$$\frac{B_{ll}}{2\pi p_T}\frac{d^2N_{J/\psi}}{dp_T dy} = \frac{1}{2\pi p_T}\frac{N_{J/\psi}}{N_{\rm evt}\Delta y \Delta p_T A\varepsilon}, \qquad (1)$$

with B_{ll} the branching ratio for $J/\psi \to l^+l^-$, $N_{J/\psi}$ the number of observed J/ψ, $N_{\rm evt}$ the number of events; Δy the rapidity range; Δp_T the transverse momentum range, and $A\varepsilon$ the acceptance and efficiency correction (including trigger efficiency).

The determination of $A\varepsilon$ is done with a full GEANT simulation. The method is described in more detail in [15]. $A\varepsilon$ decreases with the collision centrality due to overlapping hits in the RICH and the EMCal in the central arm, and in the MuTr for the forward arms, leading to an increasing fraction of misreconstructed tracks in higher multiplicity events. This effect is evaluated by embedding simulated single J/ψ events in real events. The efficiency loss in the most central collisions is 3% for dielectron measurements and 20% (16%) for dimuon measurements at positive (negative) rapidity.

Systematic uncertainties in the measured J/ψ invariant yield depend on J/ψ rapidity and transverse momentum as well as on event centrality. Systematic uncertainties are grouped into three categories: point to point uncorrelated uncertainties (type A), which can move the points independently of each other, point to point correlated uncertainties (type B), which can move the points coherently, though not necessarily by the same amount, and global systematic uncertainties (type C). In all plots point to point uncorrelated systematic uncertainties and statistical uncertainties are quadratically summed and represented by vertical bars, point to point correlated systematic uncertainties are represented by boxes, and global systematic uncertainties (if any) are quoted.

TABLE I. Systematic error sources, values, and types for $R_{\rm AA}$ vs $N_{\rm part}$ in the two rapidity intervals. Where a range is given, it is from peripheral to central collisions.

Source	$\lvert y\rvert < 0.3$	$\lvert y\rvert \in [1.2, 2.2]$	Type
Signal extraction	6%	5%–6%	A
Detector + trigger efficiency	1.4%–5%	3%	B
Run by run variation	5%	2%	B
Input $y + p_T$ distributions	2%	3%	B
$N_{\rm coll}$	14%–11%	14%–11%	B

Systematic uncertainties of type A and B for $R_{\rm AA}$ vs $N_{\rm part}$ are summarized in Table I. Some uncertainties in the invariant yield, such as that on the acceptance, cancel out for $R_{\rm AA}$ and are not shown. Global systematic uncertainties for $R_{\rm AA}$ vs $N_{\rm part}$ include the $p + p$ J/ψ yield uncertainty and some $p + p$ systematic errors that do not cancel when forming $R_{\rm AA}$.

Results for the two muon arms agree within uncertainties and are combined where appropriate. Figure 1 shows the J/ψ yield vs p_T for different Cu + Cu centrality classes at mid and forward rapidity. As was done previously for the Au + Au case [18], the mean square transverse momentum, $\langle p_T^2\rangle$, was calculated numerically from the data for $p_T < 5$ GeV/c. The Cu + Cu data are plotted vs $N_{\rm part}$ and compared with the corresponding values from

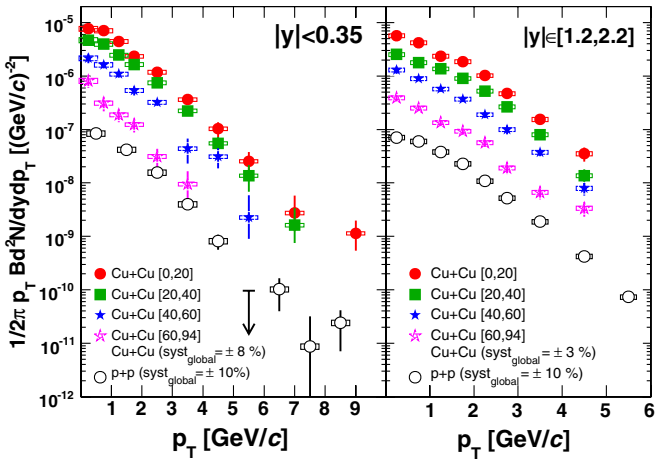

FIG. 1 (color online). J/ψ yield vs p_T at mid (left) and forward (right) rapidity for different Cu + Cu centrality bins and for $p + p$ [15]. Uncertainties are described in the text.

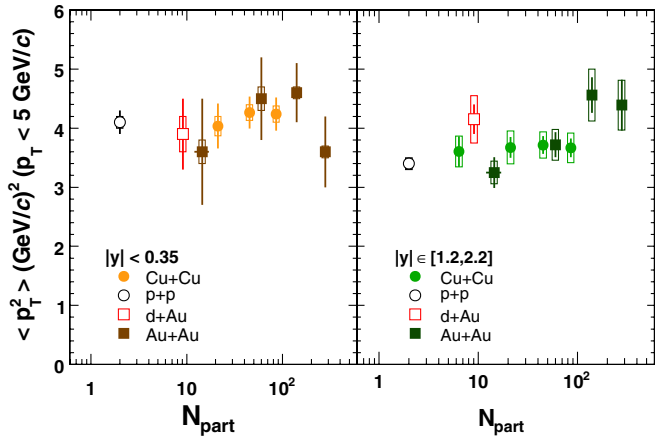

FIG. 2 (color online). The $\langle p_T^2 \rangle$ vs $N_{\rm part}$ for J/ψ production in Cu + Cu, $p + p$ [15], d + Au [16] and Au + Au [18] collisions at mid (left) and forward (right) rapidity.

Au + Au [18], d + Au [16] and $p + p$ [15] collisions in Fig. 2. Within uncertainties, the data for Cu + Cu and Au + Au agree where they overlap in $N_{\rm part}$, and the $\langle p_T^2 \rangle$ for the Cu + Cu data seems independent of $N_{\rm part}$.

The $R_{\rm AA}$ values vs p_T and rapidity are shown in Fig. 3 for the 0–20% most central Cu + Cu collisions. We see similar behavior for mid and forward rapidity, and there appears to be no p_T dependence in all centrality classes. The rms width of the rapidity distribution (evaluated directly from the data) is identical, within ~2–3% uncertainties, in $p + p$ collisions and in all centrality classes for Cu + Cu collisions.

Figures 4(a) and 4(b) show similar behavior within uncertainties for $R_{\rm AA}$ in Cu + Cu and Au + Au [18] collisions at comparable values of $N_{\rm part}$. Theoretical calculations [22] including only modified initial parton distribution functions and an added $J/\psi - N$ breakup cross section were fitted in [16] to d + Au J/ψ $R_{\rm AA}$ data. The EKS98 [23,24] and nDSg [25] shadowing models

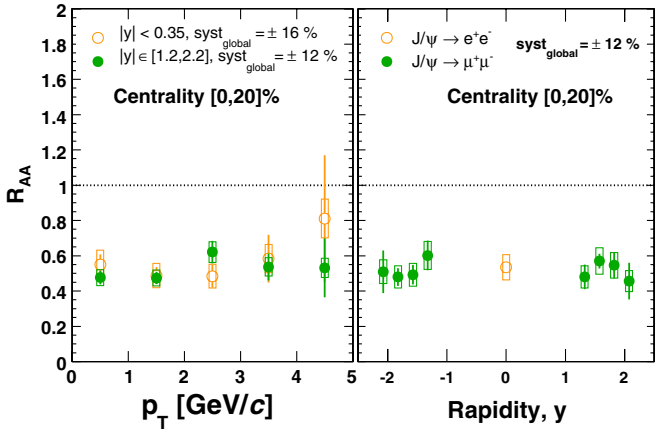

FIG. 3 (color online). $R_{\rm AA}$ vs p_T (left) and y (right) for J/ψ production in the most central Cu + Cu collisions.

were used. The fit was made simultaneously to all rapidities by optimizing the breakup cross section. While consistent with the low statistics d + Au data [16], this method leads to a model dependence of the CNM effects, since the rapidity shape is determined entirely by the shadowing model. In an attempt to reduce this model dependence, we used a data-driven *ad hoc* model to parameterize the d + Au data [16]. The *ad hoc* model uses EKS98 (method 1) and nDSg (method 2) shadowing parameterizations for the relative rapidity dependence within the fitted rapidity ranges, but the breakup cross section is replaced with a quantity, which we call f, that is optimized separately for $y = 0$ and $|y| = 1.7$. The fits using method 1 yielded $f_{dAu} = 2.3 \pm^{2.1}_{1.6}$ mb at $y = 0$ and $3.9 \pm^{1.3}_{1.2}$ mb at $|y| = 1.7$. The method 2 fits yielded $f_{dAu} = 0.9 \pm^{1.9}_{1.8}$ mb at $y = 0$ and $3.3 \pm^{1.3}_{1.2}$ mb at $|y| = 1.7$. The resulting separate parameterizations of the d + Au data vs $N_{\rm coll}$ at mid and forward/backward rapidity can be projected to Cu + Cu and Au + Au using the corresponding parton distribution functions for Cu and Au [22]. The results for method 1 are shown in Fig. 4 as cold nuclear matter baseline $R_{\rm AA}$ curves

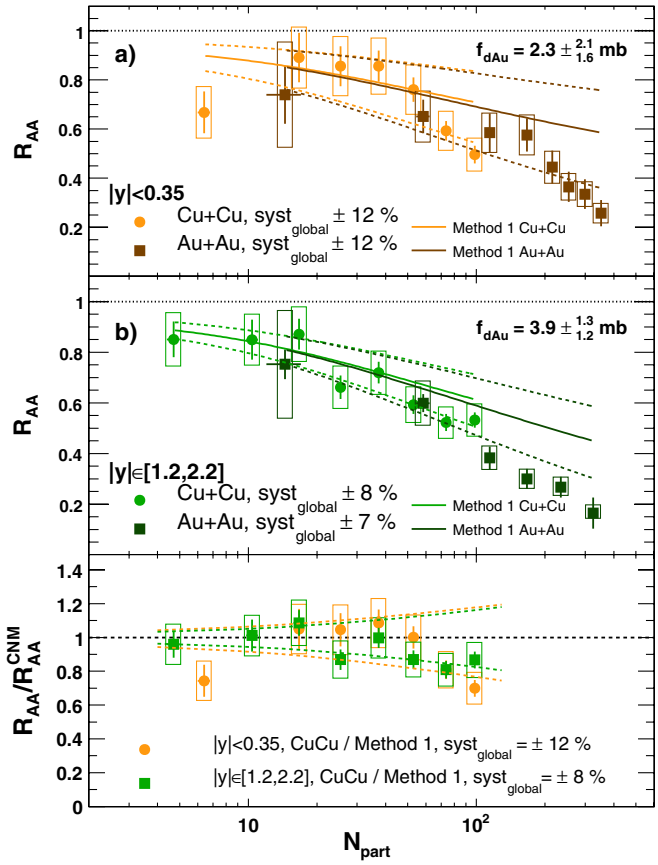

FIG. 4 (color online). (a),(b) $R_{\rm AA}$ vs $N_{\rm part}$ for J/ψ production in Cu + Cu and Au + Au [18] collisions. The curves are predictions from *ad hoc* fits to d + Au data [16] and are discussed in the text. (c) Ratios of the measured $R_{\rm AA}$ values to the predicted cold nuclear matter $R_{\rm AA}$. The dashed lines show the 1σ uncertainties from the d + Au fits.

calculated from the best fit values of f (solid lines) and the 1 standard deviation uncertainty in f (dashed lines). The method 2 heavy-ion calculations are similar to those from method 1, leading to very similar conclusions, and are not shown in Fig. 4. In Fig. 4(c) the measured R_{AA} values for Cu + Cu are shown divided by the method 1 calculations for Cu + Cu. The Cu + Cu R_{AA} is seen to be consistent with the cold nuclear matter projection within about 15% uncertainties up to $N_{part} \sim 50$. Given the uncertainty in the cold nuclear matter reference at larger N_{part} values, we can not currently draw any strong conclusions there. However PHENIX completed in February 2008 a second d + Au run, with approximately 30 times the statistics of the first d + Au run in 2003. With the new reference d + Au data, we expect to be able to identify if and where the measured Cu + Cu R_{AA} departs from the cold nuclear matter baseline.

In summary, we present high statistics J/ψ data from Cu + Cu collisions at RHIC, providing for the first time detailed information on R_{AA} and $\langle p_T^2 \rangle$ for $N_{part} < 100$. The rms values of the rapidity distributions at all centralities are consistent with that for $p + p$, and the measured $\langle p_T^2 \rangle$ for $p_T < 5$ GeV/c is nearly independent of centrality and rapidity. At similar values of N_{part}, R_{AA} and $\langle p_T^2 \rangle$ are found to agree within errors for Cu + Cu and Au + Au collisions. Cold nuclear matter calculations based on *ad hoc* fits to d + Au data reproduce the peripheral Cu + Cu data well up to $N_{part} \sim 50$, corresponding to $\epsilon_{Bjorken}\tau \sim 1.5$ GeV/fm^2/c [20], where $\epsilon_{Bjorken}$ is the Bjorken energy density and τ is the formation time. For an estimate of the thermalized energy density, hydrodynamical models give thermalization times in the range of 0.6 fm/c to 1.0 fm/c [2], which implies that cold nuclear matter effects dominate J/ψ production up to thermalized energy densities of $\sim$1.5 to 2.5 GeV/fm^3.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 28 December 2007; published 13 June 2008)

A three-dimensional correlation function obtained from midrapidity, low p_T, pion pairs in central Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV is studied. The extracted model-independent source function indicates a long range tail in the directions of the pion pair transverse momentum (out) and the beam (long). A proper breakup time $\tau_0 \sim 9$ fm/c and a mean proper emission duration $\Delta\tau \sim 2$ fm/c, leading to sizable emission time differences ($\langle|\Delta t_{\mathrm{LCM}}|\rangle \approx 12$ fm/c), are required to allow models to be successfully matched to these tails. The model comparisons also suggest an outside-in "burning" of the emission source reminiscent of many hydrodynamical models.

DOI: 10.1103/PhysRevLett.100.232301 PACS numbers: 25.75.Ld

Collisions between heavy nuclei at ultrarelativistic energies produce transient systems with energy densities much greater than that required to decompose bulk nuclear matter into quarks and gluons [1]. Such systems were predicted to have long lifetimes if a first order phase transition occurred during their formation or decay [2].

A number of interferometry studies [3] have been made to search for signals of long time delays in emissions from actual reaction sources [4]. For a Gaussian source function, assumed in the traditional Hanbury Brown–Twiss methodology, this would be signaled by an increase in the width R of the emission source function in the out direction of the Berstch-Pratt coordinate system, i.e., $R_{\rm out}/R_{\rm side} \gg 1$. In this system, ''out'' designates the direction of the pair total transverse momentum, ''long'' designates the beam direction, and ''side'' is perpendicular to ''long'' and ''out.'' No such result has been found by these Hanbury Brown–Twiss studies and the reported Gaussian source functions are spheroidal with $R_{\rm out} \approx R_{\rm side}$ in the longitudinally comoving system (LCMS) [4]. However, a recent study with a one-dimensional (1D) source imaging technique [5] has observed a long non-Gaussian tail in the radial source function and attributed it to possible lifetime effects [6,7]. This suggests that further study of the source image may give new insights into the reaction dynamics leading to source breakup.

Here, we extract and perform a detailed study of the 3D two-pion source function using the technique proposed by Danielewicz and Pratt [8,9]. Namely, the 3D correlation function is first decomposed into a basis of Cartesian surface-spherical harmonics to extract the coefficients, also called moments, of the expansion. In turn, they are then imaged or fitted with a trial function to extract the 3D source function, which is then used to probe the emission dynamics of the pion source produced.

Au + Au data (at $\sqrt{s_{NN}} = 200$ GeV) were recorded during 2004 with the PHENIX detector [10] at the Relativistic Heavy Ion Collider (RHIC). The collision vertex z (along the beam axis) was constrained to $|z| < 30$ cm of the nominal crossing point. Charged pions were detected in the east and west central arms of PHENIX, each of which subtends 90° in azimuth ϕ, and ± 0.35 units of pseudorapidity η. Tracking and momentum reconstruction were accomplished with the drift chamber and two layers of multiwire proportional chambers with pad readout (PC1 and PC3). Particle momenta were measured with a resolution $\sigma_p/p = 0.7\% \oplus 1.0\% p$ (GeV/c).

Pion identification was achieved for transverse momentum $p_t \lesssim 2.0$ GeV/c and $p_t \lesssim 1$ GeV/c in the time of flight and electromagnetic calorimeter, respectively. For this analysis, midrapidity ($-0.35 < y < 0.35$, where y is particle rapidity in the nucleus-nucleus center of mass frame) pion pairs were selected with $0.2 < p_T < 0.36$ GeV/c, where p_T is half the pion pair total transverse momentum, from semicentral (0%–20%) Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Track merging and splitting effects were removed by appropriate cuts on both the real and mixed pair distributions [7]. Systematic variations of these cuts were explored to obtain systematic error estimates; on average, they are well within the statistical uncertainty. Hence, the pair cuts do not introduce any significant bias in the correlation function.

The 3D correlation function $C(\mathbf{q}) = N_{\rm fgd}(\mathbf{q})/N_{\rm bkg}(\mathbf{q})$ was constructed as a ratio of 3D relative momentum distribution for $\pi^+\pi^+$ and $\pi^-\pi^-$ pairs in the same event $N_{\rm fgd}(\mathbf{q})$ to that from mixed events $N_{\rm bkg}(\mathbf{q})$. Here, $\mathbf{q} = \frac{(\mathbf{p}_1 - \mathbf{p}_2)}{2}$ where $\mathbf{p}_1$ and $\mathbf{p}_2$ are the momentum 4-vectors in the pair center of mass system (PCMS). The Lorentz transformation of $\mathbf{q}$ from the laboratory frame to the PCMS is made by first transforming to the pair LCMS along the beam direction and then to the PCMS along the pair transverse momentum [11]. $C(\mathbf{q})$ is flat and normalized to unity over $50 < |\mathbf{q}| < 100$ MeV/c.

To obtain the moments, the 3D correlation function $C(\mathbf{q})$ is expanded in a Cartesian harmonic basis [8,9]

$$C(\mathbf{q}) - 1 = R(\mathbf{q}) = \sum_{l,\alpha_1,\ldots,\alpha_l} R^l_{\alpha_1,\ldots,\alpha_l}(q) A^l_{\alpha_1,\ldots,\alpha_l}(\Omega_{\mathbf{q}}) \quad (1)$$

where $l = 0, 1, 2, \ldots$, $\alpha_i = x$, y or z, $A^l_{\alpha_1,\ldots,\alpha_l}(\Omega_{\mathbf{q}})$ are Cartesian harmonic basis elements ($\Omega_{\mathbf{q}}$ is the solid angle in $\mathbf{q}$ space), $R^l_{\alpha_1,\ldots,\alpha_l}(q)$ are Cartesian correlation moments given by Eq. (2), and q is the modulus of $\mathbf{q}$.

$$R^l_{\alpha_1,\ldots,\alpha_l}(q) = \frac{(2l+1)!!}{l!} \int \frac{d\Omega_{\mathbf{q}}}{4\pi} A^l_{\alpha_1,\ldots,\alpha_l}(\Omega_{\mathbf{q}}) R(\mathbf{q}). \quad (2)$$

Here, the coordinate axes are oriented so that z (long) is parallel to the beam direction and x (out) points in the direction of the total transverse momentum of the pair.

Correlation moments can be calculated from the measured 3D correlation function using Eq. (2). In this analysis, Eq. (1) is truncated at $l = 6$ and expressed in terms of independent moments only. As expected from symmetry considerations, odd moments were consistent with zero within statistical uncertainty; higher order moments were negligible [12]. Up to order 6, there are 10 independent moments: R^0, R^2_{x2}, R^2_{y2}, R^4_{x4}, R^4_{y4}, R^4_{x2y2}, R^6_{x6}, R^6_{y6}, R^6_{x4y2}, and R^6_{x2y4} (R^2_{x2} is shorthand for R^2_{xx}, dependent moments are obtained from independent ones [8,9]). These independent moments were extracted as a function of q by fitting the truncated series to the measured 3D correlation function with the moments as the parameters of the fit. The statistical error on the moments reflects the statistical error on the 3D correlation function.

Figure 1 shows the correlation moments $R^l_{\alpha_1,\ldots,\alpha_l}$ up to order $l = 6$. In 1(a), $R^0(q)$ is shown along with $R(q) = C(q) - 1$; both represent angle-averaged correlation functions, but $R^0(q)$ is obtained from the 3D correlation func-

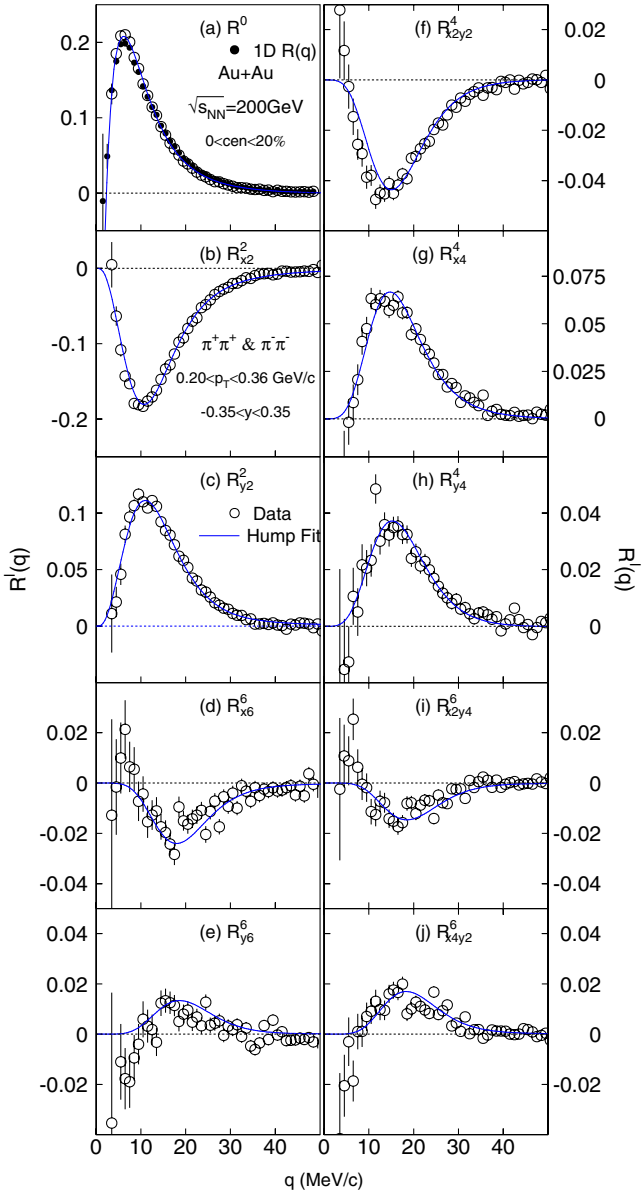

FIG. 1 (color online). Experimental correlation moments $R^l(q)$ for $l = 0, 2, 4, 6$. Panel (a) also shows a comparison between $R^0(q)$ and $R(q)$. Systematic errors are less than the statistical errors. The solid curves indicate the Hump function [Eq. (6)] fit.

tion via Eq. (1) while $R(q)$ is evaluated directly from the 1D correlation function as in Ref. [7].

The very good agreement between $R^0(q)$ and $R(q)$ underlines the absence of any significant angular acceptance issues and attests to the reliability of the moment extraction technique. Figures 1(b)–1(j) show that contributions decrease with increasing l in each direction and are relatively small for $l = 6$ [12]. This justifies truncating Eq. (1) at $l = 6$. The 3D source function $S(\mathbf{r})$ is obtained from these moments via imaging or fitting (see below).

Analogous to Eq. (1), $S(\mathbf{r})$ can be expanded in a Cartesian Surface-spherical harmonic basis [Eq. (3)]

$$S(\mathbf{r}) = \sum_l \sum_{\alpha_1,\ldots,\alpha_l} S^l_{\alpha_1,\ldots,\alpha_l}(r) A^l_{\alpha_1,\ldots,\alpha_l}(\Omega_{\mathbf{r}}). \tag{3}$$

Substitution of the series for $R(\mathbf{q})$ and $S(\mathbf{r})$ into the 3D Koonin-Pratt formalism [Eq. (4)] [3] gives a set of 1D relations [Eq. (5)] [8,9] which connects the correlation moments $R^l_{\alpha_1,\ldots,\alpha_l}(q)$ and source moments $S^l_{\alpha_1,\ldots,\alpha_l}(r)$.

$$C(\mathbf{q}) - 1 = R(\mathbf{q}) = \int d\mathbf{r} K(\mathbf{q}, \mathbf{r}) S(\mathbf{r}) \tag{4}$$

$$R^l_{\alpha_1,\ldots,\alpha_l}(q) = 4\pi \int dr r^2 K_l(q, r) S^l_{\alpha_1,\ldots,\alpha_l}(r). \tag{5}$$

$S(\mathbf{r})$ gives the probability of emitting a pair of particles with a separation vector $\mathbf{r}$ in the PCMS. The 3D kernel, $K(\mathbf{q}, \mathbf{r})$, incorporates Coulomb force and Bose-Einstein symmetrization. Strong interaction is assumed to be negligible for pions. Hence, no correction to the measured correlation function for Coulomb and other final-state interaction effects is required. The 1D imaging code of Brown and Danielewicz [5] was used to numerically invert each correlation moment $R^l_{\alpha_1,\ldots,\alpha_l}(q)$ to extract the corresponding source moment $S^l_{\alpha_1,\ldots,\alpha_l}(r)$; combining the latter as in Eq. (3) yielded the source function.

The 3D source function can also be extracted by directly fitting the 3D correlation function with an assumed functional form for $S(\mathbf{r})$. This corresponds to a simultaneous fit of the ten independent moments. A 4-parameter 3D Gaussian (ellipsoid) fit, using MINUIT minimization, gives a poor result ($\chi^2/\mathrm{ndf} = 3.7$, where ndf is the number of degrees of freedom). The solid curve in Fig. 1 shows the result of a fit to the independent moments with an empirical Hump function given by

$$S^H(r_x, r_y, r_z) = \lambda \exp\Big[-f_s\Big(\frac{x^2}{4r^2_{xs}} + \frac{y^2}{4r^2_{ys}} + \frac{z^2}{4r^2_{zs}}\Big) - f_l\Big(\frac{x^2}{4r^2_{xl}} + \frac{y^2}{4r^2_{yl}} + \frac{z^2}{4r^2_{zl}}\Big)\Big], \tag{6}$$

where λ, r_0, r_{xs}, r_{ys}, r_{zs}, r_{xl}, r_{yl}, r_{zl} are fit parameters and $f_s = 1/[1 + (r/r_0)^2]$, $f_l = 1 - f_s$. This 8-parameter Hump function achieves a better fit to the data ($\chi^2/\mathrm{ndf} = 1.4$). Smearing the track momenta by the measured resolution has a negligible effect on the data points and fits.

Figure 2(a)–2(c) shows a comparison of source function profiles in the x, y, and z directions [$S(r_x)$, $S(r_y)$, and $S(r_z)$] obtained via fitting (line) and source imaging (squares). Source image extraction makes no assumption for the shape of the 3D source function, whereas moment fitting explicitly assumes a shape. Therefore, the good agreement from the two extraction methods confirms the sufficiency of the Hump function but not its uniqueness.

The function $S(r_x)$ is characterized by a long tail, which is resolved up to ~60 fm, in contrast to $S(r_y)$ and $S(r_z)$ which range up to ~25 fm. This difference is also reflected

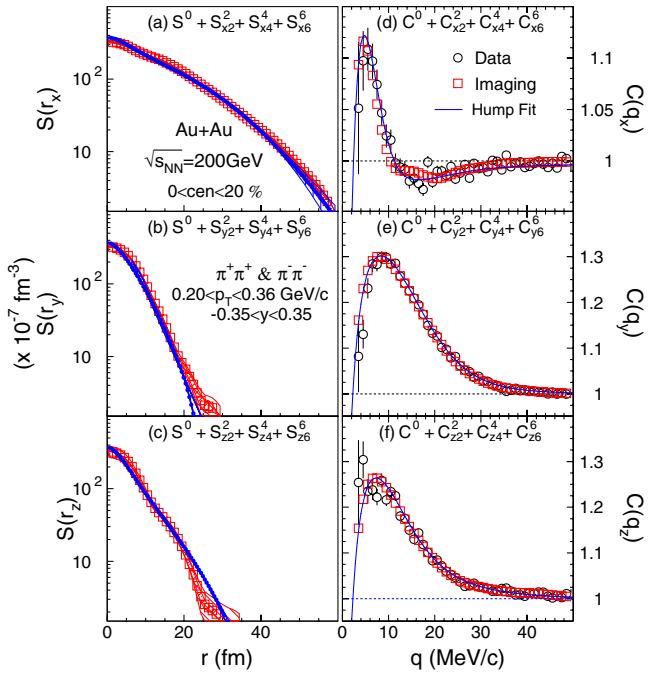

FIG. 2 (color online). Source function profiles $S(r_x)$, $S(r_y)$, and $S(r_z)$ (left panels) and their associated correlation profiles $C(q_x)$, $C(q_y)$, and $C(q_z)$ (right panels) in the PCMS. Symbols are as indicated. The bands indicate statistical and systematic errors.

in the respective correlation profiles [Figs. 2(d)–2(f)] obtained by summation of the data (circle), fit (line), and image (square) moments up to order $l = 6$ (Coulomb effects are not removed). The broader $S(r_x)$ is associated with the narrower $C(q_x)$ [Figs. 2(a) and 2(d)], as expected.

The extended tail lies along the pair total transverse momentum. Thus, the relative emission times between pions, as well as the source geometry, will contribute to $S(r_x)$. The source lifetime contributes to the range of $S(r_z)$, and $S(r_y)$ reflects its mean transverse geometric size. The difference between $S(r_x)$ and $S(r_y)$ is thus driven by the combination of the emission time difference, freeze-out dynamics, and kinematic Lorentz boost.

The event generator THERMINATOR [12,13] can shed more light on the source breakup and emission dynamics. It gives thermal emission from a longitudinally oriented cylinder of radius $\rho_{\max}$, includes all known resonance decays, and assumes Bjorken longitudinal boost invariance. The option for blast-wave transverse expansion was employed with radial velocity v_r semilinear in ρ [14], i.e., $v_r(\rho) = (\rho/\rho_{\max})/(\rho/\rho_{\max} + v_t)$, where $v_t = 1.41$. A differential fluid element is a ring defined by cylindrical coordinates z and ρ; it breaks up at proper time τ in its rest frame or at time t in the lab frame, where $t^2 = \tau^2 + z^2$. The freeze-out hypersurface is given by $\tau = \tau_0 + a\rho$, where τ_0 is the proper breakup time for $\rho = 0$ and a represents the slope of the freeze-out hypersurface in ρ-τ space (it sets the space-time correlation for particle emission: $a > 0$ implies earlier emission of particles at small ρ's, i.e., inside-out "burning" while $a < 0$ implies the reverse, i.e., outside-in "burning"). In blast-wave mode, THERMINATOR sets $a = -0.5$ for source emission from outside in as in many hydrodynamical models.

Using a set of parameters tuned to fit charged pion and kaon spectra [15], midrapidity pion pairs from THERMINATOR were obtained with the effects of all known resonance decay processes on and off. These pairs were then transformed to the PCMS, as in the data analysis, to obtain $S(r_i)$ distributions for comparison with the data.

Figure 3 shows that the 3D source function generated by THERMINATOR calculations (solid triangles) with $\tau_0 = 8.55$ fm/c, $\rho_{\max} = 8.92$ fm, and other previously tuned parameters [15], underestimates $S(r_x)$, $S(r_y)$, and $S(r_z)$. Open triangles (Fig. 3) show that resonance decays reproduce $S(r_y)$ [3(b)] and extend the calculated source function in x [3(a)] as expected, but not enough to account for the long tails in x and z (these are longer than THERMINATOR source profiles with resonance decays alone). This suggests that they have substantial contribution from pion pairs with significantly longer emission time differences. Attempts to fit the distributions by only increasing τ_0 or with $a \geq 0$ failed. The requirement of $a < 0$ in order to reproduce the extracted source function suggests a fireball burning from outside in.

The generated distribution of time differences can also be lengthened by sampling pions from a family of hyper-

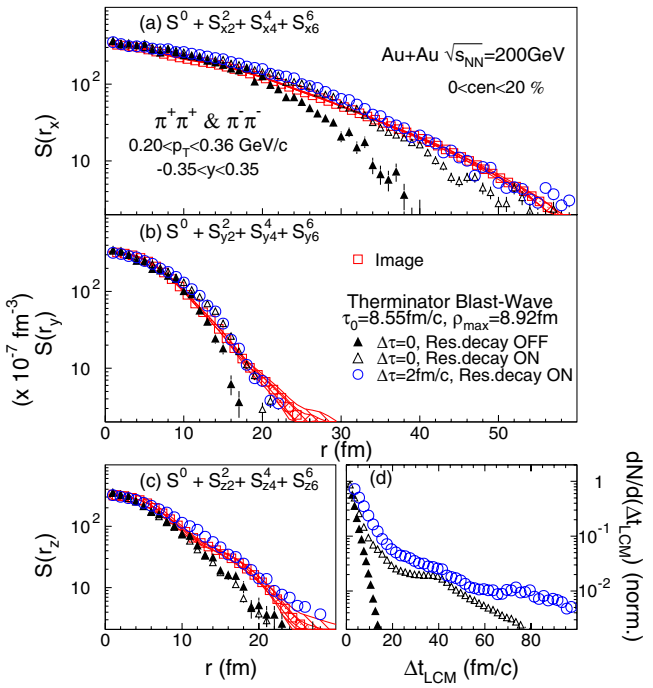

FIG. 3 (color online). Source function comparison between THERMINATOR calculation and image for (a) $S(r_x)$, (b) $S(r_y)$, (c) $S(r_z)$ in PCMS. Panel (d) compares Δt_{LCM} from THERMINATOR events with various assumptions for $\Delta\tau$ and resonance emission.

surfaces defined by a range of values of proper breakup times τ'. One such parametrization consists of replacing τ by τ' chosen from an exponential distribution $dN/d\tau' = \frac{\Theta(\tau'-\tau)}{\Delta\tau}\exp[-(\tau'-\tau)/\Delta\tau]$, where the width of the distribution $\Delta\tau$ represents the mean proper emission duration. Figure 3 shows that this approach, with $\Delta\tau = 2$ fm/c (open circles), leads to a fairly good match to the three observed source profiles. A 10% change in $\Delta\tau$ (with other parameters unchanged) spoils this match.

Figure 3(d) shows the relative emission time distribution in the LCMS, Δt_{LCM}, for pion pairs from events with the parametrizations indicated. For a fixed $\tau_0 = 8.55$ fm/c ($\Delta\tau = 0$) and resonance decays excluded, the distribution Δt_{LCM} is narrow, $\langle|\Delta t_{\mathrm{LCM}}|\rangle = 2.4$ fm/c. The addition of resonance decays adds a long tail and gives $\langle|\Delta t_{\mathrm{LCM}}|\rangle = 8.8$ fm/c. Replacing τ with the exponential distribution τ' with $\Delta\tau = 2$ fm/c results in a Δt_{LCM} distribution which is significantly broadened to give $\langle|\Delta t_{\mathrm{LCM}}|\rangle = 11.8$ fm/c. The wider distribution of time delays is needed to reproduce the source distributions. This implies a finite nonzero proper emission duration in the emission rest frame. Note that this Δt_{LCM} distribution broadening has only a small effect on $S(r_y)$.

The source distensions in Fig. 3 point to substantial time differences Δt_{LCM}; however, the interplay between proper time and breakup dynamics is model dependent. Nevertheless, the picture emerging from the data, in the context of the THERMINATOR model, is consistent with an expanding fireball of proper breakup time $\tau_0 \sim 9$ fm/c which hadronizes and emits particles over a short but nonzero mean proper emission duration $\Delta\tau \sim 2$ fm/c.

In summary, a new model-independent, three-dimensional source imaging technique has been applied to extract the 3D pion emission source function in the PCMS frame from Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The source function has a much greater extent in the out (x) and long (z) than in the side (y) direction. THERMINATOR model comparison indicates a fireball burning from outside in with proper lifetime $\tau_0 \sim 9$ fm/c and a mean proper emission duration $\Delta\tau \sim 2$ fm/c, leading to significant relative emission times ($\langle|\Delta t_{\mathrm{LCM}}|\rangle \approx 12$ fm/c), including those due to resonance decay.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We thank P. Danielewicz, A. Kisiel, and S. Pratt for their interest and input. (Received 18 December 2007; published 20 August 2008)

Measurements in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV of jet correlations for a trigger hadron at intermediate transverse momentum ($p_{T,\mathrm{trig}}$) with associated mesons or baryons at lower $p_{T,\mathrm{assoc}}$ indicate strong modification of the away-side jet. The ratio of jet-associated baryons to mesons increases with centrality and $p_{T,\mathrm{assoc}}$. For the most central collisions, the ratio is similar to that for inclusive measurements. This trend is incompatible with in-vacuum fragmentation but could be due to jetlike contributions from correlated soft partons, which recombine upon hadronization.

DOI: 10.1103/PhysRevLett.101.082301 PACS numbers: 25.75.Ld, 25.75.Gz

Recent measurements at the Relativistic Heavy Ion Collider (RHIC) have indicated the creation of a new state of matter in heavy-ion collisions [1]. The "soft" or small momentum transfer processes leading to the formation of this collision medium are sometimes accompanied by hard parton-parton scatterings. These scattered partons interact strongly with the medium and lose energy as they propagate through it, before fragmenting into jets [2]. This can lead to strong modification of both the yield and the angular correlation patterns of jets [3,4].

Parton energy loss in the nuclear collision medium [2] has been associated with the observation that the single particle yields of mesons (M) are significantly suppressed in Au + Au collisions, when compared to similar yields in $p + p$ collisions scaled by the number of binary nucleon-nucleon collisions [5,6]. This suppression factor $R_{\rm AA}^{M}$ decreases to $\sim$0.2 for transverse momentum $p_T \gtrsim 4$ GeV/c (in the absence of suppression, $R_{\rm AA} = 1.0$). A general pattern of baryon (B) enhancement (for intermediate $p_T \sim$ 2–5 GeV/c) relative to mesons has been observed in central Au + Au collisions at RHIC [7,8]. No suppression is observed for $p_T \sim 1.5$–4 GeV/c [i.e., ($R_{\rm AA}^{B} \sim 1.0$)] [9], and the proton to pion ratio is observed to be about 3 times larger than in $p + p$ collisions [1].

Quark recombination [10–13] has been used to explain the enhancement of baryon emission in the intermediate p_T range. Such models also provide an explanation for the observed dependence of the elliptic flow on hadron species in terms of the "universal" elliptic flow of constituent quarks [14,15]. However, model comparisons to jetlike hadron correlation measurements [16] indicate that jet fragmentation, in concert with the recombination of thermal quarks in a flowing medium, is insufficient to account for the dihadron correlations at intermediate p_T. Thus, the search for a consistent model, which combines fragmentation and recombination dynamics to explain all of the observations in the intermediate p_T range at RHIC, remains open.

Dihadron correlation measurements have indicated suppression of the away-side jet in Au + Au collisions [17]. Recently, modifications to the distributions of the away-side jet partner hadrons measured at lower momentum have also been observed [3,4]. Indeed, these distributions show local minima at $\Delta\phi = \pi$, which contrasts with the characteristic jet peak observed in $p + p$ collisions. This modification has been attributed to strong parton-medium interactions [4,18]. A crucial question is whether or not such interactions could lead to a change in the recombination dynamics and influence the dihadron jet correlations observed at intermediate p_T.

Fries *et al.* [19,20] have argued that such a change in the recombination dynamics is to be expected from the correlations among medium partons and an energetic jet parton, induced by a "wake effect" generated by strong parton-medium interactions. That is, the energy and momentum dissipated by a hard scattered parton are absorbed by the surrounding medium, increasing the temperature by a small amount and setting the medium into motion in the direction of the energetic parton. Thus, dihadron jet correlations could be influenced by correlated medium partons which recombine with each other or with a hard jet parton [21]. The process of recombination would also amplify these jetlike correlations for baryon creation compared to that for mesons and, hence, result in particle ratios different from the in-vacuum fragmentation values [19,21].

To gain more insight into parton-medium interactions and how they might impact recombination, we use measurements of relative azimuthal angle ($\Delta\phi$) correlation functions to make detailed investigations of the distributions and conditional yields of jet-associated baryons and mesons. Our study is made as a function of collision centrality and partner p_T, for the trigger hadron selection $2.5 < p_{T,\rm trig} < 4.0$ GeV/c.

Au + Au data (at $\sqrt{s_{NN}} = 200$ GeV) were recorded during 2004 with the PHENIX detector [22]. Collision centrality was determined with the beam-beam counters (BBCs) and zero degree calorimeters [22]. Charged particle tracking, identification, and momentum reconstruction in the central rapidity region ($|\eta| \leq 0.35$) was provided by two drift chambers, each with an azimuthal coverage $\Delta\varphi = \pi/2$, and two layers of multiwire proportional chambers with pad readout (PC1 and PC3). To reject most background (i.e., conversions, decays, etc.), a confirming hit was required within a 2σ matching window in PC3 [5].

Charged particles were identified via time-of-flight measurement with the time-of-flight (TOF) and lead scintillator (PbSc) detectors. The TOF covers $\Delta\varphi = \pi/4$ with good timing resolution $\simeq$ 120 ps (see Refs. [16,23]); the PbSc as used here covers a larger solid angle ($\Delta\varphi = 3\pi/4$) with a modest timing resolution of 400 ps. The time-of-flight measurements were used in conjunction with the measured momentum and flight-path length to generate a mass-squared (m^2) distribution [24] for charged particle identification. A cut about the baryon ($\bar{p}$, p) peak in the m^2 distribution was used to distinguish baryons and mesons ($\pi^{\pm}$, $K^{\pm}$). The kaon contamination of the baryon sample is $\lesssim 3\%$ for the highest associated p_T bin used ($1.6 < p_{T,\rm assoc}^{M,B} < 2$ GeV/c). We generated area-normalized two-particle correlation functions, in relative azimuthal angle $C(\Delta\phi)$, as the ratio of a signal distribution $N_{\rm cor}(\Delta\phi)$, constructed with correlated particle pairs from the same event, and a background distribution $N_{\rm mix}(\Delta\phi)$, for pairs obtained by mixing particles from different events having similar collision vertex and centrality [3,25]: $C(\Delta\phi) = [N_{\rm cor}(\Delta\phi) \int d\Delta\phi N_{\rm mix}(\Delta\phi)]/[N_{\rm mix}(\Delta\phi) \int d\Delta\phi N_{\rm cor}(\Delta\phi)]$.

Representative examples of the correlation functions $[C(\Delta\phi)]$, so obtained for associated mesons and baryons ($1.3 < p_{T,\rm assoc}^{M,B} < 1.6$ GeV/c) per trigger hadron ($2.5 < p_{T,\rm trig} < 4.0$ GeV/c), are shown for two centrality selections in Fig. 1. They indicate an asymmetry characteristic

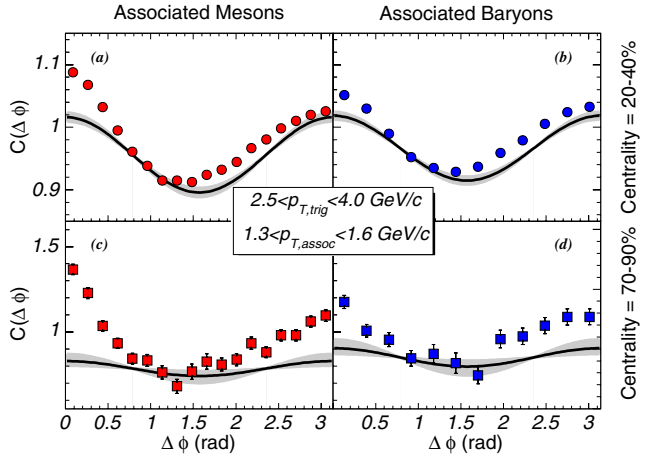

FIG. 1 (color online). Correlation functions for associated partner mesons (a),(c) and baryons (b),(d) for centrality selections of 20%–40% (top panels) and 70%–90% (bottom panels). The curves indicate elliptic flow contributions (see text).

of (di)jet-pair correlations [$J(\Delta\phi)$]and an anisotropy signaling elliptic flow [$H(\Delta\phi) = 1 + 2(v_2^{\rm trig} \times v_2^{B,M}) \times \cos(2\Delta\phi)$]with amplitude $v_2^{\rm trig} \times v_2^{M,B}$ [3]. The correlation functions for associated partner mesons are more asymmetric than those for associated partner baryons, indicating that the jet signal is stronger for hadron-meson correlations. However, clear separation of the jet and flow correlations is required for further study.

To extract $J(\Delta\phi)$ from $C(\Delta\phi)$, a two-source ansatz [25] is used [i.e., $C(\Delta\phi) = b_o H(\Delta\phi) + J(\Delta\phi)$]. Values for $v_2^{\rm trig}$ and $v_2^{M,B}$ were obtained via measurements of the single particle distributions relative to the reaction plane, determined in the BBCs [14,15]. The large (pseudo)rapidity separation ($\Delta|\eta| > 2.75$) between each BBC and the PHENIX central arms minimizes any nonflow contributions to these v_2 values [26].

To fix the value of b_o, we followed the procedure in Refs. [3,25] and assumed that $J(\Delta\phi)$ has zero yield at some minimum $\Delta\phi_{\rm min}$ (ZYAM). That is, the elliptic flow contributions are required to coincide with $C(\Delta\phi)$ at $\Delta\phi_{\rm min}$. Good precision for $\Delta\phi_{\rm min}$ was achieved via a fit to the correlation function; the systematic error on the magnitude of the integrated jet function $J(\Delta\phi)$, due to the ZYAM procedure, is estimated to be $\lesssim 3\%$ from the uncertainty in setting $J(\Delta\phi) = 0$ at $\Delta\phi_{\rm min}$. The solid lines in Fig. 1 show examples of the ZYAM-normalized elliptic flow (v_2) contributions. The gray bands represent systematic errors on the v_2 amplitudes ($\sim$6% for central and midcentral events and $\sim$40% for peripheral events) primarily due to an uncertainty in the reaction plane resolution [3].

The efficiency-corrected associated meson and baryon jet distributions $\frac{1}{N_{\rm trig}} \frac{d^2N}{dp_T d\Delta\phi}$ are shown in Fig. 2 for two associated p_T bins and for the centralities 0–20% and 20%–40%. The shaded error bars and dashed lines indicate the respective systematic error related to v_2 subtraction and fixing b_o. The associated baryon jet-pair distributions are multiplied by the indicated factors to facilitate a shape comparison with the distributions for mesons.

Figure 2 shows that the correlation strength of the near-side jet ($\Delta\phi \leq \Delta\phi_{\rm min}$, NS) is substantially weaker for associated baryons. In contrast, the shapes of the away-side jet distributions ($\Delta\phi \geq \Delta\phi_{\rm min}$, AS) are qualitatively similar for associated mesons and baryons. For the central and midcentral collisions shown, these distributions are also broad and decidedly non-Gaussian, with evidence for local minima at $\Delta\phi = \pi$ [3]. They provide confirmation that the topological signatures for strong jet modification are reflected in the jet-pair distributions for both associated baryons and mesons [27]. The latter finding for baryons and mesons is an important constraint for models of strong jet modification [11,28–30].

For a given centrality and partner p_T, the integral of the extracted $J(\Delta\phi)$ distribution is the fraction of particle pairs associated with the jet, i.e., the jet-pair fraction (JPF): $\mathrm{JPF}_{\rm NS,AS} = \sum_{i\in \rm NS,AS} J(\Delta\phi_i) / \sum_i C(\Delta\phi_i)$ [25]. We use it to determine the conditional yield $\langle N^{M,B}\rangle / \langle N_{\rm trig}\rangle$, or efficiency-corrected pairs per trigger [25],

$$\frac{\langle N^{M,B}\rangle}{\langle N_{\rm trig}\rangle} = \mathrm{JPF} \frac{\langle N_d^{M,B}\rangle}{\langle N_s^{\rm trig}\rangle \times \langle N_s^{M,B}\rangle} \langle N_{\rm eff}^{M,B}\rangle,$$

where $\langle N_d^{M,B}\rangle$ is the average number of detected hadron-meson(baryon) pairs per event, $\langle N_s^{\rm trig}\rangle$ and $\langle N_s^{M,B}\rangle$ are the detected singles rates for hadrons, mesons, and baryons, respectively, and $\langle N_{\rm eff}^{M,B}\rangle$ are the efficiency-corrected singles rates. The systematic error associated with the latter is $\sim$10%. A further division by the p_T bin width gives the conditional yield $CY = \frac{1}{N_{\rm trig}} \frac{dN}{dp_T}$, which is equivalent to an integration of the distributions shown in Fig. 2.

The conditional yields, for near- and away-side associated mesons and baryons, are shown as a function of $p_{T,\rm assoc}^{M,B}$ and collision centrality in Fig. 3. The shaded error bars reflect the combined systematic error associated with

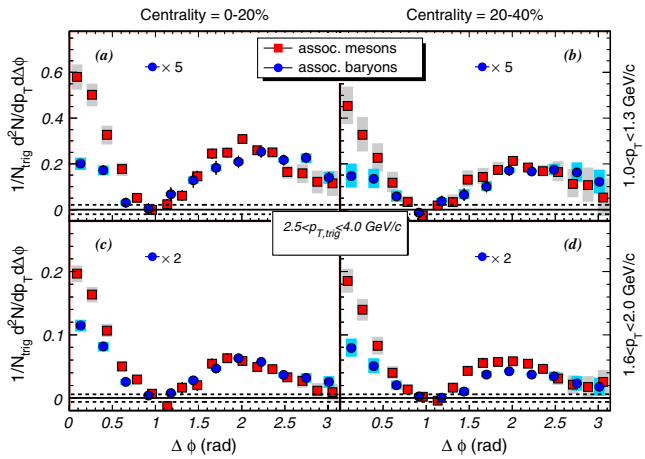

FIG. 2 (color online). Jet-pair distributions for associated mesons (squares) and baryons (circles).

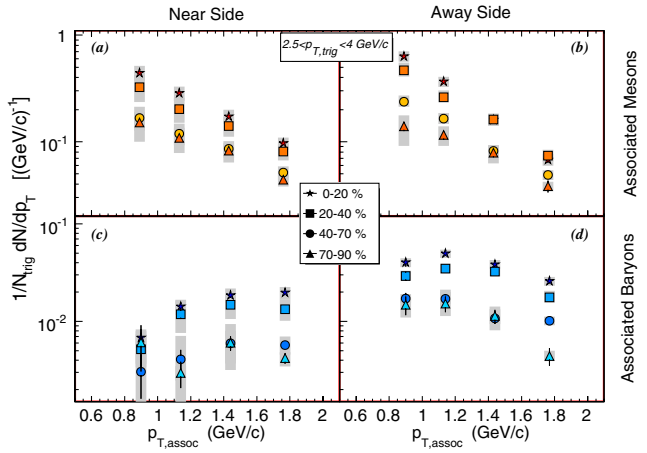

FIG. 3 (color online). Conditional jet yields for associated mesons and baryons for near-side and away-side jets.

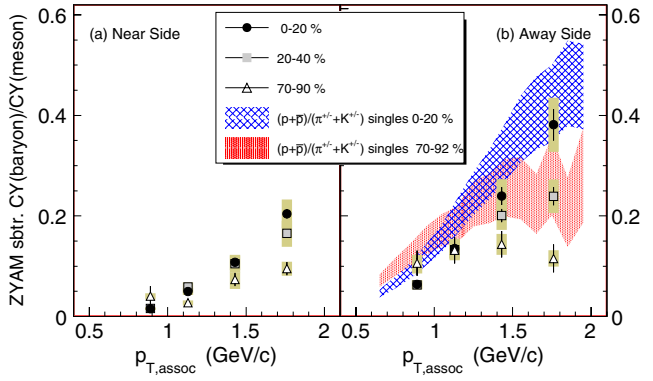

FIG. 4 (color online). Ratio of jet-associated baryons to jet-associated mesons. The hatched bands indicate inclusive B/M ratios (see text).

v_2, b_o, and the efficiency. The yields for associated mesons [Figs. 3(a) and 3(b)] indicate an essentially exponential decrease with increasing $p^M_{T,\mathrm{assoc}}$, for both the near- and away-side jets. An increase in the inverse slope parameter T_{eff} (''temperature'') from central ($T_{\mathrm{eff}} \sim 390$ MeV) to peripheral ($T_{\mathrm{eff}} \sim 700$ MeV) collisions is also apparent for the away-side distributions. For a fixed $p^M_{T,\mathrm{assoc}}$, these yields also show an increase from peripheral to central events, albeit with a stronger dependence for the away-side jet. This trend is incompatible with in-vacuum fragmentation but could be due to jetlike contributions from correlated soft partons which recombine upon hadronization [19,21], softening of the fragmentation function, and fragmentation of radiated gluons, due to energy loss [31].

The conditional yields for associated baryons differ strongly from those for associated mesons [cf. Figs. 3(c) and 3(d)]. That is, they do not show an exponential dependence on p^B_T over the measured range, and the yields for the away-side jet are substantially larger than those for the near-side jet. For a given $p^B_{T,\mathrm{assoc}}$, the near- and away-side conditional yields increase as the collisions become more central; i.e., this trend is similar to that for the associated mesons. The baryon yields show a much stronger increase with centrality [27], as might be expected if correlated soft partons recombine and contribute to the away-side jet correlations [20].

The ratio of associated baryons to associated mesons is shown as a function of associated particle p_T in Fig. 4; the left and right panels show the ratios for the near- and away-side jets, respectively, for three centrality selections as indicated. These ratios clearly increase with p_T and with centrality for $p_T \gtrsim 1.4$ GeV/c. For peripheral collisions, the near-side ratios are qualitatively similar to the p/π ratio for jets produced in $e^+ + e^-$ collisions [32]. For more central collisions, the near- and away-side ratios are much larger, suggesting that the medium influences the relative composition of the associated particles.

The hatched bands in Fig. 4(b) show the inclusive B/M ratios (uncorrected for baryon and meson feeddown) as a function of p_T for the 0–20% and 70%–92% most central Au + Au collisions [24]; an estimate of these ratios after feeddown corrections is within the systematic errors indicated by the bands. These ratios indicate that the trend of the centrality dependent baryon enhancement, apparent in the jetlike associated conditional yields, is similar to that observed for the inclusive particle yields. This suggests that the mechanisms for baryon enhancement in both the inclusive and the current away-side jet measurements have a common origin. Since recombination models can explain the enhancement of inclusive baryon yields, a qualitative explanation is that the away-side correlations result from the recombination of correlated soft partons induced via strong parton-medium interactions.

In summary, we have measured per-trigger yield distributions for jetlike associated mesons and baryons over a wide range of centrality and p_T in Au + Au collisions. The distributions for both species show similar shape modifications for the away-side jet, compatible with several jet-modification models [11,28–30]. The conditional yield distributions for mesons and baryons show different dependencies on collision centrality and associated particle p_T. The ratio of associated baryons to mesons increases with centrality and p_T, similar to the data for inclusive measurements. These results may be qualitatively understood in terms of parton-medium interactions which induce correlations between soft partons, followed by recombination at hadronization [19–21]. The observation that the baryon to meson ratio of the away-side jet approaches the ratio measured for inclusive hadrons in central Au + Au collisions suggests that the increased jetlike associated yield and large baryon to meson ratio have the same origin.

It may therefore be possible to reconcile the observed jetlike structures and the increased baryon/meson ratio at intermediate p_T in a single model for hadron production. Future quantitative model comparisons as well as measurements at higher p_T are required to fully understand the interplay between fragmentation and soft production processes.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 26 November 2007; published 28 February 2008)

We present a new analysis of J/ψ production yields in deuteron-gold collisions at $\sqrt{s_{NN}} = 200$ GeV using data taken from the PHENIX experiment in 2003 and previously published in S. S. Adler *et al.* [Phys. Rev. Lett **96**, 012304 (2006)]. The high statistics proton-proton J/ψ data taken in 2005 are used to improve the baseline measurement and thus construct updated cold nuclear matter modification factors ($R_{d\mathrm{Au}}$). A suppression of J/ψ in cold nuclear matter is observed as one goes forward in rapidity (in the deuteron-going direction), corresponding to a region more sensitive to initial-state low-x gluons in the gold nucleus. The measured nuclear modification factors are compared to theoretical calculations of nuclear shadowing to which a J/ψ (or precursor) breakup cross section is added. Breakup cross sections of $\sigma_{\mathrm{breakup}} = 2.8^{+1.7}_{-1.4}$ ($2.2^{+1.6}_{-1.5}$) mb are obtained by fitting these calculations to the data using two different models of nuclear shadowing. These breakup cross-section values are consistent within large uncertainties with the 4.2 ± 0.5 mb determined at lower collision energies. Projecting this range of cold nuclear matter effects to copper-copper and gold-gold collisions reveals that the current constraints are not sufficient to firmly quantify the additional hot nuclear matter effect.

I. INTRODUCTION

Understanding the behavior of QCD matter under different conditions of temperature and density is the subject of intense experimental and theoretical work in nuclear physics. The transition from hadronic matter to a quark-gluon plasma at high temperature is expected to be achieved in high-energy heavy-ion collisions. The hadronization of partons in vacuum or cold nuclear matter (i.e., in a nucleus) is also of keen interest and represents a nonperturbative and dynamic QCD process. The formation and interaction of heavy quarkonia (e.g., J/ψ mesons) in vacuum, cold nuclear matter, and hot nuclear matter present an excellent laboratory for gaining insights on these transformations. Recent results from the Relativistic Heavy Ion Collider reveal a significant suppression of the final J/ψ yield in central (small impact parameter) Au + Au reactions at $\sqrt{s_{NN}} = 200$ GeV, relative to expectations scaled from $p + p$ reactions at the same energy [1,2]. A possible source of this suppression is the screening of the attractive interaction between the quark-antiquark pair in the hot nuclear medium, as temperatures are expected to be above the critical temperature for a quark-gluon plasma transition. Larger J/ψ suppression is observed at forward rapidity than at midrapidity, which contradicts models with only color screening of quarkonia proportional to the local energy density.

Produced $c\bar{c}$ pairs must pass through the remaining nuclear material from the incident cold nuclei, in addition to surviving any hot medium environment. The so-called cold nuclear matter effects [3], including modification of initial parton distribution functions (shadowing, gluon saturation, antishadowing, EMC effect, etc.), initial- and final-state partonic multiple scattering, and related initial-state parton energy loss need to be accounted for before firm conclusions can be drawn about the effect of the hot medium thought to be created. In fact, these various cold nuclear matter effects are interesting in their own right, notably in terms of hadronization time scales, parton energy loss in matter, and the various initial-state effects just mentioned.

This paper presents a new analysis of the modification of J/ψ production in deuteron-gold (d + Au) collisions relative to proton-proton ($p + p$) collisions at $\sqrt{s_{NN}} = 200$ GeV and the implications for understanding the Au + Au and Cu + Cu data at the same energy. The PHENIX experiment has previously published a result using $p + p$ and d + Au data taken in 2003 [4]. A modest J/ψ suppression was observed at forward rapidity (i.e., in the deuteron-moving direction), which is a possible indication of shadowing of low-x gluons in the gold nucleus. A substantially larger (more than an order of magnitude) $p + p$ data set was recorded in 2005, with the J/ψ results published in Ref. [2], and has been used as the baseline for recent Au + Au and Cu + Cu nuclear modification factors [1,5]. The same $p + p$ data set is used in the analysis presented here to determine the d + Au nuclear modifications more accurately and in a fully consistent way with those in the Au + Au and Cu + Cu cases. In addition, during the two years between the analyses of the 2003 and 2005 data sets significant improvements in the reconstruction software and signal-extraction method were achieved along with an overall better understanding of the detector performance. These improvements have been included in this analysis, allowing maximal cancellation of systematic errors when using the 2005 $p + p$ data sample to form the J/ψ nuclear modification factor. We first describe the updated analysis, then present the new nuclear modification factors and their implications.

II. EXPERIMENT

The PHENIX apparatus is described in Ref. [6]. It consists of two sets of spectrometers referred to as the central arms,

*Deceased.
†PHENIX Spokesperson; electronic address: jacak@skipper.physics.sunysb.edu

which measure particles emitted at midrapidity ($|y| < 0.35$), and the muon arms, measuring particles emitted at backward and forward rapidity ($-2.2 < y < -1.2$ and $1.2 < y < 2.2$).

At midrapidity, J/ψ particles are measured via their decay into two electrons. Electrons are identified by matching tracks reconstructed with drift chambers (DC) and pad chambers (PC) to clusters in the electromagnetic calorimeters (EMCAL) and hits in the ring imaging Cerenkov counters (RICH). In $d + \mathrm{Au}$ collisions, a charged track is identified as an electron candidate by requiring at least three matching RICH phototube hits within a certain radius with respect to the the center defined by the track projection at the RICH, a position matching of ± 4 standard deviations between the EMCAL cluster and the reconstructed track, and a cut on the ratio of energy to momentum. In $p + p$ collisions the electron identification cuts are the same except that only two matching RICH phototube hits are required.

At forward and backward rapidity, J/ψ particles are measured via their decay into two muons. Muons are identified by matching tracks measured in cathode strip chambers (referred to as the muon tracker, or MuTR) to hits in alternating planes of Iarocci tubes and steel absorbers (referred to as the muon identifier, or MuID). Each muon arm is located behind a thick copper and iron absorber that is meant to absorb most hadrons produced during the collisions, so that the measured muons must penetrate 8 to 11 interaction lengths of material in total.

The $d + \mathrm{Au}$ data used for this analysis were recorded in 2003 using a minimum-bias trigger that required hits in each of the two beam-beam counters (BBCs) located at positive and negative rapidity ($3 < |\eta| < 3.9$) and represent integrated luminosities for the different spectrometers ranging from 1.4 to 1.7 nb^{-1} (or, equivalently, from 2.7 to 3.4 billion interactions). This trigger covers $88\% \pm 4\%$ of the total $d + \mathrm{Au}$ inelastic cross section of 2260 mb [7]. For the electrons, an additional trigger was used that required one hit above threshold in the EMCAL and a matching hit in the RICH. For the muons, two additional triggers were used at different times during the data-taking period. The muon triggers are based on information from the MuID, which has five active detector layers between the steel absorbers. For the first part of the data-taking period, one of the tracks was required to reach the fourth MuID plane, while the other was only required to reach the second MuID plane. For the latter part, the trigger required at least two tracks to reach the fourth MuID plane of Iarocci tubes.

The BBCs are also used to determine the centrality of the $d + \mathrm{Au}$ collisions by measuring the energy deposited in the counters located at negative rapidity (in the gold-going direction). For a given centrality bin, the average number of equivalent nucleon-nucleon collisions (N_{coll}) is derived from this energy by using a Glauber calculation [8] coupled to a simulation of the BBC. The centrality bins used in this analysis and the corresponding number of collisions are listed in Table I. To ensure that the centrality categories are well defined, collisions are required to be within ± 30 cm of the center of the interaction region.

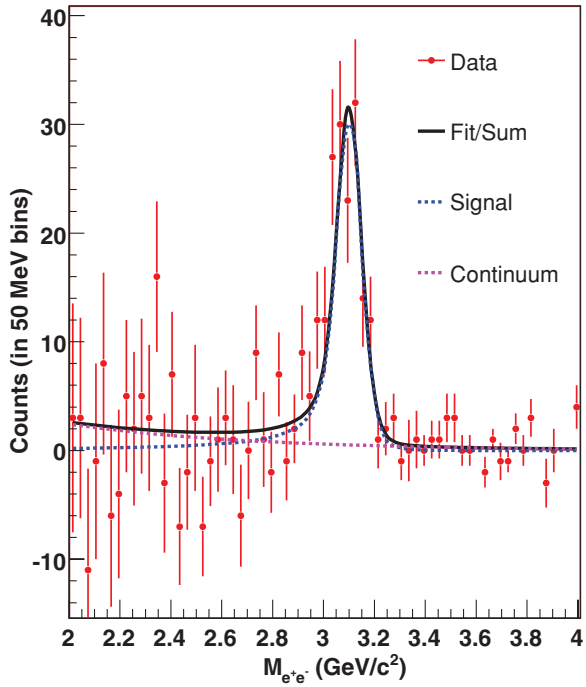

FIG. 1. (Color online) Invariant mass spectra in minimum-bias $d + \mathrm{Au}$ reactions for $J/\psi \longrightarrow e^+e^-$ at $|y| < 0.35$, with the functional forms used to extract the number of reconstructed J/ψ mesons.

III. SIGNAL EXTRACTION

The number of J/ψ particles is determined by using the invariant mass distribution of unlike-sign lepton pairs. At midrapidity, the J/ψ signal count is obtained via counting the number of unlike-sign dielectrons after subtracting the like-sign pairs in a fixed mass window of $2.6 \leqslant M_{e^+e^-} \leqslant 3.6\ \mathrm{GeV}/c^2$ or $2.7 \leqslant M_{e^+e^-} \leqslant 3.5\ \mathrm{GeV}/c^2$, depending on the number of DC hits required for track reconstruction. Figure 1 shows the J/ψ mass spectrum after subtracting the background. The solid

TABLE I. Characterization of the collision centrality for $d + \mathrm{Au}$ collisions. Listed are the centrality bins used in this analysis, the corresponding number of binary collisions, N_{coll}, and the values of $c = \epsilon^{\mathrm{BBC}}_{\mathrm{MB(cent)}}/\epsilon^{\mathrm{BBC}}_{J/\psi}$ for J/ψ mesons emitted in the three rapidity ranges used for this analysis.

Centrality	0–20%	20–40%	40–60%	60–88%	0–100%
N_{coll}	15.4 ± 1.0	10.6 ± 0.7	7.0 ± 0.6	3.1 ± 0.3	7.6 ± 0.3
c ($\lvert y\rvert < 0.35$)	0.95 ± 0.03	0.99 ± 0.01	1.03 ± 0.01	1.04 ± 0.03	0.94 ± 0.02
c ($-2.2 < y < -1.2$)	0.93 ± 0.03	0.99 ± 0.01	1.04 ± 0.01	1.05 ± 0.03	0.94 ± 0.02

black line is the sum of the J/ψ line shape (dashed curve) and an exponential function (dot-dashed curve) describing the continuum component determined from the 2005 $p+p$ data set [2]. The J/ψ line-shape function takes into account the momentum resolution of track reconstruction, internal radiative effects [9], and external radiative effects evaluated by using a GEANT [10] simulation of the PHENIX detector. The number of J/ψ particles in $d+$Au collisions is too small to allow a good fit but a comparison between $d+$Au and $p+p$ J/ψ line shapes shows good agreement. The fraction of J/ψ candidates outside of the mass window owing to the radiative effects is estimated to be $7.2\% \pm 1.0\%$ based on the line-shape functions. The J/ψ signal is also corrected for the dielectron continuum yield, which originates primarily from open charm and Drell-Yan pairs inside the mass window. The estimated contribution is $10\% \pm 5\%$, based on the fitting function and PYTHIA [11] simulations. Approximately 400 J/ψ mesons are obtained.

At backward and forward rapidity an event-mixing technique is now used to estimate the combinatorial background, whereas the like-sign pairs were used in the previous analysis [4]. The previous method suffered from a larger statistical uncertainty for bins where the signal over background is poor. A sample mass distribution after the subtraction of the mixed-event background is shown in Fig. 2. Approximately 500 and 750 J/ψ mesons are obtained for backward and forward rapidity, respectively. The signal counts are determined from this subtracted dimuon invariant mass distribution with a log-likelihood fit and for three different assumed functional forms and parameters. In all three cases, an exponential form is used to account for correlated physical background sources (e.g., Drell-Yan or open charm) and the possible systematic offset in the normalization of the mixed-event background. The number of J/ψ particles is then estimated by direct counting of the remaining number of pairs above the exponential in the mass range $2.6 \leqslant M_{\mu^+\mu^-} \leqslant 3.6$ GeV/c^2, using a Gaussian function with the center fixed to the J/ψ mass and the width and integrated yield left free, or using two Gaussian functions for which both the center and widths are fixed to the values measured in $p+p$ collisions. The two Gaussian functions account for the non-Gaussian tails in the invariant mass distribution. The normalization of the mixed background is varied by a systematic uncertainty of $\pm 2\%$ prior to its subtraction from the mass distribution. This uncertainty is determined by comparing different normalization methods. The corresponding signal variations are included in the systematic uncertainty. Because of the particular fit procedure, for all $p+p$ and $d+$Au cases this normalization uncertainty results in a very small systematic uncertainty on the number of measured J/ψ particles. This entire procedure is identical to the one used in Refs. [1,2].

IV. INVARIANT YIELD

The J/ψ invariant yield in a given centrality, transverse momentum, and rapidity bin is

$$\frac{B_{ll}}{2\pi p_{\mathrm{T}}}\frac{d^2N_{J/\psi}}{dp_T dy} = \frac{1}{2\pi p_T \Delta p_T \Delta y}\frac{N^{J/\psi}_{\mathrm{counts}}}{A\epsilon_{\mathrm{rec}}\epsilon_{\mathrm{trig}}N^{\mathrm{MB}}_{\mathrm{evt}}}\frac{\epsilon^{\mathrm{BBC}}_{\mathrm{MB(cent)}}}{\epsilon^{\mathrm{BBC}}_{J/\psi}}, \quad (1)$$

where B_{ll} is the branching ratio for $J/\psi \to l^+l^-$, $N^{J/\psi}_{\mathrm{counts}}$ is the number of reconstructed J/ψ mesons, $N^{\mathrm{MB}}_{\mathrm{evt}}$ is the number of minimum-bias events sampled, $\epsilon^{\mathrm{BBC}}_{\mathrm{MB(cent)}}$ is the BBC trigger efficiency for minimum-bias events in a given centrality

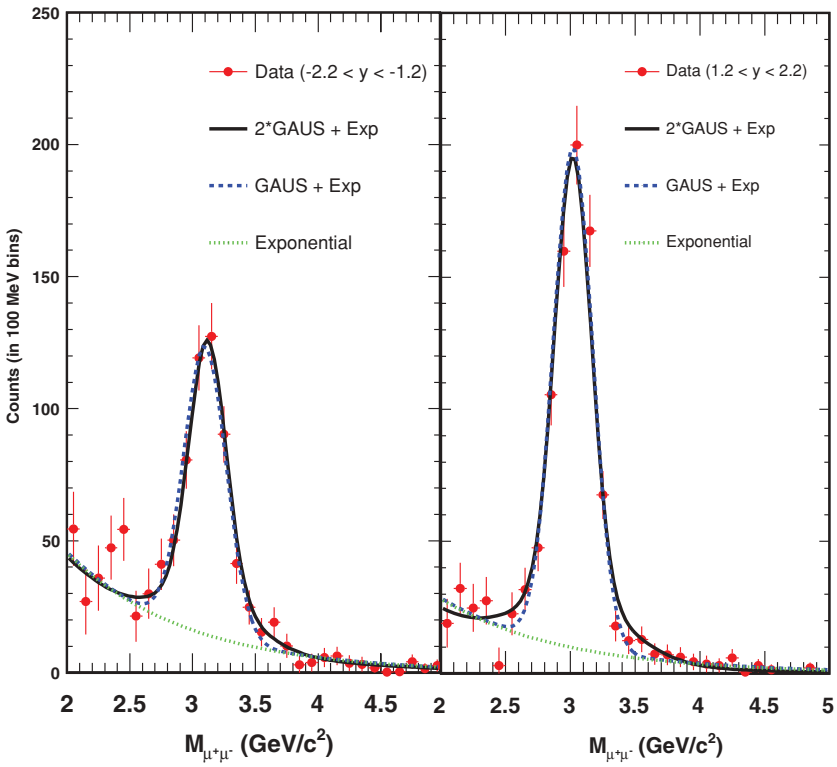

FIG. 2. (Color online) Invariant mass spectra in minimum-bias $d+$Au reactions for (left) $J/\psi \longrightarrow \mu^+\mu^-$ at $-2.2 < y < -1.2$ and (right) $J/\psi \longrightarrow \mu^+\mu^-$ at $1.2 < y < 2.2$, with the functional forms used to extract the number of reconstructed J/ψ mesons.

category, Δp_T and Δy are the p_T and y bin widths, A and ϵ_{rec} are the acceptance and reconstruction efficiency corrections, ϵ_{trig} is the additional J/ψ trigger efficiency, and $\epsilon^{\mathrm{BBC}}_{J/\psi}$ is the BBC efficiency for events containing a J/ψ. All invariant yields as a function of p_T and y including statistical and systematic uncertainties are given in Table II.

The experiment measures the number of J/ψ particles per BBC triggered events, which in $d+\mathrm{Au}$ collisions represent only $88\% \pm 4\%$ of the total inelastic cross section. An additional correction is then applied such that the invariant yield represents 100% of the total inelastic cross section (as done in previous PHENIX $d+\mathrm{Au}$ analyses). The correction factor ratio $\epsilon^{\mathrm{BBC}}_{\mathrm{MB(cent)}}/\epsilon^{\mathrm{BBC}}_{J/\psi}$ depends *a priori* on the centrality bin and the rapidity range of the measured J/ψ particles. The values are given in Table I. The same procedure is applied for $p+p$ collisions, so that the yields are normalized to the $p+p$ total inelastic cross section of 42 mb.

The acceptance and efficiency corrections are determined by using a full GEANT simulation [10] of the detector with realistic resolutions and detector plane efficiencies determined from real data. Compared to the original result [4], this simulation benefits from improvements in the understanding of the detector alignment, resolution, and overall performance. It also includes the improvements added to the reconstruction software and used for the recent $p+p$, $\mathrm{Cu}+\mathrm{Cu}$, and

TABLE III. Sources of systematic uncertainties on the J/ψ invariant yield in $d+\mathrm{Au}$ collisions. Columns 2 (3) are the average values at midrapidity (forward rapidity). When two values are given, the first (second) is for peripheral (central) collisions. Uncertainties of type A (type B) are point-to-point uncorrelated (correlated).

Source	$\lvert y\rvert < 0.35$	$\lvert y\rvert \in [1.2, 2.2]$	Type
signal extraction	6%	<10%	A
acceptance	8%	10%	B
efficiency	6%	8–20%	B
run-by-run variation	5%	8%	B
input y, p_{T} distributions	2%	4%	B
embedding	4%	5%	B

Au + Au analyses [1,2,5]. Although the additional underlying hit occupancies per event are modest in $p+p$ and $d+\mathrm{Au}$ collisions, they are accounted for by embedding the simulated J/ψ mesons in real data events. The observed differences (4–5%) between embedded and nonembedded events are not significant given the statistics of the simulations, and therefore they are included only as a contribution to the systematic uncertainty.

The systematic uncertainties in the J/ψ invariant yield (Table III) are grouped into three categories as in the previous analyses: point-to-point uncorrelated (type A), for which the points can move independently from one another; point-to-point correlated (type B), for which the points can move coherently though not necessarily by the same amount; and global uncertainties (type C), for which all points move by the same multiplicative factor. Statistical and uncorrelated systematic uncertainties (type A) are summed in quadrature and represented as vertical bars. Type B uncertainties are represented with boxes. Type C globally correlated systematic uncertainties are quoted directly on the figures.

Figure 3 shows the invariant J/ψ yield as a function of transverse momentum for $d+\mathrm{Au}$ collisions from this new analysis together with the published invariant yield measured in $p+p$ collisions [2]. From these yields, a $\langle p_{\mathrm{T}}^2\rangle$ is calculated

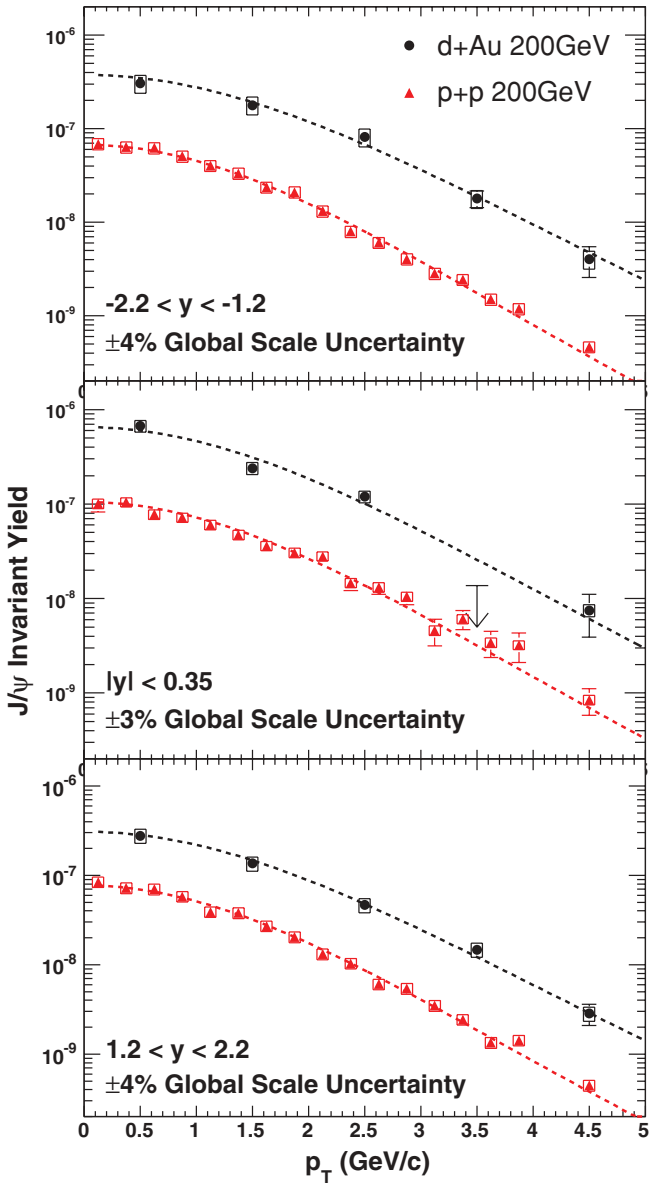

FIG. 3. (Color online) J/ψ invariant yield versus p_{T} in $d+\mathrm{Au}$ collisions and $p+p$ collisions. The three panels are for rapidity selections $-2.2 < y < -1.2$, $|y| < 0.35$, and $1.2 < y < 2.2$ from top to bottom. See text for description of the uncertainties and details of the functional fits.

TABLE IV. $\langle p_{\mathrm{T}}^2\rangle$ calculated from a fit to the data and restricted to the range $0 < p_{\mathrm{T}} < 5$ GeV/c. See text for description of the uncertainties.

Species	Rapidity	$\langle p_{\mathrm{T}}^2\rangle[0,5]$
$d+\mathrm{Au}$	$[-2.2,-1.2]$	$4.3\pm0.3\pm0.4$
$d+\mathrm{Au}$	$[-0.35,0.35]$	$3.9\pm0.3\pm0.3$
$d+\mathrm{Au}$	$[1.2,2.2]$	$4.0\pm0.2\pm0.4$
$p+p$	$[-2.2,-1.2]$	$3.4\pm0.1\pm0.1$
$p+p$	$[-0.35,0.35]$	$4.1\pm0.2\pm0.1$
$p+p$	$[1.2,2.2]$	$3.4\pm0.1\pm0.1$

by using the following generic functional form to fit the data:

$$\frac{d^2N}{p_T dp_T} \sim A[1+(p_{\mathrm{T}}/B)^2]^{-6}. \quad (2)$$

To account for finite p_{T} binning, the fit function is first integrated over each Δp_{T} range and the integral is compared to data in the corresponding bin. The measured $\langle p_{\mathrm{T}}^2\rangle$ values as well as the associated statistical and systematic uncertainties are shown in Table IV.

In previous J/ψ analyses [1,2], it was found that only for the high-statistics $p+p$ data set (where the measurement has good precision out to $p_{\mathrm{T}} \approx 8$ GeV/c) is the functional form of the p_{T} spectrum well constrained. In the Au + Au case,

the functional form is not well constrained and leads to a very large systematic uncertainty on $\langle p_T^2 \rangle$ if integrated from 0 to ∞. The integral was therefore limited to $p_T < 5$ GeV/c, where it is best constrained by the data. The $d + \text{Au}$ data set suffers from the same statistical limitations and the same truncation to $p_T < 5$ GeV/c is applied. Finally, this constraint is also applied to the $p + p$ case to make a direct comparison possible.

Two uncertainties are quoted in Table IV. The first corresponds to the statistical and point-to-point uncorrelated systematic uncertainties (type A) on the measured yields. It is obtained directly from the fit by using the second derivatives of the χ^2 surface at the minimum. The second corresponds to the point-to-point correlated systematic uncertainties (type B). The contribution from type B uncertainty is estimated independently by coherently moving the measured points within the one-standard-deviation limit given by these uncertainties, allowing them to be either correlated or anticorrelated, and then redoing the fit in all cases. The largest difference observed in the values obtained by the fit is used as an upper limit to the one-standard-deviation point-to-point correlated uncertainties on $\langle p_T^2 \rangle$.

In our previous publication [4] values for the fully integrated $\langle p_T^2 \rangle$ in $p + p$ and $d + \text{Au}$ collisions are quoted. However, a significant systematic uncertainty originating from not knowing the functional form to best describe the data was found that was not included in the uncertainty quoted in the paper. In addition, the new analysis revealed a bias in the previous result that increased the signal, particularly in the lowest p_T bin. This bias is now corrected by using the mixed-event background-subtraction technique described here together with the modified log-likelihood fit over a more appropriate range, corresponding to the region where the physical background can accurately be described by a single exponential function. Finally, no separate treatment of the point-to-point correlated systematic uncertainties was performed at that time, because it was assumed that it would move all points in the same direction (positive correlation) and thus have no impact on the measured $\langle p_T^2 \rangle$.

The data, within uncertainties, include the possibility of a modest broadening of the transverse momentum distribution relative to $p + p$ collisions. This is often attributed to initial- and final-state multiple scattering, sometimes referred to as the "Cronin effect." However, in calculating $\Delta\langle p_T^2 \rangle = \langle p_T^2 \rangle_{d\text{Au}} - \langle p_T^2 \rangle_{pp}$ one finds that this effect needs reduced uncertainties from future larger data sets to make any firm conclusions.

Figure 4 shows the J/ψ invariant yield, integrated over all p_T, as a function of rapidity for $d + \text{Au}$ collisions. Shown are the results of the new analysis presented in this paper, as well as the previously published results [4] using the same data set. Overall the agreement of the two analysis results is good. The two sets of points differ in the reconstruction software, analysis cuts, and signal-extraction technique. Thus many of the systematic uncertainties are different, and even the statistical uncertainties are not identical owing to the different analysis cuts and the use of event mixing to estimate the combinatorial background in the new analysis, as opposed to the like-sign mass distribution used in Ref. [4].

Figure 5 shows the J/ψ invariant yield for $p + p$ collisions, from both the published high-statistics result from Run-5 [2], as well as the lower statistics result from Run-3 as published in Ref. [4]. In both cases the points are in good agreement within the systematic uncertainty bands. A new analysis of the Run-3 $p + p$ lower statistics data set was also performed by using the same technique and analysis cuts as for $d + \text{Au}$ collisions. It also shows good agreement with these two sets of measurements, albeit with larger statistical uncertainties.

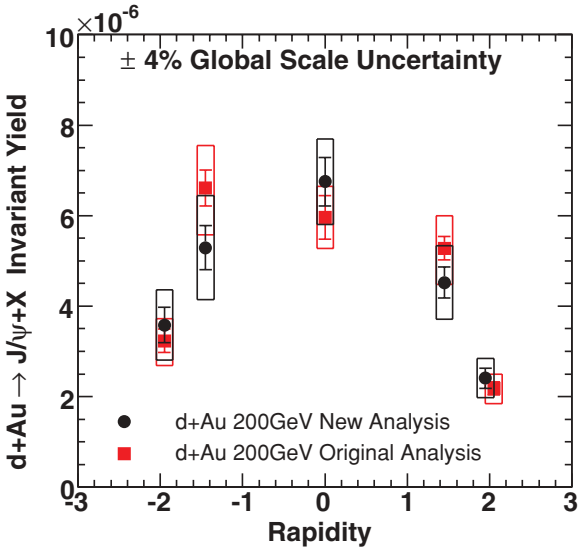

FIG. 4. (Color online) J/ψ invariant yield as a function of rapidity for $d + \text{Au}$ collisions. Shown are the new analysis results from this paper, in addition to the originally published results [4] using the same data. The global systematic uncertainty quoted is for the new analysis.

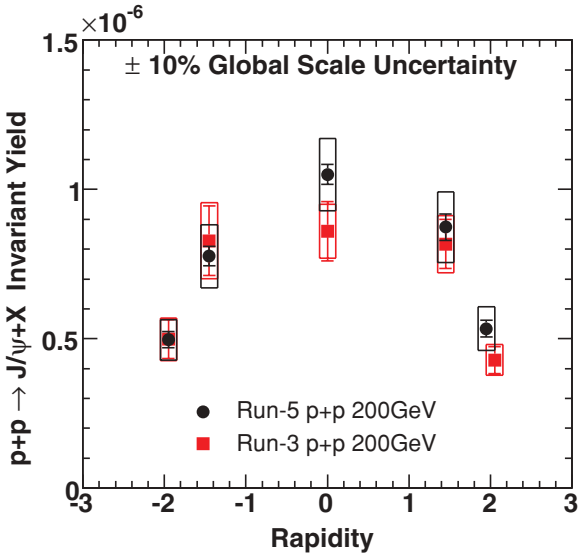

FIG. 5. (Color online) J/ψ invariant yield as a function of rapidity for $p + p$ collisions. Shown are the high statistics results from the 2005 $p + p$ PHENIX data-taking period [2] and the originally published results [4] using the 2003 $p + p$ data set. The global systematic uncertainty quoted is for the new analysis.

In Figs. 4 and 5, the highest rapidity point is not located exactly at the same rapidity position between the original and the new analysis. This is because the positive-rapidity muon arm has a slightly larger rapidity coverage than the negative-rapidity arm. This property was used in the 2003 analysis to include additional J/ψ mesons at forward rapidity to probe a slightly lower region of x. It was found, however, that there were very few counts in this region and that the asymmetric rapidity range created additional difficulties when comparing the results measured at forward and backward rapidity (in case of symmetric collisions) and when comparing the results obtained in $p+p$ collisions to Cu + Cu or Au + Au collisions, for which this extra rapidity coverage was not available (because of high-occupancy limitations at forward rapidity). As a consequence, it was decided for the later analyses to forgo the extra few J/ψ counts at very forward rapidity and use the same-width rapidity bins at both positive and negative rapidity.

V. NUCLEAR MODIFICATION FACTOR

The J/ψ nuclear modification factor in a given centrality and rapidity bin is

$$R_{d\mathrm{Au}} = \frac{1}{\langle N_{\mathrm{coll}} \rangle} \frac{dN_{J/\psi}^{d+\mathrm{Au}}/dy}{dN_{J/\psi}^{p+p}/dy}, \tag{3}$$

where $dN_{J/\psi}^{d\mathrm{Au}}/dy$ is the J/ψ invariant yield measured in $d+$ Au collisions, $dN_{J/\psi}^{pp}/dy$ is the J/ψ invariant yield measured in $p+p$ collisions for the same rapidity bin, and $\langle N_{\mathrm{coll}} \rangle$ is the average number of binary collisions in the centrality bin under consideration, as listed in Table I. All $R_{d\mathrm{Au}}$ values as a function of p_T, y, and centrality including statistical and systematic uncertainties are given in Table II.

Figure 6 shows the nuclear modification factor $R_{d\mathrm{Au}}$ calculated by using the $d+$Au new analysis presented in this paper for the numerator and the 2005 $p+p$ data for the denominator. In contrast to the previous analysis [4], where the $p+p$ results were symmetrized around $y=0$ before calculating $R_{d\mathrm{Au}}$ to compensate for lower J/ψ statistics in the 2003 $p+p$ data set, in this case the $R_{d\mathrm{Au}}$ values are calculated independently at each rapidity.

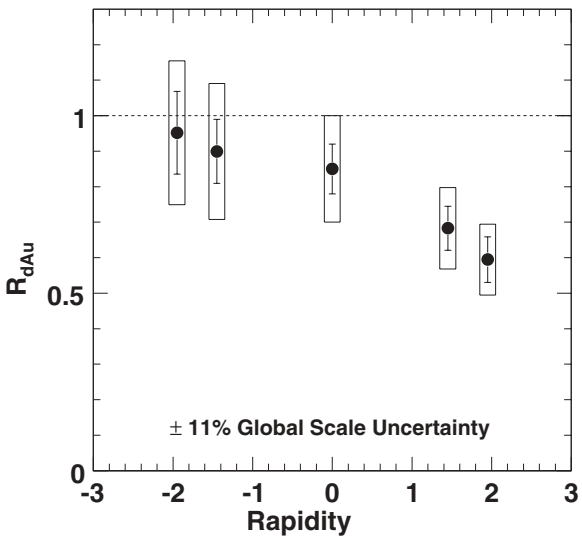

FIG. 6. J/ψ nuclear modification factor $R_{d\mathrm{Au}}$ as a function of rapidity.

The understanding of the detector performance in terms of alignment, resolution, and efficiency has significantly improved between this analysis and previously published PHENIX $d+$Au results [4]. This resulted in changes in the reconstruction software, analysis cuts, signal-extraction technique, and handling of both the physical and combinatorial background in the dilepton invariant mass distribution. Simultaneously, the systematic uncertainties associated with the measurement have also been reevaluated in a way consistent with what was learned for the $p+p$, Cu + Cu, and Au + Au analyses. The new uncertainties are in general larger, although some of them cancel with their $p+p$ counterpart when forming $R_{d\mathrm{Au}}$. This approximately counterbalances the reduction of the statistical uncertainty achieved by using the 2005 $p+p$ data set as a reference. Additionally, the J/ψ production cross sections in $p+p$ collisions measured in 2005 [2] are compatible within uncertainties but higher than the values used in Ref. [4] (based on the 2003 $p+p$ data set) by about 13%. As a consequence, the new nuclear modification factors are systematically lower than the ones previously published by about 5–20% for most points, depending on the p_{T}, y, or centrality bin considered.

Within uncertainties, the nuclear modification factors are consistent with $R_{d\mathrm{Au}} = 1.0$ at negative and midrapidities and are significantly lower than 1.0 at forward rapidity only, that is, in the deuteron-going direction. This trend is similar to that shown in Fig. 1 of Ref. [4], although the new values are systematically smaller for all rapidity bins.

Figure 7 shows the J/ψ nuclear modification factor in $d+$ Au collisions as a function of the number of binary collisions for three rapidity ranges and four centrality classes. Only at forward rapidity is there statistically significant suppression.

VI. DISCUSSION

As stated in the Introduction, the $d+$ Au data are interesting both to fundamentally understand issues of quarkonia and cold nuclear matter and also to separate these effects from hot nuclear matter effects in heavy-ion collisions. To address both issues, we compare the experimental data with two different models including both modification of the initial parton distribution functions (PDFs) and a free parameter to account for the breakup of correlated $c\bar{c}$ pairs that might have otherwise formed J/ψ mesons. Note that, often in the literature, this breakup process in cold nuclear matter is referred to as an absorption cross section of the J/ψ particles on the nucleons in the nucleus. Here we avoid this nomenclature, both because the object that is "absorbed" is generally not a fully formed J/ψ but rather a $c\bar{c}$ pair, and because the actual process is more a breakup of this pair, rather than the absorption of it.

Shown in Fig. 8 is the nuclear modification factor $R_{d\mathrm{Au}}$ as a function of rapidity in comparison to theoretical calculations [3] that include either EKS [12] or NDSG [13] shadowing

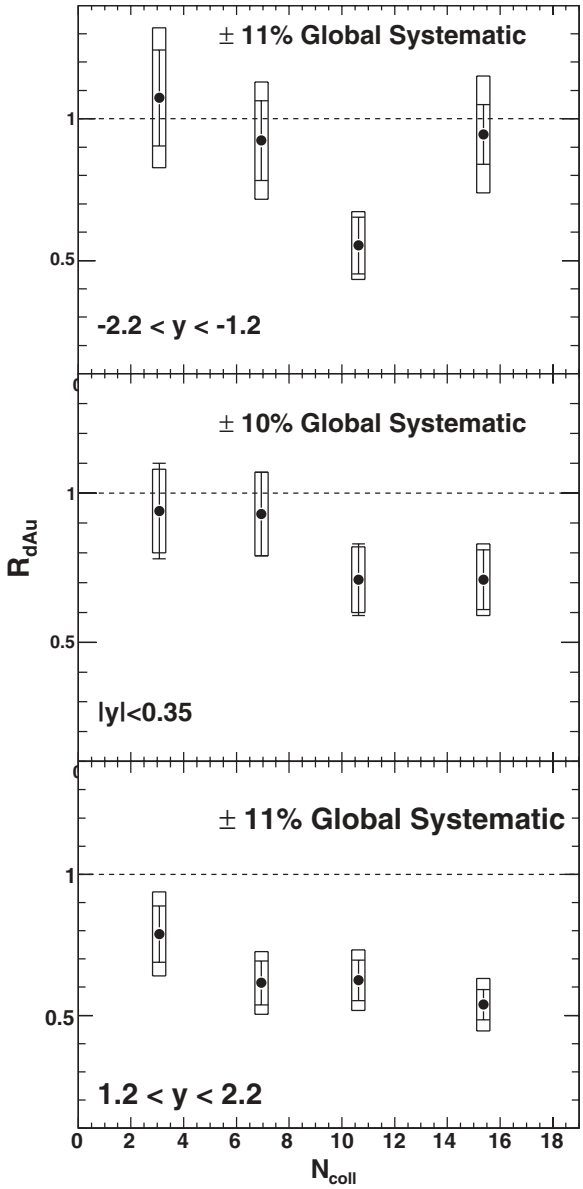

FIG. 7. J/ψ nuclear modification factor $R_{d\mathrm{Au}}$ as a function of N_{coll} for three rapidity ranges.

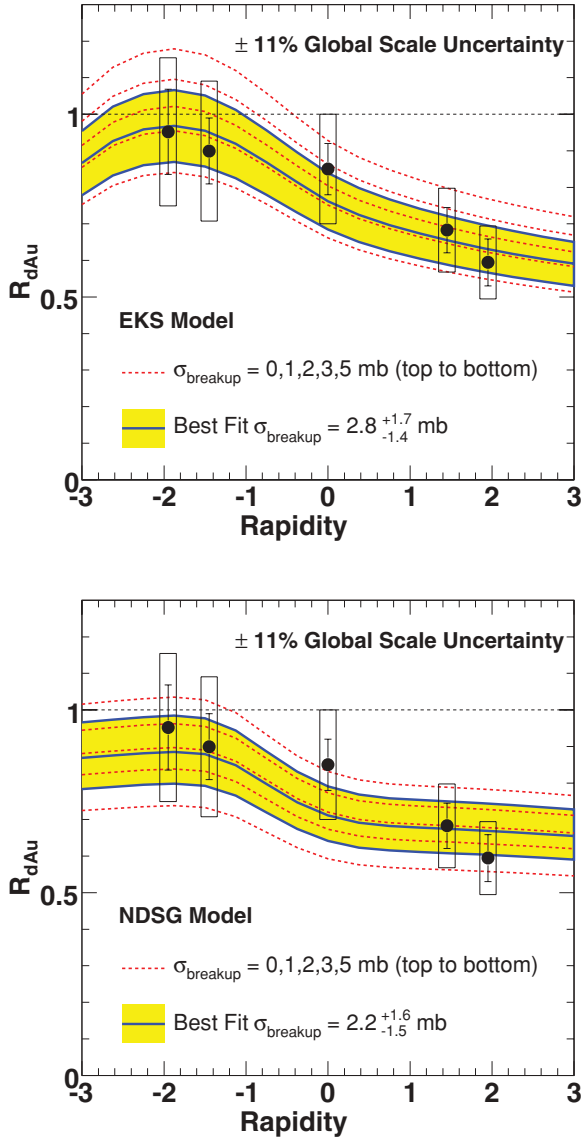

FIG. 8. (Color online) $R_{d\mathrm{Au}}$ data compared to various theoretical curves for different $\sigma_{\mathrm{breakup}}$ values. Also shown as a band are the range of $\sigma_{\mathrm{breakup}}$ values found to be consistent with the data within one standard deviation. The top panel is a comparison for EKS shadowing [12]; the bottom panel is for NDSG shadowing [13].

models for the nuclear PDFs. In each case an additional suppression associated with a $\sigma_{\mathrm{breakup}}$ is also included. Note that there is no *ab initio* calculation of this cross section, and although one might expect a similar value to results at lower energy [14], it need not be identical.

Taking full account of the statistical and systematic uncertainties on the experimental data, we can determine the breakup cross section under certain assumptions. We have followed the statistical procedure detailed in Ref. [15]. If we assume that the EKS-modified nuclear PDFs are exactly correct, and that the only additional suppression is accounted for by $\sigma_{\mathrm{breakup}}$, then the data constrain $\sigma_{\mathrm{breakup}} = 2.8^{+1.7}_{-1.4}$ mb with the uncertainties as one standard deviation. Similarly, if we assume the NDSG-modified nuclear PDFs, then we obtain $\sigma_{\mathrm{breakup}} = 2.2^{+1.6}_{-1.5}$ mb. These breakup cross-section values are consistent (within the large uncertainties) with the 4.2 ± 0.5 mb value determined at lower energies at the CERN-SPS [14]. The extracted breakup cross section at lower energies are found by assuming no contribution from the modification of nuclear PDFs. At the lower energies, J/ψ production is sensitive to higher x partons in the antishadowing regime where the modifications are expected to be smaller and in the opposite direction [16].

The modified nuclear PDFs from EKS and NDSG are constrained from other experimental measurements such as deep inelastic scattering from various nuclear targets and the resulting $F_2(A)$ structure functions. A geometric parametrization of these PDFs based on the path of the parton through the nucleus is described in Refs. [17] and [3]. One can test this geometric dependence by comparison with the $d + \mathrm{Au}$ nuclear modification factors as a function of N_{coll}. Using this

TABLE V. Most probable values and one standard deviations of σ_{breakup} determined by assuming two different shadowing models, from a fit to minimum-bias $R_{d\text{Au}}$ points as a function of rapidity (Fig. 8), and fits to $R_{d\text{Au}}$ as a function of N_{coll} in three separate rapidity bins (Fig. 9).

Fit range in y	EKS (mb)	NDSG (mb)
All	$2.8^{+1.7}_{-1.4}$	$2.2^{+1.6}_{-1.5}$
$[-2.2, -1.2]$	$5.2^{+1.6}_{-1.8}$	$3.3^{+2.0}_{-1.7}$
$[-0.35, 0.35]$	$2.4^{+1.9}_{-1.6}$	$1.0^{+1.8}_{-1.7}$
$[1.2, 2.2]$	$3.2^{+1.6}_{-1.5}$	$3.3^{+1.5}_{-1.5}$

geometric dependence, we can calculate the most probable σ_{breakup} values independently in three rapidity ranges (see Table V). The corresponding nuclear modification values and their one-standard-deviation bands are shown as a function of N_{coll} in Fig. 9. The two calculations with EKS and NDSG nuclear PDFs yield almost identical bands since the same geometric dependence is used in both cases. However, each band represents a different balance of modification owing to the nuclear PDF and the breakup cross section.

For both the EKS and the NDSG PDFs, the values of σ_{breakup} extracted from the overall rapidity dependence of $R_{d\text{Au}}$ and from the N_{coll} dependence of $R_{d\text{Au}}$ within the different rapidity ranges are consistent within the large systematic uncertainties. It should be noted that though the confidence level for the best fit is poor at backward rapidity (as can be seen in Fig. 9), there is still a well-defined maximum in the likelihood function for σ_{breakup}. A future higher precision $R_{d\text{Au}}$ measurement as a function of centrality will be crucial to constrain the exact geometric dependence.

One can also utilize this model to do a consistent calculation of the contribution from cold nuclear matter effects that should be present in Cu + Cu and Au + Au collisions. These contributions, obtained using the best-fit value of σ_{breakup} and their one-standard-deviation values extracted from the data in Fig. 8 for each of the two shadowing models, are shown in Figs. 10 and 11. In the Cu + Cu case, J/ψ production is not suppressed beyond cold nuclear matter effects at midrapidity or at forward rapidity, within the limits of the large error bands, and the midrapidity data in the Au + Au case are similarly inconclusive. However, there is a significant suppression in the data at forward rapidity, beyond the uncertainties in both the data and the projection. It should be noted that the uncertainty bands at forward rapidity and midrapidity are entirely correlated, as they reflect only the uncertainty in σ_{breakup}. There is no systematic uncertainty included for the choice of modified nuclear PDF model, which is the only way to change the relative suppression between forward rapidity and midrapidity within the context of this calculation. The more data-driven calculation described later in this section, however, is performed independently at different rapidities and does not suffer the same stipulation.

It should also be noted that the theoretical calculations yield R_{AA} as a continuous function of the number of participants, whereas the data points are at discrete values

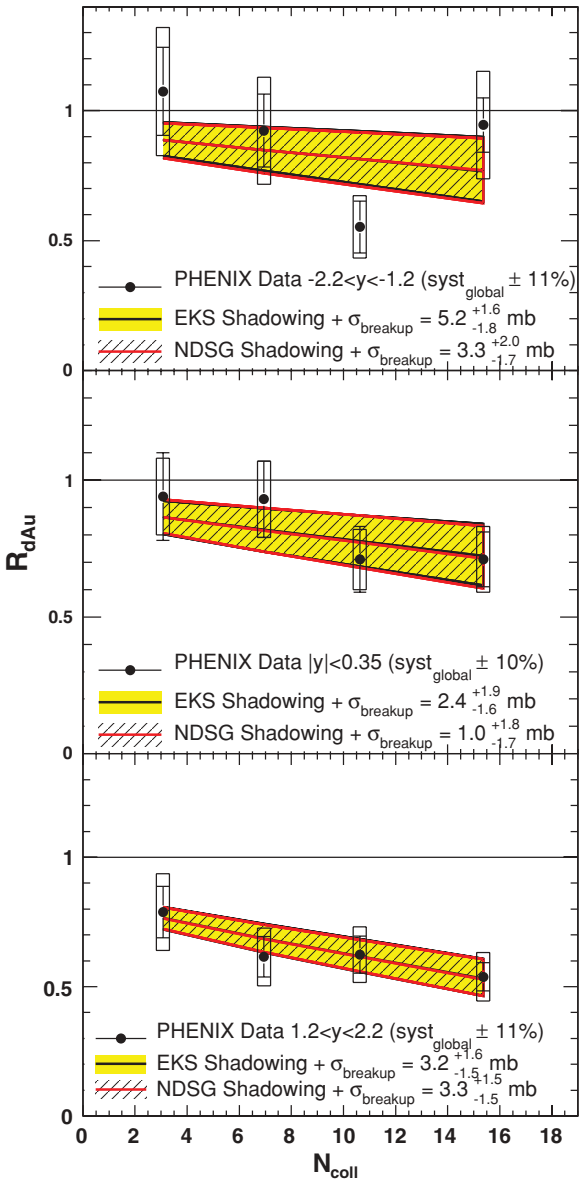

FIG. 9. (Color online) $R_{d\text{Au}}$ data as a function of N_{coll} for three different rapidity ranges. Overlayed are theoretical curves representing the best-fit σ_{breakup} values as determined in each rapidity range separately, utilizing EKS and NDSG nuclear PDFs and a simple geometric dependence. Also shown as bands are the range of σ_{breakup} values found to be consistent with the data within one standard deviation.

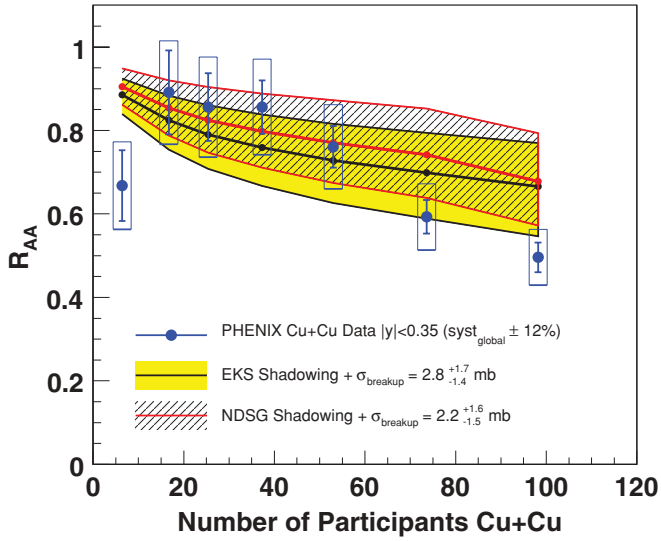
representing a convolution of the modification factor with the N_{part} distribution within a particular centrality category. A Glauber simulation combined with a Monte Carlo simulation of the PHENIX experimental trigger and centrality selection is utilized to convert the continuous theory predictions into discrete predictions in the simulated PHENIX centrality categories. Thus, the results shown in the figures are in fact predictions for the matched event selection categories of the experimental data points.

To explore the cold nuclear matter constraints further, an alternative data-driven method proposed in Ref. [18] is



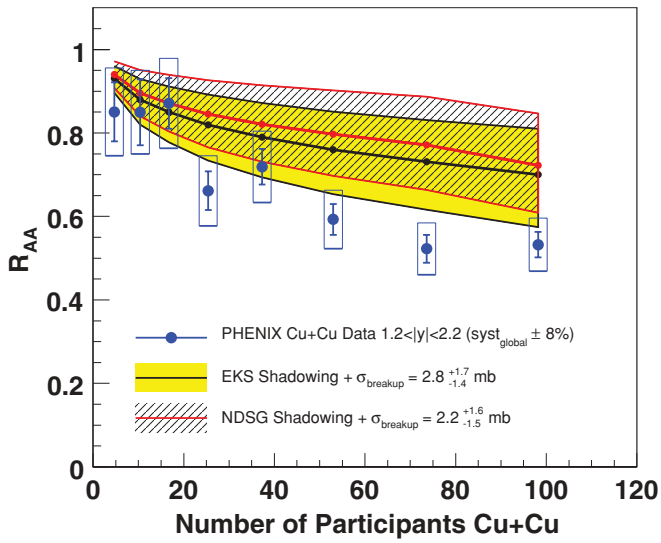


FIG. 10. (Color online) R_{AA} for Cu + Cu [5] collisions compared to a band of theoretical curves for the σ_{breakup} values found to be consistent with the d + Au data as shown in Fig. 8. The top figure includes both EKS shadowing [12] and NDSG shadowing [13] at midrapidity. The bottom figure is the same at forward rapidity.

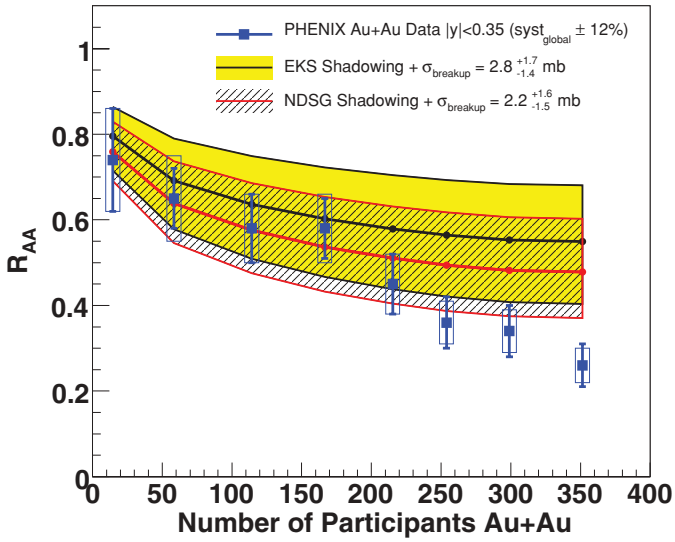

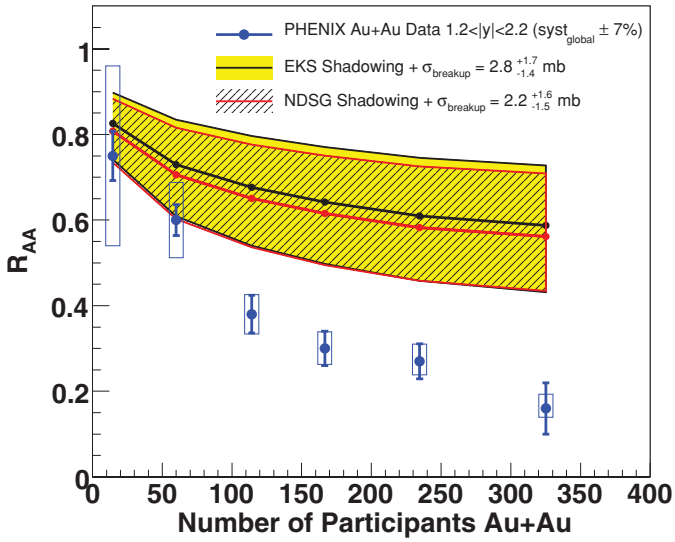

FIG. 11. (Color online) R_{AA} for Au + Au [1] collisions compared to a band of theoretical curves for the σ_{breakup} values found to be consistent with the d + Au data as shown in Fig. 8. The top figure includes both EKS shadowing [12] and NDSG shadowing [13] at midrapidity. The bottom figure is the same at forward rapidity.

used. In this approach it is assumed that there is a single modification factor parametrizing all cold nuclear matter effects that is a simple function of the radial position in the nucleus. This computation has the advantage of our not having to assume a specific shadowing scheme and a specific breakup cross section, but instead relies only on the measured impact parameter dependence. The cold nuclear matter effects suffered by a J/ψ in a Au + Au collision at a given rapidity are assumed to be the product of the modifications measured in d + Au collisions at the same rapidity and the modifications measured at the opposite rapidity (or, equivalently, in a Au + d collision). This assumption holds for the two effects considered so far, namely, shadowing and subsequent breakup. In the computation it is also assumed that the same parton distributions are sampled by the J/ψ particles observed in the (wide) rapidity range in Au + Au and d + Au collisions. Note that since this model implicitly includes any possible modified nuclear PDFs, the modification factors may have an x dependence that is accounted for by considering the backward, mid, and forward rapidity d + Au data. The different rapidity regions are sensitive to the initial-state partons in the gold nucleus in three broad ranges of x, corresponding to $x \approx$ 0.002–0.01, 0.01–0.05, and 0.05–0.2, as determined from PYTHIA.

A Glauber Monte Carlo simulation and a simulation of the BBC detector used for centrality determination and triggering are done. The resulting four centrality categories (0–20%, 20–40%, 40–60%, and 60–88%) in d + Au collisions are characterized by a distribution in the number of binary collisions, as shown in the top panel of Fig. 12. In addition,

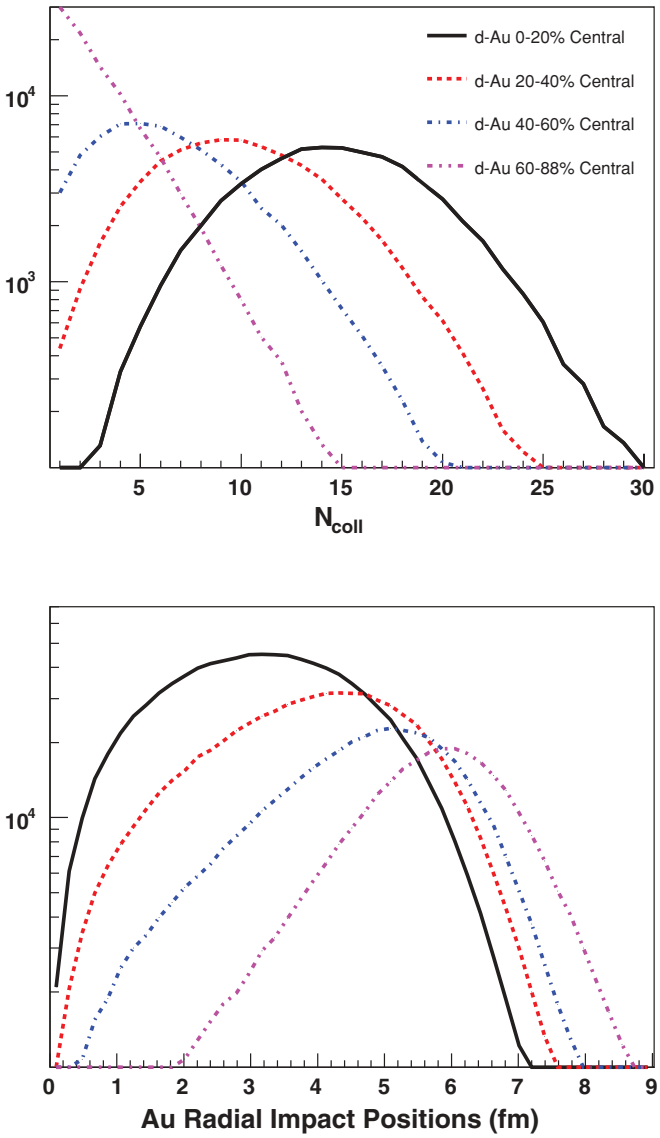

FIG. 12. (Color online) Results from a Glauber model Monte Carlo simulation of the $d + \mathrm{Au}$ centrality selection and triggering based on the PHENIX BBC. The top panel shows the distribution of the number of binary collisions for events in each of the four centrality classes 0–20%, 20–40%, 40–60%, and 60–88%. The distribution for radial impact points in the gold nucleus of binary collisions is shown in the lower panel.

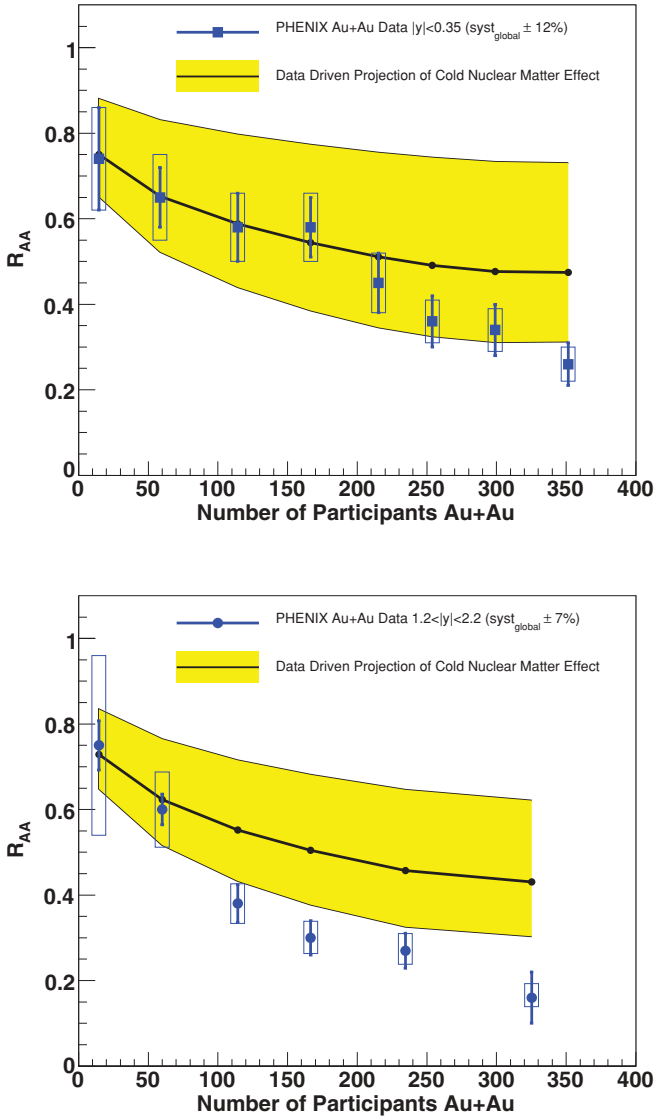

FIG. 13. (Color online) Predictions of the data-driven method [18] constrained by $R_{d\mathrm{Au}}$ as a function of collision centrality for the $\mathrm{Au} + \mathrm{Au}$ R_{AA} for midrapidity (top) and at forward rapidity (bottom).

the distribution of radial positions r in the Au nucleus of binary collisions is calculated and shown in the bottom panel of Fig. 12.

The procedure is to use the forward, mid, and backward rapidity centrality-dependent $R_{d\mathrm{Au}}$ values to constrain the modification factor $\Re(r)$ for three broad regions of initial parton x ($\Re_{\mathrm{low}}$, $\Re_{\mathrm{mid}}$, and $\Re_{\mathrm{high}}$, respectively). Then one can use these parametrizations to project the cold nuclear matter effect in the $\mathrm{Au} + \mathrm{Au}$ case. The current $d + \mathrm{Au}$ data are insufficient to constrain the functional form of $\Re(r)$. As a simplifying case, $\Re(r)$ is assumed to be linear in r and to be fixed at $\Re(r \geqslant 8\,\mathrm{fm}) = 1.0$ at the edge of the gold nucleus. Thus, the only free parameter is the slope (or, equivalently, the magnitude of the modification factor at $r = 0$). Other functions were tried and essentially differ by their extrapolation to lower and higher radial positions, because the data are not precise enough to constrain the shape. This has a particularly strong impact on the most peripheral collisions for which our assumption that $\Re(r \geqslant 8\,\mathrm{fm}) = 1.0$ adds a significant constraint to the shape.

For all possible slope parameters, consistency with the experimental data is checked by using the procedure detailed in Ref. [15], which utilizes the full statistical and systematic uncertainties. The range of parameters within one standard deviation of the uncertainties is determined separately for backward, mid, and forward rapidity. Using this range of parameters, we can project the cold nuclear matter suppression expected in $\mathrm{Au} + \mathrm{Au}$ collisions as a function of collision centrality and for midrapidity and forward rapidity. Note that the forward rapidity $\mathrm{Au} + \mathrm{Au}$ J/ψ production is sensitive to the low-x partons in one gold nucleus and the high-x

partons in the other gold nucleus. Thus, in the Monte Carlo simulation, for every binary collision at r_1 and r_2 (the radii with respect to the center of each nucleus) the expected modification is $\Re_{\rm low}(r_1) \times \Re_{\rm high}(r_2)$. The midrapidity Au + Au J/ψ production is predominantly sensitive to the mid-x partons from both gold nuclei and therefore the expected modification is $\Re_{\rm mid}(r_1) \times \Re_{\rm mid}(r_2)$. The total modification expected is calculated by taking the average over all correlated r_1 and r_2 positions for binary collisions within overall Au + Au collisions in each Au + Au centrality class.

The results of these calculations matched to the experimentally measured Au + Au centrality bins are shown in Fig. 13. It is notable that the midrapidity cold nuclear matter extrapolation agrees within the uncertainty of the experimental data at midrapidity. Thus, it is not possible within the current constraints to determine the potential extent of hot nuclear matter effects. This conclusion is qualitatively similar to that reached from the previous model calculations as shown in Fig. 11. However, at forward rapidity, this method projects a somewhat larger range of possible cold nuclear matter effects than the previous models.

Neither the predictions of cold nuclear matter effects in heavy-ion collisions based on fitting of the d + Au data with theoretical curves (Figs. 10 and 11) nor those obtained directly from the d + Au data points (Fig. 13) are well-enough constrained to permit quantitative conclusions about additional hot nuclear matter effects.

VII. CONCLUSIONS

A new analysis of J/ψ production in d + Au collisions at $\sqrt{s_{NN}} = 200$ GeV has been presented using the PHENIX 2003 d + Au data set. Cuts and analysis techniques that are consistent with the previously published results for $p + p$, Cu + Cu, and Au + Au collisions at the same energy [1,2,5] are used. The new analysis also benefits from the significantly larger $p + p$ data set from Run-5.

A statistical comparison of these new results to theoretical calculations has been performed with a detailed handling of the experimental uncertainties to estimate a J/ψ (or precursor) breakup cross section in cold nuclear matter on top of models for the modifications of the parton distribution functions in the nucleus. Using EKS (NDSG) shadowing, we obtain a breakup cross section of $2.8^{+1.7}_{-1.4}$ ($2.2^{+1.6}_{-1.5}$) mb. These breakup cross-section values are consistent within large uncertainties with the 4.2 ± 0.5 mb determined at lower energies at the CERN-SPS [14]. The measured values are then used to predict the expected cold nuclear matter effects on J/ψ production in Cu + Cu and Au + Au collisions, and these are compared to the measured nuclear modification factors for those systems. These predictions are found to be similar to those from a less model-dependent and more data-driven method based on the variation of the nuclear modification factor measured in d + Au collisions as a function of both rapidity and centrality [18]. It is notable that the latter method yields a somewhat larger possible suppression in the forward rapidity case. In all cases the large error bars associated with the extrapolation prevent us from making firm quantitative statements on any additional J/ψ suppression in Au + Au collisions beyond that expected from cold nuclear matter effects. A d + Au data set with much improved statistical precision is needed to both reduce the statistical uncertainties and permit better control over the systematic uncertainties.

ACKNOWLEDGMENTS

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions. We also thank Ramona Vogt for useful discussions and for the calculations used to set the level of the breakup cross sections. FIG. 1. (Color online) R_{dAu} data compared to various theoretical curves for different $\sigma_{breakup}$ values. Also, shown as a band are the range of $\sigma_{breakup}$ found to be consistent with the data within one standard deviation. The top panel is a comparison for EKS shadowing [1], while the bottom panel is for NDSG shadowing [2].

distribution functions (PDFs) combined with a nuclear breakup cross section ($\sigma_{breakup}$). Under the assumption that a given modified nuclear PDF is correct, we put constraints on the $\sigma_{breakup}$ values as presented in the original paper in Table V,

TABLE I. Most probable values and one standard deviations of $\sigma_{breakup}$ assuming two different shadowing models, from a fit to minimum bias R_{dAu} points as a function of rapidity (Fig. 1), and fits to R_{dAu} as a function of N_{coll} in three separate rapidity bins (Fig. 2).

Fit range in y	EKS (mb)	NDSG (mb)
All	$2.8^{+2.3}_{-2.1}$	$2.6^{+2.2}_{-2.6}$
$[-2.2, -1.2]$	$5.2^{+2.4}_{-2.8}$	$3.3^{+2.9}_{-2.7}$
$[-0.35, 0.35]$	$2.3^{+3.6}_{-1.9}$	$0.8^{+3.6}_{-0.8}$
$[1.2, 2.2]$	$3.4^{+2.0}_{-2.5}$	$3.5^{+2.0}_{-2.7}$

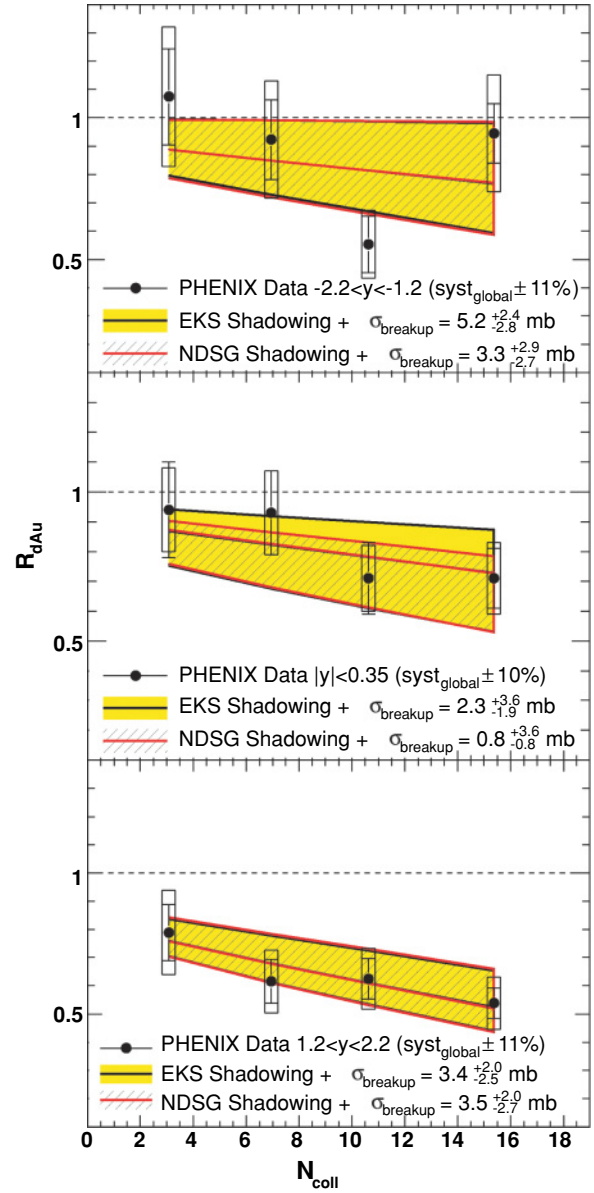

FIG. 2. (Color online) R_{dAu} data as a function of N_{coll} for three different rapidity ranges. Overlayed are theoretical curves representing the best fit $\sigma_{breakup}$ values as determined in each rapidity range separately, utilizing EKS and NDSG nuclear PDFs and a simple geometric dependence. Also, shown as bands are the range of $\sigma_{breakup}$ found to be consistent with the data within one standard deviation.

Sec. VI. In the code that calculated these constrained $\sigma_{breakup}$ values we discovered a mistake, which we now correct. Table I shows the new results, for which all of the most probable $\sigma_{breakup}$ values differ by less than 0.4 mb from those originally presented. However, the one standard deviation uncertainties (that include contributions from both the statistical and systematic uncertainties on the experimental data points) are approximately 30–60% larger than originally reported.

Thus, the one standard deviation uncertainty bands on $\sigma_{breakup}$ in Figs. 8–11 of the original paper need updating with the corrected constraints. Figures 1–4 here show the

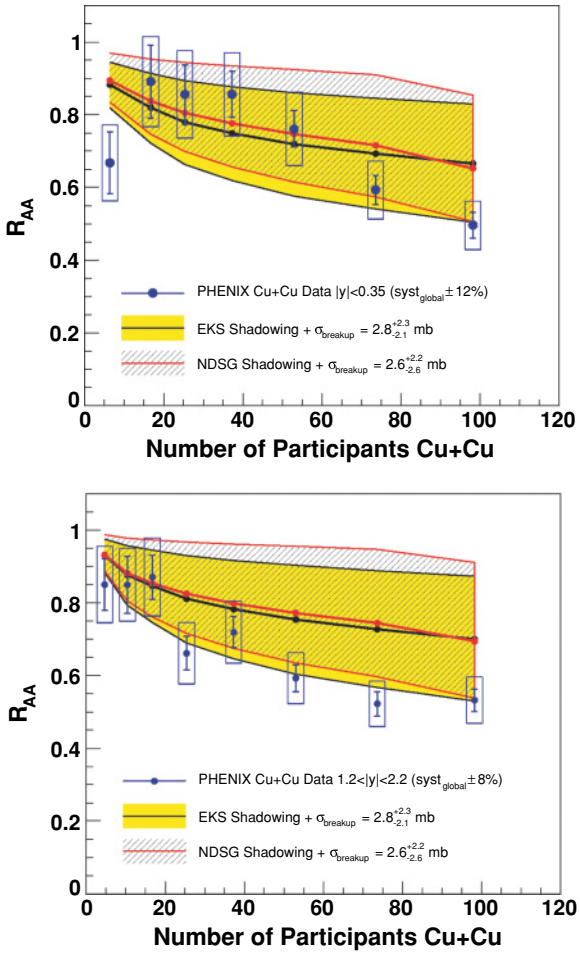

FIG. 3. (Color online) R_{AA} for Cu + Cu [3] collisions compared to a band of theoretical curves for the σ_{breakup} values found to be consistent with the d + Au data as shown in Fig. 1. The top figure includes both EKS shadowing [1] and NDSG shadowing [2] at midrapidity. The bottom figure is the same at forward rapidity.

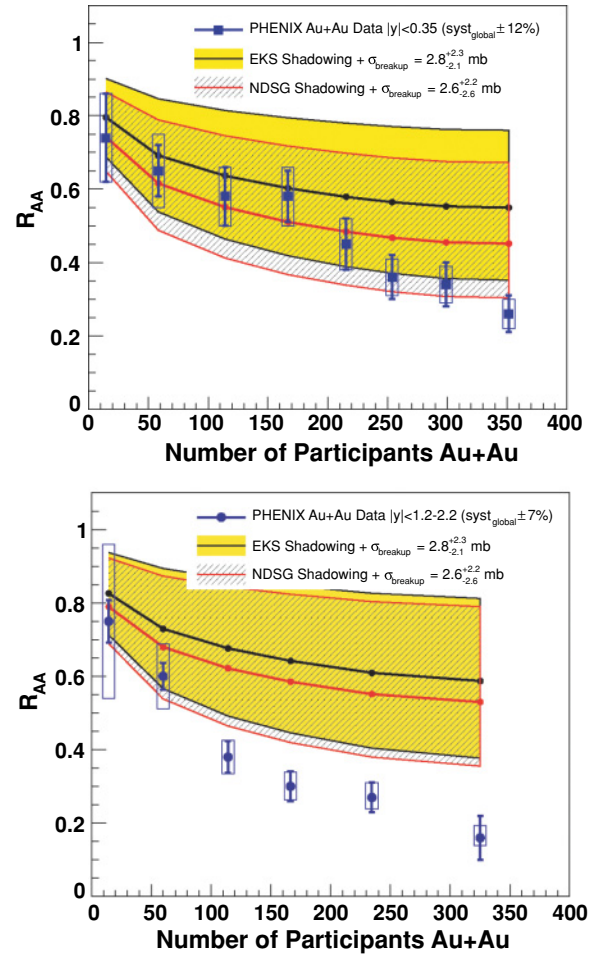

FIG. 4. (Color online) R_{AA} for Au + Au [4] collisions compared to a band of theoretical curves for the σ_{breakup} values found to be consistent with the d + Au data as shown in Fig. 1. The top figure includes both EKS shadowing [1] and NDSG shadowing [2] at midrapidity. The bottom figure is the same at forward rapidity.

corrected constraints. Although the uncertainties are significantly larger with these corrected σ_{breakup} values, there is no qualitative change in the physics conclusions to be drawn from comparisons between these theoretical models (and their extrapolation) and the Au + Au and Cu + Cu measurements. Stronger conclusions can only come from future higher statistics data for d + Au collisions. Note that no correction is needed for results from the data-driven method in Fig. 13 of the original paper.

Abstract. Two-proton and two-deuteron correlations have been studied in the target fragmentation region of central Pb+Pb collisions at 158 A GeV. Protons and deuterons were measured with the Plastic Ball spectrometer of the WA98 experiment at the CERN SPS. The results of one-dimensional and multi-dimensional analyses using both the Bertsch-Pratt and Yano-Koonin-Podgoretsky parameterizations of the two-particle correlation functions are presented. The proton source exhibits a volume emission, while the deuteron source, with small outward radius, appears opaque. Both proton and deuteron sources have cross-terms R_{ol}^2 and longitudinal velocities β consistent with zero, indicat-

ing a boost-invariant expansion. The invariant radius parameter R follows an approximate $A/\sqrt{m}$ scaling while the longitudinal and transverse radii, R_L and R_T, scale approximately as $A/\sqrt{m_T}$ with $A \approx 3$ fm GeV$^{1/2}$ in both cases.

PACS. 25.75. Gz

1 Introduction

In this paper we report on an analysis of quantum-statistical and final state induced correlations [1] of proton and deuteron pairs emitted from 158 A GeV central Pb+Pb collisions. The study of these two particle species in the same system is of special interest as one would expect that deuterons, due to their loose structure and small binding energy, will survive only in the late, low density environment when scatterings are rare. The generally accepted mechanism of deuteron production is by coalescence of a proton and neutron [2,3,4] at the time of freeze-out. The deuteron measurement thus provides an unique means to measure the geometry of the source in the late time interval of the expansion. Experimental results on Fermi-Dirac correlations for protons are not as abundant as those on Bose-Einstein correlations for mesons, and are very scarce for deuteron correlations. A remarkable feature of the existing proton and deuteron correlation data in hadron-nucleus and nucleus-nucleus collisions, spanning over four orders of magnitude of incident energy from 0.02 to 450 A GeV is the small variation of the extracted source radius parameter [5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21].

2 Experimental setup

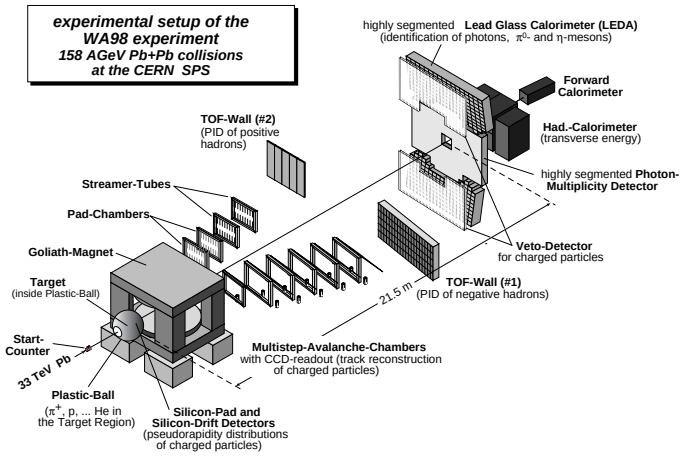

Fig. 1. Experimental setup of the WA98 experiment for the 1996 run.

The CERN SPS experiment WA98 (for details see [22] and references therein) is a general purpose apparatus that consists of large acceptance photon and hadron spectrometers, detectors for charged particle and photon multiplicity measurements, and calorimeters for transverse and forward energy measurements. The layout of the WA98 experimental setup for the 1996 SPS run period is shown in Fig. 1. The results presented in this report were obtained from an analysis of data taken in 1996 with the 158 A GeV ^{208}Pb beam on a 239 mg/cm^2 ^{208}Pb target and made use of the Midrapidity Calorimeter(MIRAC) [23], the Zero Degree Calorimeter(ZDC) [24], and the Plastic Ball spectrometer [25].

The ZDC registers energy emitted along the beam direction in the 3° forward cone. The MIRAC measures the total transverse energy in the pseudorapidity region of $3.5 \leq \eta \leq 5.5$. It is a sampling calorimeter that consists of a lead-scintillator electromagnetic section, followed by an iron-scintillator hadronic section. MIRAC plays the central role in the WA98 minimum bias trigger where the measured transverse energy E_T is required to be above a minimum threshold. MIRAC is used to classify the centrality of each event. The analysis presented here has been performed on the 10% most central events of the measured minimum bias cross section of ≈ 6400 mb. About 3 millions central Pb+Pb events were analyzed with an average of 6.1 identified protons and 2.9 identified deuterons per event.

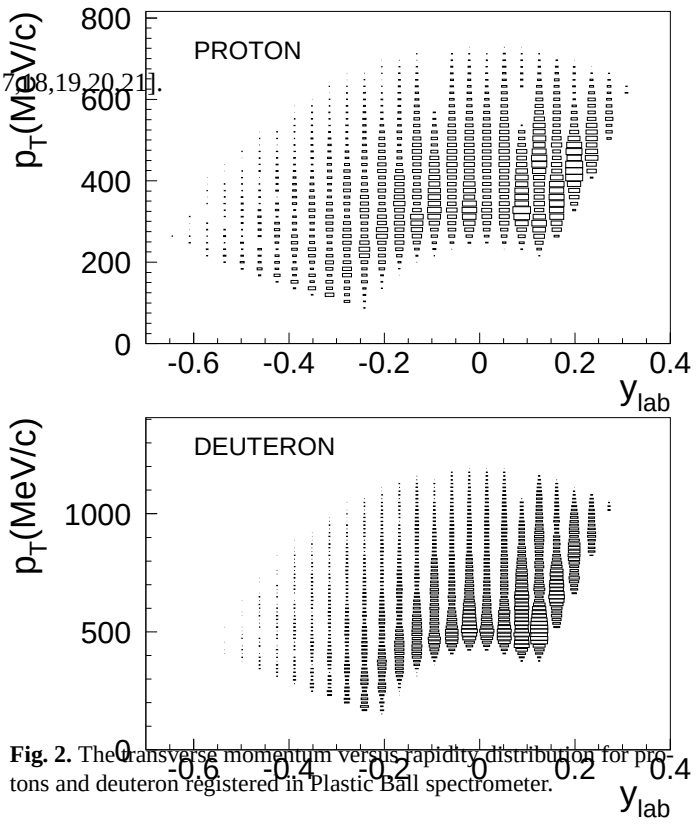

Fig. 2. The transverse momentum versus rapidity distribution for protons and deuteron registered in Plastic Ball spectrometer.

The identification and momentum measurement of protons and deuterons has been made using the Plastic Ball spectrometer [25]. The Plastic Ball consists of 655 detector modules surrounding the target over the range of polar angles ϑ from 30° to 160° with full azimuthal acceptance. Each of the modules consists of a ΔE and E section. The ΔE section is a CaF_2(Eu) crystal scintillator and the E section is a plastic scintillator. The light emission of the plastic scintillator is approximately 100

times faster than that of the CaF_2(Eu), so signals from both scintillators can be read out by a single photomultiplier with subsequent separation of the signals by pulse shape analysis. The $\Delta E-E$ identification technique was used and is capable of identifying pions and charged fragments up to the helium isotopes. Because of the relatively low yield of pions as compared to baryons, an additional positive pion identification is made by means of its sequential decay $\pi^+ \rightarrow \mu^+(\nu_\mu) \rightarrow e^+(\nu_e\bar{\nu_\mu})$. The thickness of the ΔE crystal scintillator was chosen to be 4 mm with 35.6 cm as the length of the E plastic scintillator. This assures that protons up to 200 MeV are fully stopped in the E-counter and provide a complete $\Delta E - E$ signal. Additionally, the mis-identification of punch through deuterons do not disturb the proton spectra below 200 MeV.

The WA98 experimental setup has been implemented in the GEANT Monte Carlo simulation package [26]. This has been used to study the response of the Plastic Ball in order to extract the particle identification efficiency and the kinetic energy resolution for different particle species, as well as two-particle variables and takes into account the granular structure of the Plastic Ball. GEANT transports the particles through the experimental setup taking into account the geometrical material boundaries and particle interactions. The particles are traced through the experimental setup where they may interact with the material they encounter on their way to the detector. When a particle reaches the detector the output signal of the Plastic Ball module is simulated. The particle distributions used as input to the GEANT simulations were adjusted to reproduce the measured momentum and angular distributions of particles. The Plastic Ball acceptance is illustrated in Fig. 2 as the distribution of protons and deuterons that pass the acceptance cuts.

3 One-dimensional analysis

The one-dimensional experimental correlation function was constructed as:

$$C(q) = N\,\frac{Y_{12}(q)}{Y^*_{12}(q)} \tag{1}$$

where $\mathbf{q} = \frac{1}{2}(\mathbf{q_1}-\mathbf{q_2})$ is the two-particle three-momentum difference in the laboratory frame, N is a normalization constant, and the numerator is the coincidence yield while the denominator is the uncorrelated background yield. In this analysis, the event-mixing technique was used to construct the background yields, using the same central event data set as used to construct the numerator. To insure that only particles from comparable events were mixed, the central event sample was further subdivided into 8 subsets according to the measured transverse energy. Particles were picked randomly from different events belonging to the same centrality selection with the additional condition to have the same multiplicities of the studied particle and all particles registered in the Plastic Ball. The number of mixed background pairs was chosen to be 10 times larger than the number of coincident pairs to insure a small statistical error contribution from the background pair yield, Y^*_{12}.

The measurement resolution of the variable q in the Plastic Ball spectrometer had an average value of $\sigma(q) \simeq 10.5$ MeV/c and 12.5 MeV/c for the two-proton and two-deuteron systems, respectively. For small values of q, the resolution was around 7.5 MeV/c for the two-proton system. A bin size of 7.5 MeV/c was chosen for the one-dimensional correlation analyses. It should be noted that the one-dimensional correlation functions presented here have been studied as a function of the momentum difference q rather than the more commonly used invariant four-momentum difference $q_{inv} = \frac{1}{2}\sqrt{-(p^\mu_1 - p^\mu_2)^2}$. The experimental resolution for the pp (dd) system in q_{inv} at 20 (40) MeV/c is about 15 (20) MeV/c. It increases to 20 (27) MeV/c at q_{inv}=100 (200) MeV/c and approximately levels off above that.

3.1 Final state interaction

To calculate the pair-wise final state interaction we used two computer codes for the proton-proton system: (i) the CRAB code written by S.Pratt [27] which includes Coulomb and strong final state interactions, and (ii) the static model developed by A. Deloff [28,29] with both Coulomb and strong S-wave interactions included. The latter incorporates a potential of the delta-shell form

$$2\mu V(r) = -(s/R)\,\delta(r-R), \tag{2}$$

characterized by the range R and the dimensionless parameter s representing the strength of the force (μ is the reduced mass). Only the $^1S_0$ partial wave in the strong interaction was retained. This pp interaction is well known experimentally and the measured phase shifts can be satisfactorily reproduced up to q=150 MeV/c by taking the delta-shell potential parameters as s=0.906 and R=1.84 fm. Both codes gave consistent results for the proton-proton system.

For the deuteron-deuteron case the model by A. Deloff [28] was used in which the strong s-wave interaction in S=0,2 spin states was included together with the Coulomb repulsion between two extended-size deuterons. The Coulomb interaction between two deuterons is different from that between two protons because the deuteron is composite and relatively large. For two extended-size deuterons located at $\mathbf{r}_1$ and $\mathbf{r}_2$, the Coulomb potential can be written as

$$V(|\mathbf{r}_1 - \mathbf{r}_2|) = \alpha \int \mathrm{d}^3\mathbf{x}_1 \mathrm{d}^3\mathbf{x}_2\, \frac{\rho(|\mathbf{x}_1-\mathbf{r}_1|)\rho(|\mathbf{x}_2-\mathbf{r}_2|)}{|\mathbf{x}_1-\mathbf{x}_2|} \tag{3}$$

where $\rho(x)$ is the charge density and α is the fine structure constant. Since the right hand side of Eq. (3) is translationally invariant, the potential $V(r)$ depends only upon the difference $r = |\mathbf{r}_1 - \mathbf{r}_2|$, and for r larger than twice the deuteron radius takes the usual point-like form $V(r) = \alpha/r$. For an assumed uniform charge distribution, this integral can be obtained in analytic form as:

$$V(r) = \begin{cases} \frac{\alpha}{R_c}\,\frac{1}{x}\{1-3(1-x)^4 \\ \quad \times[1-\frac{2}{15}(1-x)(5+x)]\} & 0 \le x \le 1 \\ \frac{\alpha}{r} & x > 1 \end{cases} \tag{4}$$

where $x = r/R_C$ and $R_C = 3.86$ fm is twice the deuteron radius. A comparison of the Coulomb potential for extended-size and point-like deuterons is shown in Fig. 3. The Coulomb repulsion is observed to be substantially reduced when the extended deuteron size is taken into account.

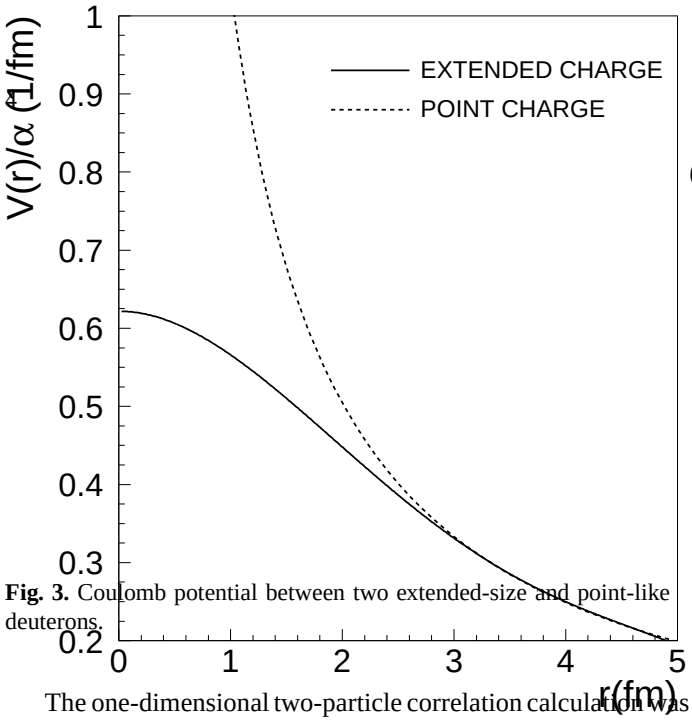

Fig. 3. Coulomb potential between two extended-size and point-like deuterons.

The one-dimensional two-particle correlation calculation was based on a static spherical gaussian shaped source, specified by radius R_0:

$$\rho(x) = (2\pi\, R_0^2)^{-3/2}\, \mathrm{e}^{-x^2/2R_0^2}. \qquad (5)$$

In the case of a non-zero emission lifetime this approach gives an *upper* limit for the spatial extent of the source.

To account for the Plastic Ball resolution all of the calculated correlation functions presented in this paper were calculated as:

$$C(q) = \int r(q,q')C(q')\mathrm{d}q' \qquad (6)$$

with the predicted correlation function $C(q')$ convoluted with the Gaussian resolution function of the Plastic Ball $r(q,q')$.

$$r(q,q') = \frac{1}{(2\pi)^{3/2}}\,\frac{1}{\sigma(q)}\,\mathrm{e}^{-\frac{1}{2}\frac{(q-q')^2}{\sigma(q)^2}}\,\mathrm{d}q' \qquad (7)$$

as determined from the GEANT simulations.

3.2 Systematic errors

The systematic errors have been evaluated by comparison of the results obtained under different conditions. The systematic uncertainties are mainly introduced by the granularity of the detector and, to some extent, by the procedure used to construct the background pair distribution. The following sources of systematic errors have been investigated leading to variations (rms estimates) of the radius parameters given in brackets, with the first and second numbers referring to the pp and dd system, respectively:

(i) Different periods of data taking during the run [0.05, 0.05 fm].
(ii) Different particle identification windows [0.09, 0.12 fm].
(iii) The width of the transverse energy E_T bin used for centrality selection in the background pair distribution calculations: the centrality bin size was halved and the result was compared to the nominal bin size result [0.01, 0.05 fm].
(iv) Non-conservation of momentum in the background pair correlations: local (transverse) momentum conservation in real events, although not expected to be exact, may influence the correlation between real particle pairs due to the fact that a significant fraction, but not all, of the particles in the target rapidity region are measured in the Plastic Ball. To investigate the sensitivity of the fitted parameters to the effect of momentum conservation, in addition to the requirement that the full background event have the same number of particles as the real event detected in the Plastic Ball, it was further required that the background event have a total momentum of all measured particles equal to that of the real event: $P_{Tot}(\mathrm{measured}) = P_{Tot}(\mathrm{reference}) \pm \Delta$, where Δ should be 0 in the ideal case. In practice, Δ was chosen to be 300 MeV/c and 600 MeV/c for the two-proton and two-deuteron background events, respectively [0.07, 0.06 fm].
(v) The granular structure of the Plastic Ball spectrometer: the GEANT program has been used to study the distortion of the correlation function due to the granularity of the Plastic Ball detector [0.15, 0.10 fm].
(vi) The bin width of the correlation function: to examine the dependence of the radius parameters on the q bin width, the analysis was also performed with bin widths of 10 MeV/c and 5 MeV/c [0.06, 0.06 fm].
(vii) Detector variation: the analysis was performed separately in two different azimuthal angle intervals: $0^\circ - 180^\circ$ and $180^\circ - 360^\circ$ [0.01, 0.02 fm].
(viii) The effect of possible mis-identification of protons and deuterons due to the multiple hits to the same Plastic Pall module. Since the multi-hit probability depends very strongly on θ, the analysis was performed with two subsamples with θ intervals of protons and deuterons: $60^\circ - 90^\circ$ and $90^\circ - 160^\circ$. The ratio of contaminations due to multi-hits in these θ intervals is about 10:1. The GEANT simulations also demonstrated that the contamination from spurious protons and deuterons contribute uniformly to their correlation functions. As a result, this background contamination does not affect the shape of the correlation function, leading to the same, within errors, radius parameters [0.15, 0.10 fm].

The total systematic uncertainty was calculated by adding in quadrature the contributions listed above.

3.3 Two-proton system

The measured two-proton correlation function is shown in Fig. 4. The solid line represents the result of the theoretical calculation which gives the best fit to the data using the delta-shell potential. The final state Coulomb and strong interactions, the Fermi-Dirac effect, and the experimental resolution have been implemented in the theoretical calculation. The resulting radius parameter is 3.14$\pm$ 0.03(stat.)$\pm$ 0.21(syst.) fm.

Although the delta-shell potential may not be realistic, its main advantage is that both the phase shift and the enhancement factor can be obtained in an analytic form. Furthermore, it is desirable to use the same model for calculation of both proton and deuteron correlation functions. It was demonstrated in [29] that the calculated pp phase shifts as obtained from both the delta-shell potential and the REID soft core potential [30]

agree well with the experimental data, up to about 150 MeV/c. As a cross check, the REID potential was also used to fit the experimental two-proton correlation function. The resulting correlation function is shown in Fig. 4 as the dashed line. The fitted radius parameter is 3.05 $\pm$ 0.02(stat.)$\pm$ 0.24(syst.) fm which, within errors, is consistent with the delta-shell potential calculation. The calculated two-proton correlation functions without Coulomb interaction and without any final state interactions are also shown in Fig. 4 as the dotted and dot-dashed lines, respectively.

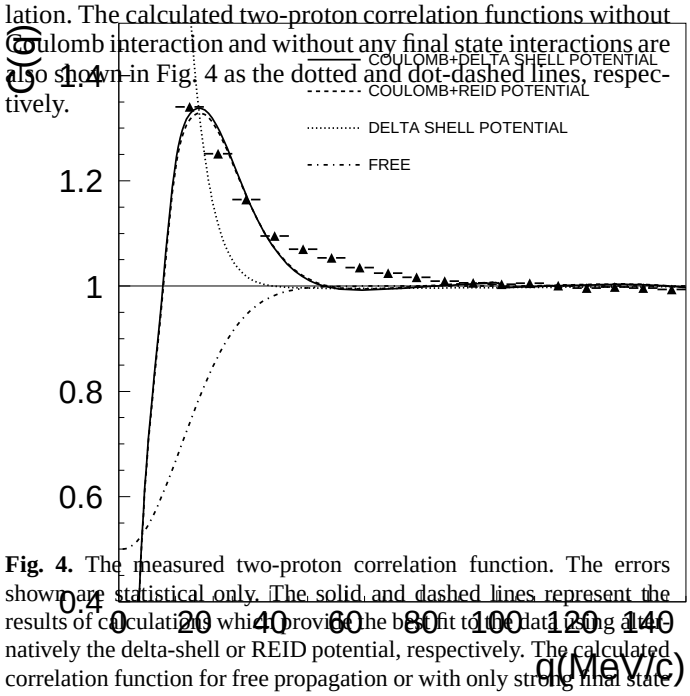

Fig. 4. The measured two-proton correlation function. The errors shown are statistical only. The solid and dashed lines represent the results of calculations which provide the best fit to the data using alternatively the delta-shell or REID potential, respectively. The calculated correlation function for free propagation or with only strong final state interaction included are shown as dot-dashed and dotted lines.

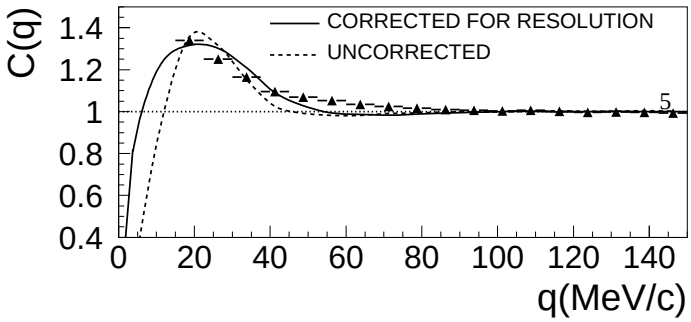
In order to make a direct comparison with other experimental results, the CRAB package [27], provided by Pratt, was also used to extract the radius parameter for the two-proton system. The CRAB calculation takes into account the Coulomb and strong final state interactions. To describe the latter for the two-proton system the REID potential was taken. The measured momentum distribution of protons was used as input to the CRAB calculation. To obtain a radius parameter, the calculation was performed for a set of different radius parameters and then compared to the experimental data by calculating the χ^2 value. This gave a best fit radius parameter of 2.83 ± 0.20 fm, that is consistent, within errors, with the delta-shell model calculation. The CRAB calculation result is shown in Fig. 5. The experimental correlation as a function of q_{inv} is also shown in Fig. 5 with the CRAB calculation. The solid and dashed lines represent the CRAB calculations with and without the experimental resolution effect included, respectively.

The polar angle (or rapidity) dependence of the proton source radius parameter was also investigated. Within errors, the two-proton source radius, R_0 showed no rapidity dependence, as seen from Fig. 6, over the entire polar angle interval.

Two-proton correlations have also been studied in the target fragmentation region at the SPS in the WA80 experiment using the Plastic Ball spectrometer. Measurements were made with 200 A GeV proton, Oxygen, and Sulphur projectiles, on targets of C, Al, Ag, and Au [11]. The source radius extracted from the present analysis of the two-proton correlation for central Pb+Pb collisions at 158 A GeV is compared to the radius



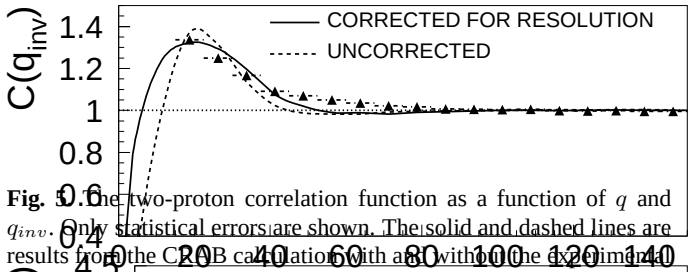


Fig. 5. The two-proton correlation function as a function of q and q_{inv}. Only statistical errors are shown. The solid and dashed lines are results from the CRAB calculation with and without the experimental resolution applied, respectively.

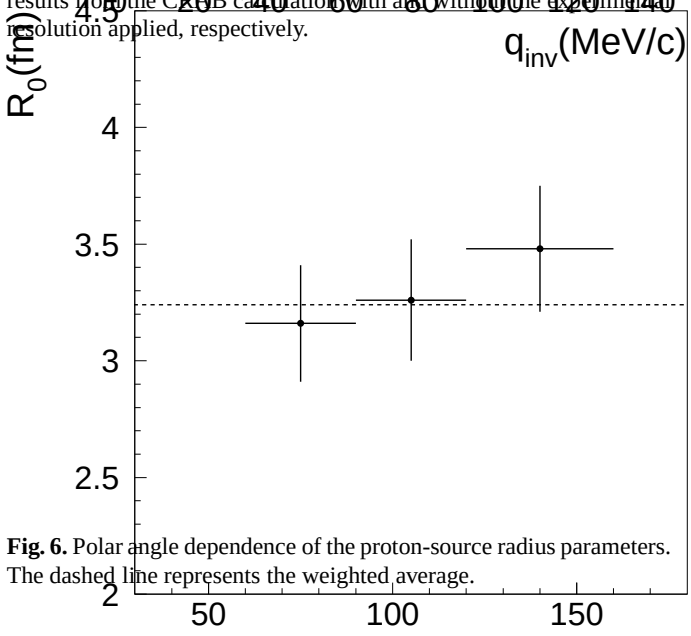

Fig. 6. Polar angle dependence of the proton-source radius parameters. The dashed line represents the weighted average.

parameters extracted in the WA80 experiment in Fig. 7. The radius parameters are plotted as a function of $A^{1/3}_{\rm Target}$. All radii have been converted to root-mean-square radii. Within errors, the radius parameters measured in the WA80 and WA98 experiments at the SPS closely follow the target nuclear radius dependence of $A^{1/3}_{Target}$ with little apparent dependence on the projectile mass. Since the size of the participant overlap region depends on both target and projectile mass, the observation of little projectile mass dependence indicates that the protons detected in the target fragmentation region are emitted from the entire target volume, following substantial rescattering [11].

3.4 Two-deuteron system

Figure 8 shows the measured two-deuteron correlation function and the theoretical calculation which gives the best fit to the data. The solid and dashed line represent the correlation functions calculated with final state interaction taken into account and that for free propagation. The fitted radius parameter is 1.59$\pm$ 0.02(stat.)$\pm$ 0.20(syst.) fm. The range R and the strength s for the delta-shell potential are found to be 0.52 ± 0.01 fm and 1.08 ± 0.01, respectively. The measured two-deuteron

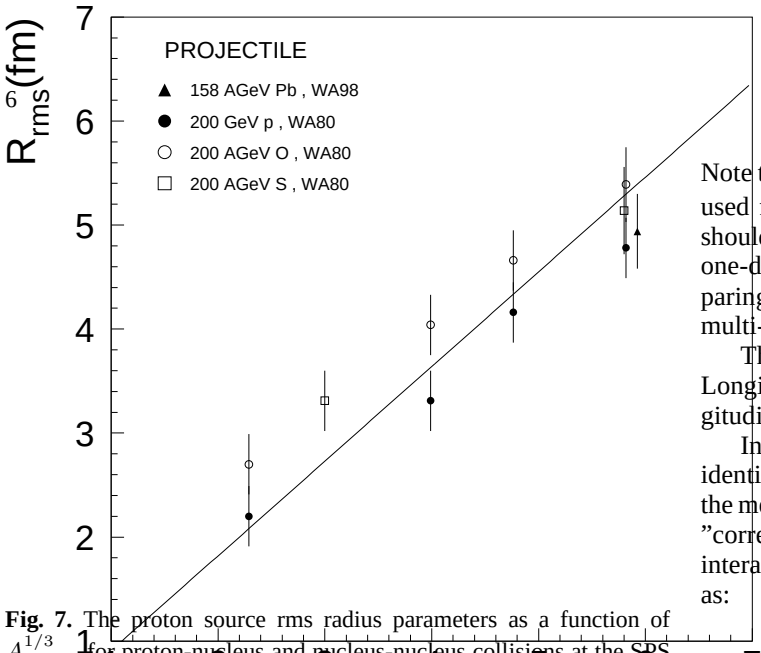

Fig. 7. The proton source rms radius parameters as a function of $A^{1/3}_{\rm Target}$ for proton-nucleus and nucleus-nucleus collisions at the SPS from this measurement and from the WA80 experiment [11]. The protons have been measured in the target fragmentation region with -0.6 $< y <$0.6 and 100 MeV/c $< p_T <$ 650 MeV/c . The symbols are slightly displaced for the Au and Pb target points for clarity. The line represents the fitted function $R_{rms} = aA^{1/3}_{\rm Target}(a = 0.91 \pm 0.02, \chi^2/n = 1.68)$. The WA98 experimental result was obtained using the CRAB code.

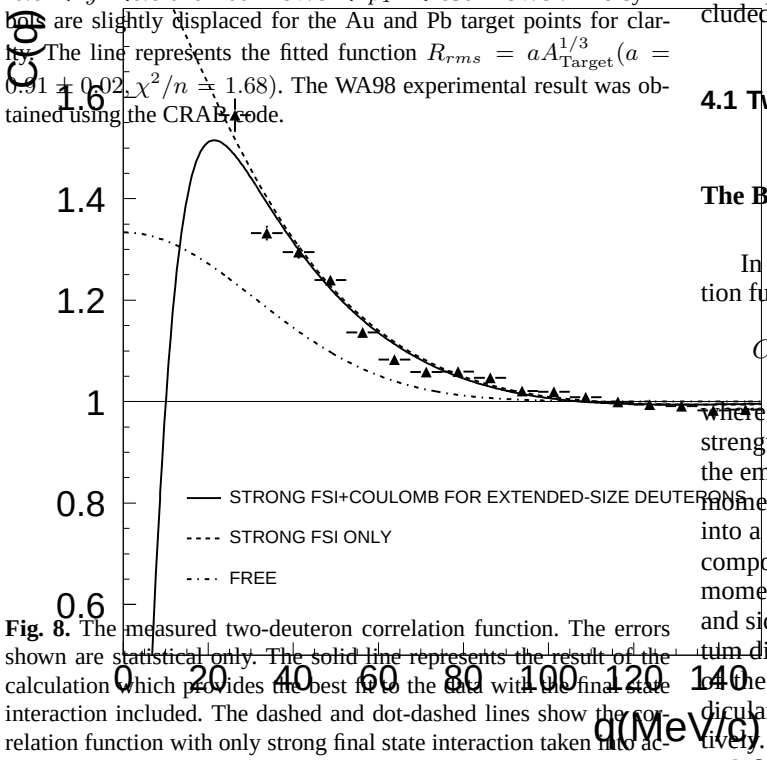

Fig. 8. The measured two-deuteron correlation function. The errors shown are statistical only. The solid line represents the result of the calculation which provides the best fit to the data with the final state interaction included. The dashed and dot-dashed lines show the correlation function with only strong final state interaction taken into account and that for free propagation, respectively.

correlation and extracted radius parameters show no dependence on the polar angle, similar to observations for the two-proton correlation (see Fig. 6).

4 Multi-dimensional analysis

For consistency of notation with previous analyses, the momentum difference $\mathbf{Q} = (\mathbf{p}_1 - \mathbf{p}_2)$ is used in the multi-dimensional analysis. In this case the two-particle correlation $C(Q)$ is given by:

$$C(Q) = 1 + \tilde{\rho}(Q)^2. \quad (8)$$

Note that since the correlation function $C(q) = 1 + \tilde{\rho}(2q)^2$ was used for the calculations presented in section 3, a factor $\sqrt{2}$ should be applied to the radius parameters obtained from the one-dimensional analysis results presented above when comparing with the radius parameters obtained from the following multi-dimensional analysis.

The multi-dimensional analysis has been performed in the Longitudinally CoMoving System (LCMS), in which the longitudinal pair momentum vanishes ($\mathbf{p}_{z1} + \mathbf{p}_{z2} = 0$).

In order to extract that part of the correlation function of identical particles that is due to quantum statistical effects only, the measured multi-dimensional correlation functions have been "corrected" for the effect of the strong and Coulomb final state interactions (FSI). The corrected correlation function is defined as:

$$C(p_1, p_2) = K\, C_{raw}(p_1, p_2) \quad (9)$$

where $K = C_{FREE}(Q)/C_{FSI}(Q)$ is the correction factor, and $C_{FREE}(Q)$ and $C_{FSI}(Q)$ are the calculated correlation functions for free propagation and with final state interactions included, respectively.

4.1 Two-proton system

The Bertsch-Pratt (BP) parametrization

In the Bertsch-Pratt parameterization [31,32], the correlation function for two fermions has the form:

$$C = N\left(1 - \lambda \mathrm{e}^{-Q_l^2 \cdot R_l^2 - Q_s^2 \cdot R_s^2 - Q_o^2 \cdot R_o^2 - 2 \cdot Q_o Q_l \cdot R_{ol}^2}\right) \quad (10)$$

where N is the normalization constant and $0 \leq \lambda \leq 1$ is the strength of the correlation which depends on the chaoticity of the emitter and on the purity of the measured data sample. The momentum difference vector $\mathbf{Q}$ of two particles is decomposed into a longitudinal component along the beam axis (Q_l) and a component transverse to the beam axis (Q_T). The transverse momentum difference is further decomposed into the outward and sideward components. The outward and sideward momentum differences (Q_o) and (Q_s) are defined as the components of the transverse momentum difference parallel and perpendicular to the total transverse momentum of the pair, respectively. The sign convention is that Q_s is always positive, Q_l and Q_o are allowed to be positive or negative. R_{ol}^2 is the "out-longitudinal" cross term [33]. Its value can be either positive or negative. In the LCMS system the average resolutions in the Q_s, Q_l, and Q_o components for the pp system are 20, 23, and 24 MeV/c, respectively.

Figure 9 shows projections of the measured two-proton correlation functions, corrected for final state interactions (Eq. (9)), onto the Q_l, Q_s, and Q_o axes. Also shown are the corresponding projections of the fit of Eq. (10), shown as solid lines. The projected results and the fit results for a given Q component have been integrated up to 75 MeV/c over the other two $|Q|$ components.

The parameters extracted from fits to the data using either the delta-shell corrected and CRAB corrected correlation functions are presented in Table 1. Also listed in this table are the

Table 1. Fitted parameters of the Bertsch-Pratt parametrization of the two-proton correlation function using the delta-shell model or CRAB model final state interaction calculations. Errors are statistical + systematic.

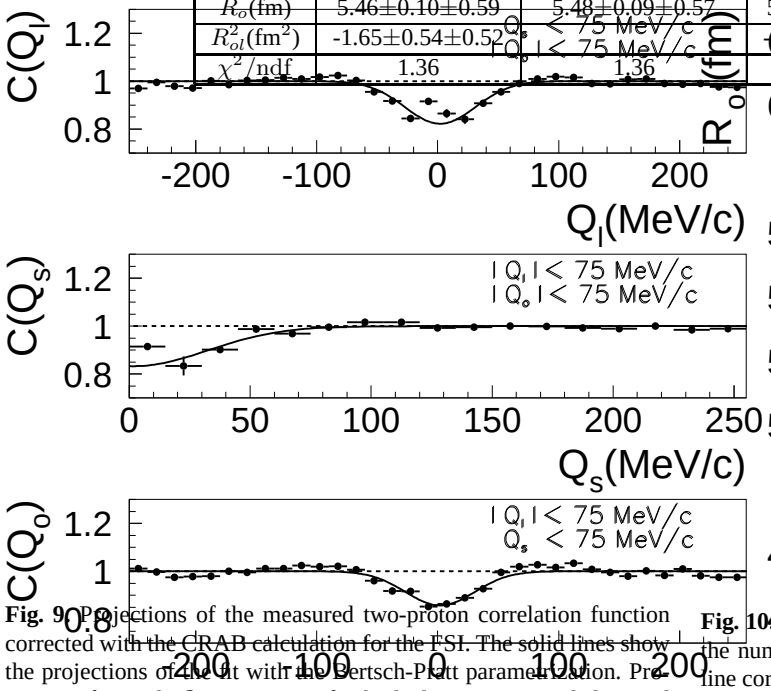

Fig. 9. Projections of the measured two-proton correlation function corrected with the CRAB calculation for the FSI. The solid lines show the projections of the fit with the Bertsch-Pratt parametrization. Projections for each Q component, for both the experimental data and the fit, have been integrated up to 75 MeV/c over the other two $|Q|$ components. The errors shown are statistical only.

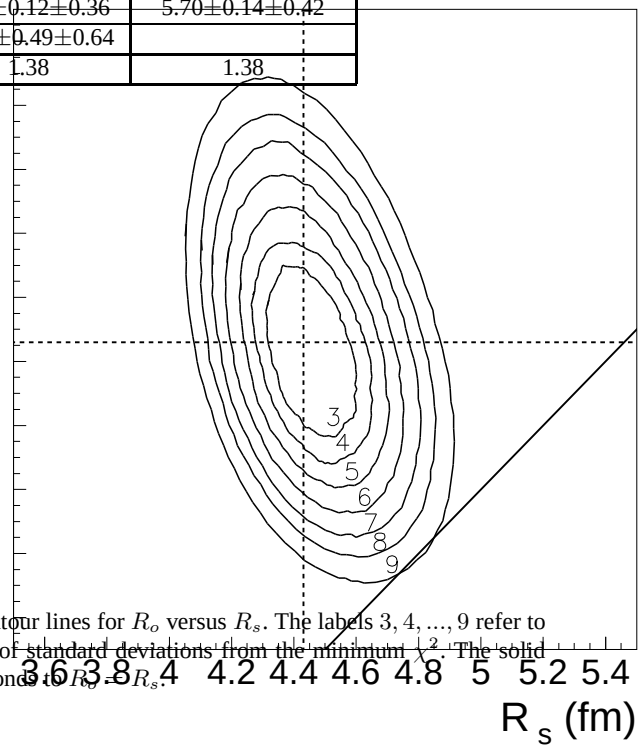

Fig. 10. Contour lines for R_o versus R_s. The labels $3, 4, ..., 9$ refer to the number of standard deviations from the minimum χ^2. The solid line corresponds to $R_o = R_s$.

fitted parameters without the cross term R^2_{ol}. Within errors, the delta-shell and CRAB corrections lead to the same values of fitted parameters. The fitted radius parameters with and without the cross term do not differ within errors. The cross term R_{ol} vanishes in the LCMS frame for longitudinally *boost-invariant* systems. The observation that the cross-term R^2_{ol} is small, indicates that the proton source undergoes an approximate boost invariant expansion.

The statistical significance of the fit is demonstrated in Fig. 10, where contour lines of equal confidence level for R_o versus R_s are plotted. The spacing of contours corresponds to one standard deviation in χ^2 value. The solid line, which represents equal sideward and outward radii, is 9 standard deviations from the minimum χ^2 value.

For transparent sources, where particles are emitted from throughout the entire volume, the longitudinal radius R_l is interpreted to measure the longitudinal size of the system directly, while the sideward radius provides a measurement of the transverse size. The duration of emission $\Delta\tau$ is related [34,35] to the sideward radius R_s and outward radius R_o as:

$$\Delta\tau = \frac{1}{\beta_T}\sqrt{R_o^2 - R_s^2}, \qquad (11)$$

where β_T is the transverse velocity of the particle pair. Notice that Eq. (11) is valid only when opacity effects and transverse flow are ignored. The excess of R_o over R_s is due to the duration of emission from the source in which particles with transverse velocity β_T travel a distance $\beta_T\Delta\tau$ towards the detector, resulting in an apparent extension of the source in that direction. The sideward radius parameter R_s is not affected by the duration of emission since it is perpendicular to β_T.

Within errors, the radius parameters (R_l, R_s, R_o) of the BP fit are quite close to each other (Table 1) which suggests a volume emission of the protons. The extracted R_o and R_s parameters, and the measured average value of $\beta_T = 0.278 \pm 0.09$ for the proton pairs, gives 11.5 ± 2.5 fm/c as an estimate of the emission duration.

In the case of a Bjorken scenario, with longitudinal expansion of the system without transverse flow, the m_T dependence of the longitudinal radius reflects the lifetime of the source[36]:

$$R_l = \tau_f (T_f/m_T)^{1/2}, \qquad (12)$$

where T_f is the freeze-out temperature and $m_T = \sqrt{m^2 + p_T^2}$. Under the assumption that $T_f = 120$ MeV, a source lifetime of about 13 fm/c is obtained.

Strictly speaking, the interpretation of τ_f as the freeze-out time is based on the assumption that the longitudinal boost-invariant velocity profile existed not only at the time of freeze-out but also throughout the dynamical evolution of the reaction

zone. If this were not the case, then τ_f would be larger. Hence, τ_f estimated by Eq. (12) gives a *lower* limit for the lifetime of the source [1].

The Yano-Koonin-Podgoretsky (YKP) parametrization

In the Yano-Koonin-Podgoretsky parameterization[37,38], the two-proton correlation function is defined by the formula:

$$C = N\left(1 - \lambda \mathrm{e}^{-Q_T^2 R_T^2 - (Q_l^2 - Q_0^2) R_l^2 - (Q\cdot U)^2 (R_0^2 + R_l^2)}\right) \quad (13)$$

where $U = \gamma(1, 0, 0, \beta)$ is a 4-velocity with only a longitudinal component, $\gamma = 1/\sqrt{1-\beta^2}$, Q_T and Q_l are the components of the momentum difference projected onto the transverse and longitudinal directions, respectively, Q_0 is the difference in energies. The sign convention is Q_0 is always positive and Q_l can be either positive or negative. This parametrization has an advantage in that the three YKP radius parameters do not depend on the longitudinal velocity of the measurement frame, and the velocity β is closely related to the velocity of the effective particle emitter.

The parameters extracted from YKP fits to the delta-shell corrected or CRAB corrected correlation functions are listed in Table 2. Within errors, the fitted parameters obtained with the two different final state interaction corrections are consistent with each other.

Table 2. Fitted parameters of the YKP parametrization of the two-proton correlation functions using either the delta-shell model or CRAB model FSI corrections. Errors are statistical + systematic.

	Delta-shell Model	CRAB Model
λ	0.75±0.04±0.04	0.77±0.03±0.03
R_l(fm)	4.64±0.16±0.36	4.97±0.08±0.46
R_T(fm)	4.42±0.13±0.40	4.73±0.06±0.46
R_0(fm)	10.54±0.46±1.18	10.58±0.46±1.12
β	0.032±0.023±0.010	0.036±0.014±0.011
χ^2/ndf	1.42	1.47

Since the YKP velocity β is close to 0, it demonstrates that the LCMS frame coincides with the YK frame (the frame for which the YKP velocity parameter β vanishes). For *transparent sources*, and in the absence of flow, the radius parameters in the YK frame have a convenient physical interpretation. R_l and R_T are then interpreted as measures of the longitudinal and transverse size of the source, while R_0 reflects directly the duration of emission from the source.

With similar fitted R_l and R_T parameters, and longitudinal velocity β compatible with 0, the YKP fit indicates a symmetric emission geometry with approximate boost invariant expansion of the source. The emission duration extracted from the YKP or BP fits are in agreement within errors.

The fitted YKP parameters are seen to be consistent with the BP parameters. Since the BP and YKP parametrizations are mathematically equivalent and differ only in the choice of independent components of q, the agreement between the two sets of fitted parameters serves additionally as a consistency check of the fitting procedures.

4.2 Two-deuteron system

The Gaussian parametrization in the LCMS

Fig. 11 shows the experimental one-dimensional two-deuteron correlation function in the LCMS frame, after correction for final state interactions using the delta-shell model described in section 3. The correlation is fitted to the Gaussian correlation function:

$$C(Q) = N\left(1 + \lambda \mathrm{e}^{-Q^2 R^2}\right). \quad (14)$$

The fitted parameters are: $\lambda = 0.43\pm0.03$(stat.)±0.08(syst.), $R = 2.50\pm0.10$(stat.)±0.28(syst.) fm. The radius parameter is in agreement within errors with the radius ($R = 1.59 \times \sqrt{2} = 2.25$ fm) extracted by fit to the one-dimensional correlation function with the full delta-shell model calculation (see Fig. 8).

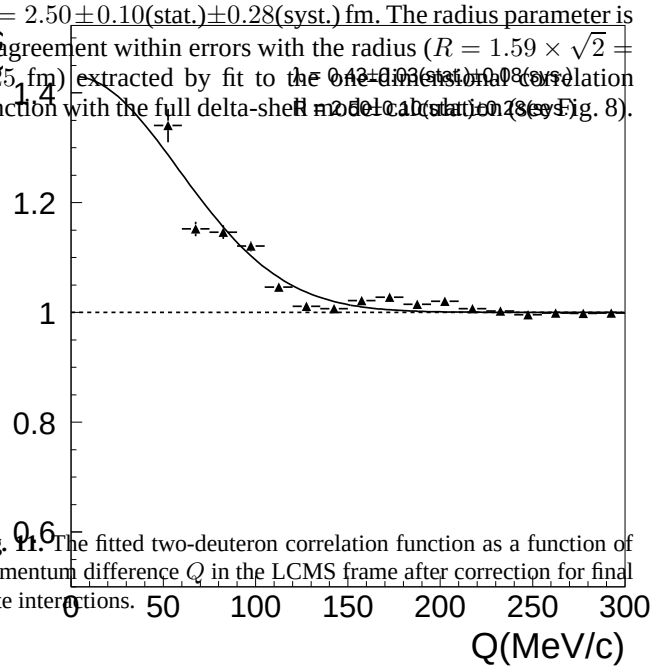

Fig. 11. The fitted two-deuteron correlation function as a function of momentum difference Q in the LCMS frame after correction for final state interactions.

The Bertsch-Pratt parametrization

The two-deuteron correlation function has been corrected by the calculated delta-shell model two-deuteron final state interaction and fitted with the two-boson correlation function using the Bertsch-Pratt parametrization:

$$C = N\left(1 + \lambda \mathrm{e}^{-Q_l^2\cdot R_l^2 - Q_s^2\cdot R_s^2 - Q_o^2\cdot Q_o^2 - 2\cdot Q_o Q_l \cdot R_{ol}^2}\right). \quad (15)$$

Projections of the measured two-deuteron correlation function on the Q_l, Q_s, and Q_o axes are shown in Fig. 12. The measured and fitted projections in a given Q component have been integrated up to 75 MeV/c in the other two $|Q|$ components. All Q components have approximately the same average resolution of 32 MeV/c.

The fitted parameters, with and without the cross term R_{ol}^2, are listed in Table 3. Within errors, the values of parameters extracted from the two different fits are the same. Similar to the result for the proton source, the small cross-term indicates that the deuteron source also experienced an approximate boost invariant expansion.

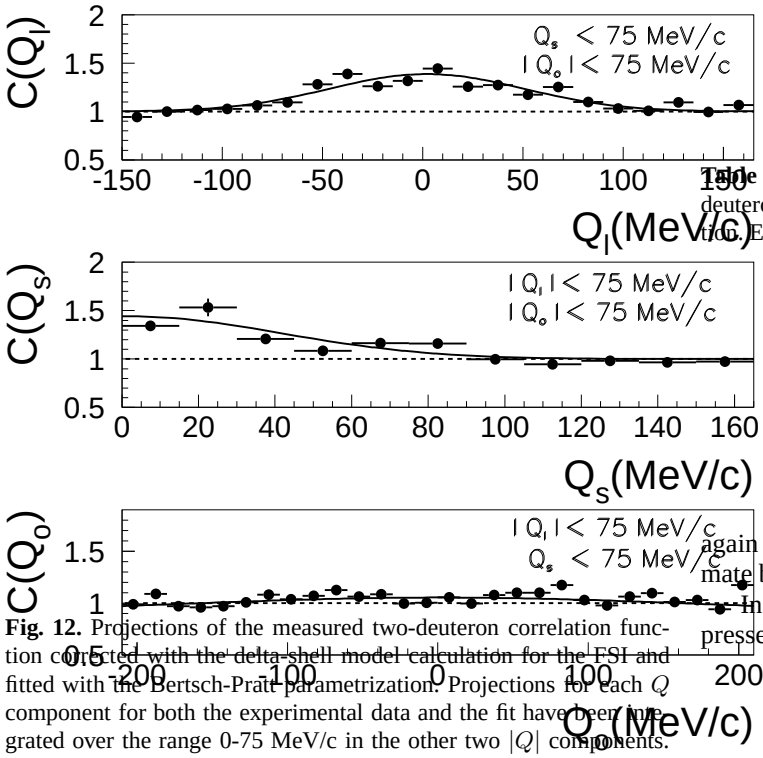

Fig. 12. Projections of the measured two-deuteron correlation function corrected with the delta-shell model calculation for the FSI and fitted with the Bertsch-Pratt parametrization. Projections for each Q component for both the experimental data and the fit have been integrated over the range 0-75 MeV/c in the other two $|Q|$ components. The errors shown are statistical only.

Table 3. Fitted parameters of the Bertsch-Pratt parametrization of the two-deuteron correlation functions using the delta-shell model FSI correction. Errors are statistical + systematic.

	with cross term	without cross term
λ	0.37±0.02±0.19	0.37±0.02±0.19
R_l(fm)	2.17±0.10±0.24	2.13±0.08±0.18
R_s(fm)	3.14±0.11±0.78	3.10±0.10±0.67
R_o(fm)	0.01±0.08±0.02	0.01±0.04±0.03
R^2_{ol}(fm^2)	0.20± 0.08 ±0.69	
χ^2/ndf	1.52	1.52

Within errors, the fitted R_l and R_s parameters are close to the radius value obtained from the one-dimensional fit, while R_o is consistent with 0. For a transparent, azimuthally symmetric emission source, it is expected that R_s and R_o should be similar, except that R_o will be extended by the duration of emission, as discussed with respect to Eq. (11). The observation that $R_o << R_s$ is inconsistent with such a transparent source, but may result naturally from surface emission from an opaque source [39,40]. Since deuterons are relatively large weakly bound objects, it might be expected that only those deuterons produced on the freeze-out surface via coalescence of an emitted proton and neutron survive. This would naturally lead to an opaque emission source, as observed.

The Yano-Koonin-Podgoretsky parametrization

The two-boson correlation function in the Yano-Koonin-Podgoretsky parametrization is given by:

$$C = N\left(1+\lambda \mathrm{e}^{-Q_T^2R_T^2-(Q_l^2-Q_0^2)R_l^2-(Q\cdot U)^2(R_0^2+R_l^2)}\right). \quad (16)$$

The parameters of the YKP fit to the two-deuteron correlation are listed in Table 4. The longitudinal velocity β is close to 0 indicating that the LCMS coincides with the YK frame and again indicates that the deuteron source undergoes an approximate boost invariant expansion.

Table 4. Fitted parameters of the YKP parametrization of the two-deuteron correlation functions using the delta-shell model FSI correction. Errors are statistical + systematic.

λ	0.29±0.02±0.09
R_l(fm)	1.29±0.07±0.42
R_T(fm)	2.35±0.05±0.39
R^2_0(fm^2)	-46.95±1.69±8.82
β	0.020±0.002±0.007
χ^2/ndf	1.42

In the YK frame the YKP radius parameter R_0 can be expressed as [41]:

$$R_0^2 = \frac{1}{\beta_\perp^2}\left(R_o^2 - R_s^2\right), \quad (17)$$

where $\beta_\perp$ is the velocity of the particle pair transverse to the beam direction, and R_o and R_s are the outward and sideward radii of the BP parametrization. The negative value of $R_0^2 \approx -47$ fm^2 obtained from the YKP fit is in agreement with the observation of strong opacity [1,39,42] of the deuteron source made in the previous section.

5 Discussion

Although one does not necessarily expect boost-invariance in the target fragmetnation region at SPS energies, the small values of the cross-term R_{ol} in the BP parametrization as well as the consistency with zero longitudinal velocity β in the YKP parametrization of the correlation functions, indicates that both proton and deuteron sources exhibit boost-invariant expansion.

The measured one-dimensional radius parameter extracted for protons is markedly larger than that for deuterons. Comparison of the present results for protons and deuterons with those for π^+, also measured in the Plastic Ball [43], and π^- measured in the WA98 negative-charged particle spectrometer [44,45], and with K^+ measured in the NA44 experiment [46] for central Pb+Pb collisions at 158 A GeV, reveals that the radii are observed so show a mass ordering with $R_{\pi\pi} > R_{\mathrm{KK}} > R_{\mathrm{pp}} > R_{\mathrm{dd}}$. This observation is in agreement with previous reports [47] that lighter particles tend to give larger radius parameters. It is interesting that a large loosely bound composite object like the deuterons follows the same trend as observed for elementary particles. It has been shown by Alexander [47,48] that the source-size mass dependence of hadrons emerging from Z^0 decays produced in e^+e^- annihilation can be reproduced using the Heisenberg uncertainty relations to derive the relations:

$$R = \frac{A}{\sqrt{m}}, \quad (18)$$

and

$$R_l = \frac{A}{\sqrt{m_T}}, \quad (19)$$

where $A = c\sqrt{\hbar \Delta t}$ is a time scale constant, R_l is the longitudinal radius parameter, and m and m_T are the mass and the mean transverse mass, respectively. An alternative explanation using a QCD derived potential [47] proved to be equally successful. A different approach to explain the R and R_l mass dependence was given by Bialas and Zalewski [49,50,51]. In this description the radius parameter of the source is mass independent and its apparent decrease is a consequence of the momentum-position correlation expressed in the Bjorken-Gottfried condition [52,53]. However, a study of purely kinematical considerations [54] led to the conclusion that this is unlikely to account for the observed $R(m)$ dependence.

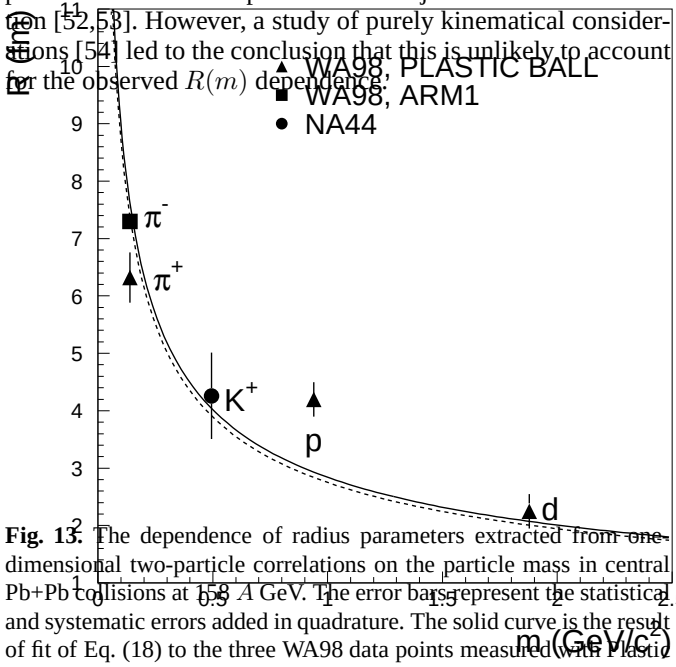

Fig. 13. The dependence of radius parameters extracted from one-dimensional two-particle correlations on the particle mass in central Pb+Pb collisions at 158 A GeV. The error bars represent the statistical and systematic errors added in quadrature. The solid curve is the result of fit of Eq. (18) to the three WA98 data points measured with Plastic Ball spectrometer. The dashed curve includes also the π^- data from WA98 and kaon data from the NA44 experiment.

Radius parameters extracted from one-dimensional two-particle correlation functions for central Pb+Pb collisions at 158 A GeV are shown as a function of the particle mass in Fig. 13. The $\pi^-\pi^-$ radius parameter was measured with the negative-charged particle spectrometer of the WA98 experiment [44,45] and the two-kaon radius parameter was reported by the NA44 Collaboration [46], both measured near mid-rapidity $\langle y \rangle \sim 2.9$. In general, the radii follow the $\sqrt{m}$ dependence expectation of Eq. (18). A fit of Eq. (18) to the π^+ [43], proton, and deuteron radii measured with the WA98 Plastic Ball gives $A = 2.84 \pm 0.13$ fm GeV$^{1/2}$ with χ^2/ndf = 12, as shown by the solid curve. This corresponds to a time scale of $\Delta t = 40.8$ fm/c using the above expression for A, or to a freeze-out lifetime of $\tau_f = 8.2$ fm/c using Eq. (12). A fit to all data points (dashed line) results in $A = 2.75 \pm 0.04$ fm GeV$^{1/2}$ with χ^2/ndf = 7.2.

Previous results on pion and kaon interferometry for S+Pb and Pb+Pb reactions at the SPS have demonstrated scaling of the R_l and R_T radius parameters on the transverse mass, m_T [55,56]. The longitudinal and transverse radius parameters from the multi-dimensional YKP analysis of the two-proton and two-deuteron correlation functions are plotted as a function of the mean transverse mass in Figs. 14 and 15. Also shown are radius parameters for π^+ measured with the Plastic Ball [43]. Radii measured near mid-rapidity for π^- in WA98 [44,45], and for kaons from the NA44 [56] and NA49 [57] experiments are also shown. The

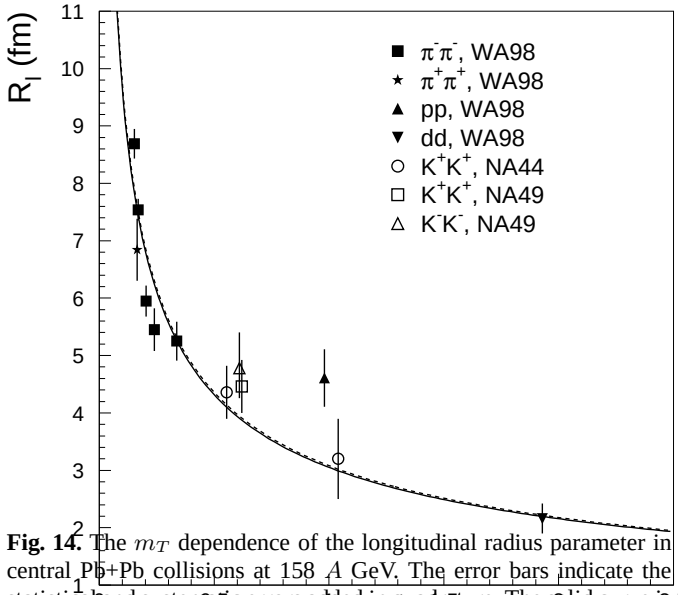

Fig. 14. The m_T dependence of the longitudinal radius parameter in central Pb+Pb collisions at 158 A GeV. The error bars indicate the statistical and systematic errors added in quadrature. The solid curve is the result of a fit of $R = A/\sqrt{m_T}$ to the WA98 data points measured with the Plastic Ball spectrometer, while the dashed curve includes also mid-rapidity π^- data from WA98 and kaon data from the NA44 and NA49 experiments.

data are compared to fits of the form $R_i = A_i/\sqrt{m_T}$, where $i = l, T$. As can be seen from Figs. 14 and 15, within experimental uncertainties, the fitted R_l and R_T radius parameters are consistent with $A/\sqrt{m_T}$ scaling. A fit to the three WA98 data points measured near mid-rapidity with the Plastic Ball spectrometer yields $A_l = 3.05 \pm 0.17$ fm GeV$^{1/2}$ with χ^2/ndf = 3.6. When all data points are included in the fit, the fit yields $A_l = 3.08 \pm 0.05$ fm GeV$^{1/2}$ with χ^2/ndf = 3.4.

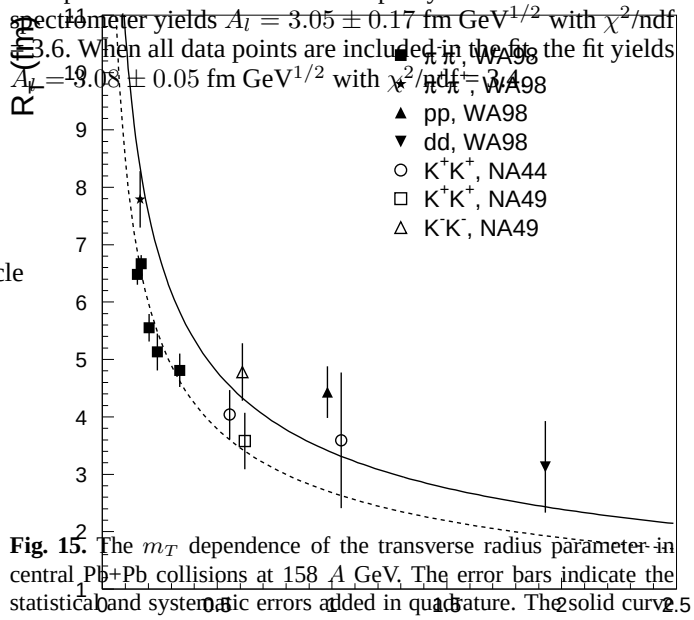

Fig. 15. The m_T dependence of the transverse radius parameter in central Pb+Pb collisions at 158 A GeV. The error bars indicate the statistical and systematic errors added in quadrature. The solid curve is a fit of $R_T = A/\sqrt{m_T}$ to the WA98 data points measured with the Plastic Ball spectrometer only, while the dashed curve includes also mid-rapidity π^- data from WA98 and kaon data from the NA44 and NA49 experiments.

Although there is no theoretical justification to expect an R_T=$A/\sqrt{m_T}$ dependence, the data are seen (Fig. 15) to follow such a dependence, within errors. A fit to the three WA98 data points measured near mid-rapidity with the Plastic Ball spectrometer yields $A_T = 3.38 \pm 0.18$ fm GeV$^{1/2}$ with χ^2/ndf = 2.4 When all data points are included in the fit, the fit yields $A_T = 2.68 \pm 0.04$ fm GeV$^{1/2}$ with χ^2/ndf = 3.3. A fit to the

pion and kaon data from NA44 experiment alone gave $A_T = 3.0 \pm 0.2$ fm GeV$^{1/2}$ [56].

6 Summary

In summary, we have measured two-proton and two-deuteron correlation functions in the target fragmentation region for central Pb+Pb collisions at 158 A GeV.

In the one-dimensional analysis, the radius parameters were extracted from the measured correlations using calculations that assume a static Gaussian-shaped source. The extracted proton source radius parameter is about two times larger than that of the deuteron source. Comparison of the proton and deuteron radius parameters with those extracted from one-dimensional two-pion and two-kaon correlations reveals a common $A/\sqrt{m}$ dependence with $A \approx 3$ fm GeV$^{1/2}$. Such a dependence can be explained as a consequence of the Heisenberg uncertainty relations, under the assumption of a common duration of emission.

The multi-dimensional analysis demonstrates that the proton source exhibits a volume emission with long emission time, whereas the deuteron source is strongly opaque. The cross-term R_{ol}^2 from the Bertsch-Pratt parametrization fit and the longitudinal velocity β from the Yano-Koonin-Podgoretsky parametrization fit are consistent with zero, suggesting that the proton and deuteron sources undergo an approximate longitudinal boost invariant expansion.

The longitudinal and transverse radius parameters, R_l and R_T, extracted from the multi-dimensional correlation analysis follow a common $A/\sqrt{m_T}$ scaling for pions, kaons, protons, and deuterons, with $A \approx 3$ fm GeV$^{1/2}$ in both cases. The existence of a universal function describing the dependence of the radius parameters on the transverse mass for different particle species in the mass interval from pion to deuteron may indicate an approximately simultaneous freeze-out of the studied hadrons.

We wish to express our gratitude to Professor A. Deloff for supplying his codes for the pp and dd FSI calculations, and for his guidance and helpful discussions. We wish to thank the CERN accelerator division for the excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians, and support staff who have participated in the construction of this experiment. This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR and FRN, the Dutch Stichting FOM, the Polish MEiN under Contract No. 1P03B02230 and CERN/88/2006 The Grant Agency of the Czech Republic under contract No. 202/95/0217, the Department of Atomic Energy, the Department of Science and Technology, the Council of Scientific and Industrial Research and the University Grants Commission of the Government of India, the Indo-FRG Exchange Program, the PPE division of CERN, the Swiss National Fund, the INTAS under Contract INTAS-97-0158, ORISE, Grant-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science and Culture, the University of Tsukuba Special Research Projects, and the JSPS Research Fellowships for Young Scientists. ORNL is managed by UT-Battelle, LLC, for the U.S. DOE under contract DE-AC05-00OR22725. The MIT group has been supported by the U.S. Dept. of Energy under the cooperative agreement DE-FC02- 94ER40818.

(Received 21 August 2007; revised manuscript received 12 May 2008; published 19 June 2008)

Neutral pion transverse momentum spectra were measured in p + C and p + Pb collisions at $\sqrt{s_{NN}} = 17.4$ GeV at midrapidity ($2.3 \lesssim \eta_{\rm lab} \lesssim 3.0$) over the range $0.7 \lesssim p_T \lesssim 3.5$ GeV/c. The spectra are compared to π^0 spectra measured in Pb + Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV in the same experiment. For a wide range of Pb + Pb centralities ($N_{\rm part} \lesssim 300$), the yield of π^0's with $p_T \gtrsim 2$ GeV/c is larger than or consistent with the p + C or p + Pb yields scaled with the number of nucleon-nucleon collisions ($N_{\rm coll}$), while for central Pb + Pb collisions with $N_{\rm part} \gtrsim 350$, the π^0 yield is suppressed.

The study of hadron production at high transverse momentum (p_T) is a sensitive tool to characterize the matter created in ultrarelativistic heavy-ion collisions, and, in particular, to detect the possible formation of a quark-gluon plasma (QGP), i.e., a thermalized phase in which quarks and gluons are the relevant degrees of freedom. Particles at high-p_T result from quark and gluon scatterings with high momentum transfer (''hard scattering'') which can be described by perturbative quantum-chromodynamics (pQCD). The scattered quarks and gluons will traverse the created medium and fragment into the observable hadrons. High-p_T particle production in nucleus-nucleus ($A + A$) collisions was predicted to be suppressed [1] as a consequence of the energy loss of the scattered partons in the dense matter (''jet quenching''). Such suppression was observed by experiments at the Relativistic Heavy Ion Collider (RHIC) in central Au + Au and Cu + Cu collisions at a center-of-mass energy of up to $\sqrt{s_{NN}} = 200$ GeV [2–6]. Within jet-quenching models, the suppression can be related to medium properties, such as the initial gluon density or the transport coefficient [7–9].

A crucial test for the idea of parton energy loss in the hot and dense medium created in $A + A$ collisions is the measurement of the $\sqrt{s_{NN}}$ dependence of high-p_T hadron production [7,8,10–13]. In central Pb + Pb collisions at the CERN SPS energy of $\sqrt{s_{NN}} = 17.3$ GeV ($p_{\mathrm{lab}} = 158A$ GeV/c), the initial energy density, as estimated from the measured transverse energy [14], is above the critical value $\varepsilon_c \approx 1$ GeV/fm^3 [15] for the transition to the QGP. On the other hand, the initial gluon density and the lifetime of a deconfined phase produced at $\sqrt{s_{NN}} = 17.3$ GeV will be significantly reduced as compared to RHIC energies. Results at SPS energies thereby provide a sensitive test of jet-quenching model predictions.

Results on high-p_T particle production in central Pb + Pb collisions at the CERN SPS have already been published [16,17]. However, the interpretation of these data has been complicated by the lack of reference $p + p$ data to allow to quantify nuclear effects. Instead, parameterizations of $p + p$ data have been employed to search for nuclear effects [16,18], but with substantial systematic uncertainties. Moreover, hadron suppression due to parton energy loss might be compensated by an enhancement due to multiple soft scatterings of the incoming partons prior to the hard scattering process (''nuclear k_T-enhancement'' or ''Cronin effect''). Measurements in $p + A$ and $d + A$ collisions at different $\sqrt{s_{NN}}$ suggest that such enhancement is significantly stronger at $\sqrt{s_{NN}} \approx 20$ GeV than at $\sqrt{s_{NN}} = 200$ GeV [11].

In this Letter, π^0 spectra are presented from $p + \mathrm{C}$ and $p + \mathrm{Pb}$ collisions at $\sqrt{s_{NN}} = 17.4$ GeV ($p_{\mathrm{lab}} = 160$ GeV/c) measured in the WA98 experiment. Since the nuclear k_T-enhancement in $p + \mathrm{C}$ is expected to be small [19], this measurement should provide a useful substitute for a $p + p$ reference. Information on the magnitude of the nuclear k_T-enhancement may be obtained by comparison of the $p + \mathrm{Pb}$ and $p + \mathrm{C}$ spectra. The spectra are compared to π^0 spectra measured in Pb + Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV with the same WA98 experimental setup [16].

In the WA98 experiment, π^0 yields were measured by detection of photons from the $\pi^0 \rightarrow \gamma\gamma$ decay branch with a highly-segmented lead-glass calorimeter. This detector was located 21.5 m downstream from the target and subtended the pseudorapidity range $2.3 \lesssim \eta_{\mathrm{lab}} \lesssim 3.0$. A 400 GeV/$c$ proton beam from the CERN SPS impinged on a beryllium production target to provide a mixed secondary beam selected to have momentum of 160 GeV/c. The secondary beam consisted primarily of protons and pions with roughly equal content. Protons were identified with use of two gas Cherenkov counters located upstream of the 1879 mg/cm^2 ^{12}C (495 mg/cm^2 ^{208}Pb) target. The WA98 minimum bias trigger condition required a minimum amount of transverse energy (E_T) in the region $3.5 \lesssim \eta_{\mathrm{lab}} \lesssim 5.5$, measured with a sampling calorimeter with electromagnetic and hadronic sections. The measured minimum bias cross section σ_{mb} for $p + \mathrm{C}$ ($p + \mathrm{Pb}$) of 193 mb (1422 mb) corresponds to 86% (81%) of the total geometric cross section. The number of analyzed minimum bias events was 1.2×10^6 (1.0×10^6) for $p + \mathrm{C}$ ($p + \mathrm{Pb}$). A high-energy photon (HEP) trigger based on the sum energy signal of overlapping 4×4 groups of towers in the lead-glass calorimeter was used to enhance the sample of high-p_T events. The efficiency of the HEP trigger reached ~100% for photons with $p_T \gtrsim 0.8$ GeV/c. An additional 1.5×10^6 (0.5×10^6) $p + \mathrm{C}$ ($p + \mathrm{Pb}$) HEP events were analyzed which corresponded to 3.9×10^7 (8.2×10^6) sampled minimum bias events.

Neutral pion yields were determined statistically by counting photon pairs with invariant mass in the π^0 mass range after subtraction of the normalized background from uncorrelated pairs. The shape of this background was determined by mixing photons from different events. Only photon pairs with an energy asymmetry $\alpha = |E_1 - E_2|/(E_1 + E_2) < 0.7$ were used in the analysis. A correction for geometrical acceptance and reconstruction efficiency was applied to the raw π^0 yields. The reconstruction efficiency takes into account the loss of π^0's due to the photon identification and energy asymmetry cuts. It also modifies the π^0 yield to account for the p_T shift that results from the finite energy resolution of the lead-glass calorimeter convoluted with the steeply falling π^0 p_T spectrum. Effects of overlapping showers in the calorimeter, which were important in central Pb + Pb collisions, are negligible in $p + \mathrm{C}$ and $p + \mathrm{Pb}$ collisions. The dominant systematic uncertainties are listed in Table I. The systematic uncertainties of the peak extraction, acceptance correction, and efficiency correction are approximately independent of p_T. The energy scale of the calorimeter was confirmed by comparison

TABLE I. Systematic uncertainties (in %) on the π^0 yields in $p + C$ and $p + Pb$ collisions at three p_T values.

p_T (GeV/c)	1	2	3
peak extraction	6	6	6
geometric acceptance	2.5	2.5	2.5
π^0 reconstruction efficiency	11	11	11
energy scale	5	10	20
total	14	16	24

of the measured p_T-dependent π^0 peak positions with GEANT simulations. The estimated uncertainty of 1.5% on the energy scale leads to an uncertainty on the π^0 yields that increases with p_T.

The spectra of the invariant π^0 yields in $p + C$ and $p + Pb$ collisions at $\sqrt{s_{NN}} = 17.4$ GeV are shown in Fig. 1. The transition between the minimum bias and the HEP sample occurs at $p_T = 1.7$ GeV/c. The $p + C$ spectrum is compared to a next-to-leading-order (NLO) pQCD calculation for $p + p$ at the same energy [20]. The calculation was performed with the CTEQ6M [21] parton distribution functions and the "Kniehl-Kramer-Pötter" (KKP) set of fragmentation functions [22] with renormalization and factorization scales set to be the same at $\mu = p_T/2$, p_T, or $2p_T$. For comparison with the $p + C$ data, the pQCD calculations have been scaled by the average number of

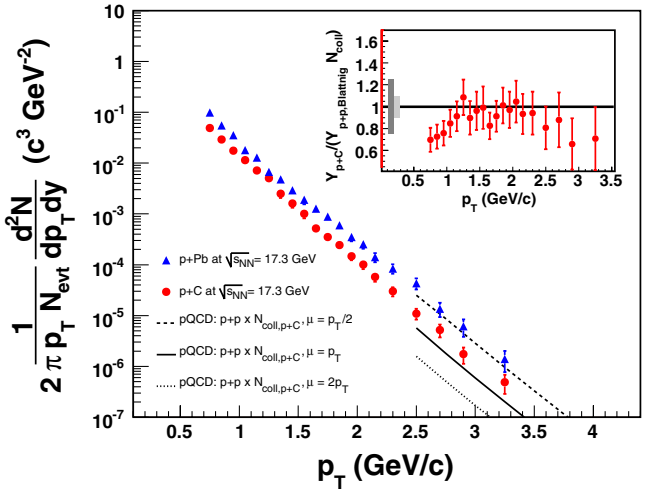

FIG. 1 (color online). Invariant π^0 yields in minimum bias $p + C$ and $p + Pb$ collisions at $\sqrt{s_{NN}} = 17.4$ GeV. The error bars represent the quadratic sum of statistical and systematic uncertainties. The lines represent next-to-leading-order pQCD calculation of the π^0 yield in $\sqrt{s} = 17.4$ GeV $p + p$ collisions for three different scales, scaled by $\langle N_{\rm coll}^{p+C} \rangle = 1.7$. The inset shows a comparison of the $p + C$ spectrum to a parameterization of the yield in $p + p$ collisions at $\sqrt{s} = 17.3$ GeV from [23]. The dark gray box indicates the uncertainty of the parameterization estimated in [18], the light gray box the uncertainty of $\langle N_{\rm coll}^{p+C} \rangle$.

nucleon-nucleon collisions in $p + C$. The pQCD calculation shows a large uncertainty related to the arbitrary choice of scale. It has been suggested that the NLO perturbative expansion is not sufficient at low energies and that threshold resummation corrections must be taken into account [20]. The large theoretical uncertainties demonstrate that pQCD calculations cannot be used as a reliable reference at CERN SPS energies. The inset of Fig. 1 shows that the π^0 yields per nucleon-nucleon collision measured in $p + C$ are in good agreement with a parameterization of π^0 spectra in $p + p$ from Blattnig *et al.* [23] that has been employed to study nuclear effects in Pb + Pb collisions [18].

Nuclear effects in π^0 production can be quantified with the nuclear modification factor defined as

$$R'_{AA} = \frac{\langle N_{\rm coll}^{p+B} \rangle}{\langle N_{\rm coll}^{A+A} \rangle} \frac{dN_{\pi^0}/dp_T|_{A+A}}{dN_{\pi^0}/dp_T|_{p+B}}. \quad (1)$$

In the absence of nuclear effects, R'_{AA} is expected to be unity for $p_T \gtrsim 2$ GeV/c where hard scattering is expected to dominate particle production. $\langle N_{\rm coll} \rangle$ was determined with a Glauber Monte Carlo calculation [24] using an inelastic nucleon-nucleon cross section of $\sigma_{\rm inel}^{NN} = (31.8 \pm 2)$ mb [25]. The same Glauber calculation was used to extract $\langle N_{\rm coll} \rangle$ values in Pb + Pb collisions. In the Glauber calculation, the transverse energy E_T was modeled by sampling a negative binomial distribution to determine the E_T contribution of each participating nucleon [24]. The bias due to the trigger selection on the measured E_T was taken into account. For minimum bias $p + C$ and $p + Pb$ collisions, values of $\langle N_{\rm coll} \rangle_{p+C} = 1.7 \pm 0.2$ and $\langle N_{\rm coll} \rangle_{p+Pb} = 3.8 \pm 0.4$ were obtained.

The $\langle N_{\rm coll} \rangle$ values for Pb + Pb collisions were determined by applying cuts to the simulated E_T that corresponded to the same fraction of $\sigma_{\rm mb}^{\rm Pb+Pb}$ as the cuts applied to the measured E_T. These $\langle N_{\rm coll} \rangle$ values are listed in Table II and agree within systematic uncertainties with those of Ref. [16] that were determined with the VENUS 4.12 event generator in which $\sigma_{\rm inel}^{NN} = 29.6$ mb was used. With the large acceptance of the WA98 E_T measurement, and good description of the E_T distribution, including fluctuations [14], a centrality class corresponding to the 1% most central Pb + Pb collisions could be defined to access very large $\langle N_{\rm coll} \rangle$ values.

The $p + Pb$ π^0 spectrum appears to be flatter than the $p + C$ spectrum (see Fig. 1). The ratio of the $N_{\rm coll}$-normalized $p + Pb$ and $p + C$ spectra is shown in Fig. 2. At low p_T (~1 GeV/c), the ratio is consistent with scaling with the number of participating nucleons ($N_{\rm part} = N_{\rm coll} + 1$ in $p + A$) while scaling with $N_{\rm coll}$ is observed at higher p_T (~2 GeV/c). In fact, for $p_T \gtrsim 2$ GeV/c, the ratio tends to be above unity, consistent with an expected stronger nuclear k_T-enhancement in $p + Pb$ than in $p + C$.

Neutral pion spectra from Pb + Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV were published by WA98 in [16]. Figure 3 shows

TABLE II. Results of the Glauber calculation for Pb + Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV ($\sigma_{\text{inel}}^{NN} = 31.8$ mb). Centrality classes are given as a fraction (%) of $\sigma_{\text{mb}}^{\text{Pb+Pb}} \approx 6300$ mb [16]. The systematic uncertainty of $\langle N_{\text{coll}} \rangle$ was parameterized as $\sigma_{N_{\text{coll}}}^2 = 0.1^2 + [0.4 \exp(-N_{\text{coll}}/100)]^2$.

class	1	2	3	4	5	6	7	8	6 − 8
from	82.8	67.0	48.8	25.3	13.0	6.8	1.0	0	0
to	100	82.8	67.0	48.8	25.3	13.0	6.8	1.0	13.0
$\langle N_{\text{part}} \rangle$	8.2	23	54.2	123.2	218.2	289.1	347.8	382.6	322.5
$\langle N_{\text{coll}} \rangle$	6.3	22.1	67.1	202.9	433.1	627.0	803.7	912.0	727.8

the π^0 nuclear modification factor R'_{AA} as defined in Eq. (1) for three Pb + Pb collision centralities. For the 25.3–48.8% (of $\sigma_{\text{mb}}^{\text{Pb+Pb}}$) most central collisions, the data points at high-p_T ($p_T \gtrsim 2$ GeV/c) suggest a stronger nuclear k_T-enhancement than in p + C. On the other hand, for the 0–13% most central Pb + Pb collisions, R'_{AA} is smaller than for the 25.3–48.8% class but still consistent with unity at high-p_T. For the 0–1% most central collisions, the π^0 yield is significantly suppressed compared to either p + Pb or p + C as reference. An apparent suppression of the π^0 yield in very central Pb + Pb collisions compared to peripheral collisions was noted in Ref. [16]. However, the large uncertainty of using the peripheral distribution as a reference did not allow to draw a firm conclusion. The observed suppression is qualitatively consistent with expectations from jet-quenching.

The centrality dependence of the average R'_{AA} for $2 < p_T < 2.5$ GeV/c and $2.5 \leq p_T < 3.0$ GeV/c is shown in Fig. 4. The π^0 yields in Pb + Pb in these p_T ranges are not suppressed for $N_{\text{part}} \lesssim 300$ ($\langle R'_{AA} \rangle \gtrsim 1$). For more central Pb + Pb collisions, $\langle R'_{AA} \rangle$ decreases with centrality indicating significant suppression of the high-p_T π^0 yield. The apparent lack of suppression, or enhancement even, for $N_{\text{part}} \lesssim 300$ may be due to competing effects of suppression due to parton energy loss and nuclear k_T-enhancement.

In summary, π^0 spectra were measured in minimum bias p + C and p + Pb collisions at $\sqrt{s_{NN}} = 17.4$ GeV in the range $0.7 \lesssim p_T \lesssim 3.5$ GeV/c. Based on these spectra, the nuclear modification factors R'_{AA} for Pb + Pb collisions at CERN SPS energies could be determined using a measured $p + A$ reference. In very central Pb + Pb collisions (0–1% of $\sigma_{\text{mb}}^{\text{Pb+Pb}}$), a significant suppression of high-p_T neutral pions was observed ($R'_{AA} \approx 0.5 \pm 0.14$) that is reminiscent of the high-p_T hadron suppression observed in Cu + Cu and Au + Au collisions at RHIC. The pion suppression reported here, together with the results at higher energies from RHIC, constrain jet-quenching models and may help clarify the behavior of the energy loss of partons in strongly interacting matter.

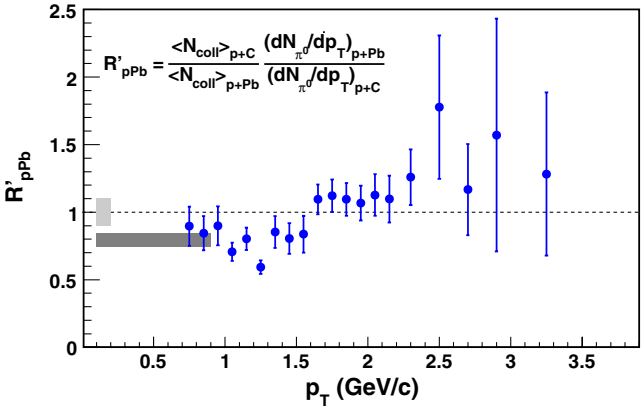

FIG. 2 (color online). The N_{coll}-normalized ratio of π^0 yields in p + Pb and p + C collisions. The box at $R'_{p\text{Pb}} \approx 0.8$ represents the expectation for the case of scaling with N_{part} rather than N_{coll}. The box at unity indicates the N_{coll} systematic uncertainty. The error bars represent the quadratic sum of the statistical and remaining systematic uncertainties. The energy scale uncertainty was assumed to cancel.

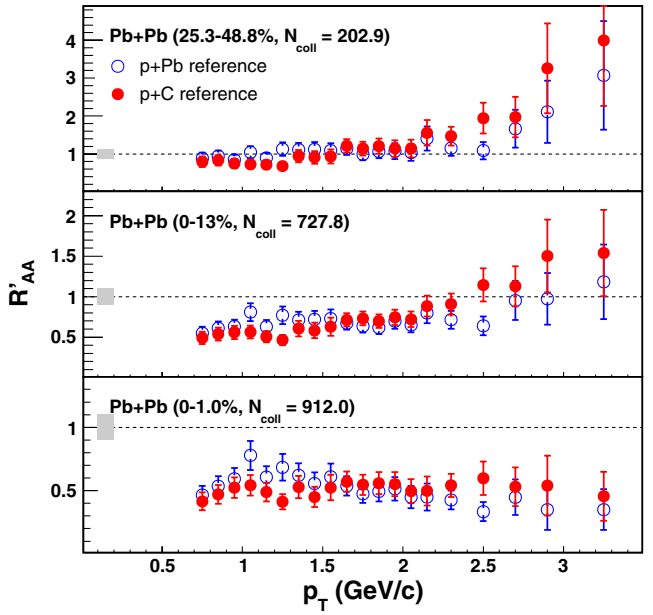

FIG. 3 (color online). π^0 R'_{AA} in Pb + Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV for three centrality classes using p + C or p + Pb spectra as a reference. The boxes around unity reflect the systematic uncertainties related to $\langle N_{\text{coll}} \rangle$.

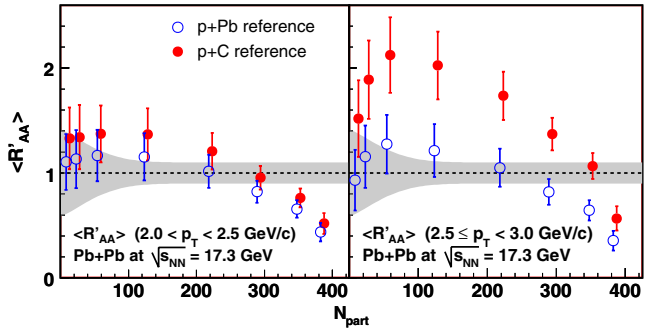

FIG. 4 (color online). Centrality dependence of the average $\langle R'_{AA}\rangle$ for $2 < p_T < 2.5$ GeV/c and $2.5 \leq p_T < 3.0$ GeV/c. The bands around unity indicate the systematic uncertainty of $\langle N_{\rm coll}\rangle$. The error bars represent the quadratic sum of the statistical and systematic uncertainties. The $N_{\rm part}$ values for the full points were shifted by $+5$ for better visibility.

We would like to thank the CERN-SPS accelerator crew for the excellent beam provided and the Laboratoire National Saturne for the loan of the magnet Goliath. We thank W. Vogelsang for providing the QCD calculation shown in this Letter. This work was supported jointly by the German BMBF, DFG, and the Helmholtz-Gemeinschaft (No. VI-VH-146), the U.S. DOE, the Swedish NFR, the Dutch Stichting FOM, the Swiss National Fund, the Humboldt Foundation, the Stiftung für deutsch-polnische Zusammenarbeit, the Department of Atomic Energy, the Department of Science and Technology and the University Grants Commission of the Government of India, the Indo-FRG Exchange Programme, the PPE division of CERN, the INTAS under Contract No. INTAS-97-0158, the Polish KBN under the Grant No. 2P03B16815, the Grant-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science, Sports and Culture, JSPS, the University of Tsukuba Special Research Projects, and ORISE. ORNL is managed by UT-Battele, LLC, for the U.S. Department of Energy under Contract No. DE-AC05-00OR22725.

Centrality dependence of charged hadron production in deuteron+gold and nucleon+gold collisions at $\sqrt{s_{NN}} = 200$ GeV

(Received 17 August 2007; published 24 January 2008)

We present transverse momentum (p_T) spectra of charged hadrons measured in deuteron-gold and nucleon-gold collisions at $\sqrt{s_{NN}} = 200$ GeV for four centrality classes. Nucleon-gold collisions were selected by tagging events in which a spectator nucleon was observed in one of two forward rapidity detectors. The spectra and yields were investigated as a function of the number of binary nucleon-nucleon collisions, ν, suffered by deuteron nucleons. A comparison of charged particle yields to those in $p+p$ collisions show that yield per nucleon-nucleon collision saturates with ν for high momentum particles. We also present the charged hadron to neutral pion ratios as a function of p_T.

I. INTRODUCTION

The measurement of hadron spectra at high transverse momenta (p_T) has been a powerful tool in studying the modification of particle production and propagation in the nuclear medium at the BNL Relativistic Heavy Ion Collider

*Deceased.
†PHENIX spokesperson: jacak@skipper.physics.sunysb.edu

(RHIC). One of the most intriguing results observed so far at RHIC is the strong suppression of the yield of hadrons with p_T above $\sim$2 GeV/c in midcentral and central Au+Au collisions relative to the corresponding yield in $p+p$ collisions scaled by the sum of independent nucleon-nucleon collisions in the Au+Au interaction [1–3]. This is consistent with a picture in which the hard scattered parton loses significant energy when it traverses the medium created during the collision [4]. There is additional evidence for the strong interaction of partons with the final state medium. For example, two particle azimuthal correlations demonstrate significant modifications of jets such as width and particle content [5,6]. In the p_T region, $2 < p_T < 5$ GeV/c, an anomalously large baryon/meson ratio is observed [7]. The coalescence of thermal and shower partons offers a possible explanation of this phenomenon as a final state effect [8].

The hadron spectrum is sensitive to final state effects including jet quenching, parton recombination, and scattering of produced particles, in addition to initial state effects, such as gluon saturation and nuclear shadowing [9], and the Cronin effect [10,11]. If shadowing or gluon saturation are actually responsible for the large suppression seen in Au+Au collisions, these same effects would also produce a suppression of 20–30% in the yield of high p_T [9] hadrons even in d+Au collisions.

To study the role of initial state effects in the high p_T suppression, d+Au collisions at RHIC serve as a control experiment, since no dense matter is expected to be formed in these collisions. Earlier measurements on inclusive hadron production in d+Au collisions show no suppression of high p_T hadrons [12,13]. Rather, there is a small enhancement in the yield of high momentum particles in d+Au collisions. This result implies that the effects seen in central Au+Au collisions are largely due to final state interactions in the dense medium.

In this paper, we extend our investigation of charged hadron production in d+Au collisions at $\sqrt{s_{NN}} = 200$ GeV at midrapidity with detailed centrality selections and with significantly higher statistics. The centrality selection allows one to make quantitative statements about the impact parameter dependence of particle production.

The nuclear modification of high p_T hadron production in proton reactions with heavy nuclei has previously been studied at lower center of mass energies [10,11]. It was found that hadron yield at high p_T in $p+A$ collisions increases faster than the nuclear mass A. This effect, known as the Cronin effect, is conventionally parametrized as A^α. At $\sqrt{s} \sim$ 10–30 GeV, α depends on p_T and is found to be greater than unity for $p_T >$ 2 GeV/c. The exponent α also depends on the particle species; it was found to be larger for baryons than for mesons. The Cronin effect is often attributed to the multiple scattering of projectile partons propagating through the target nucleus [14].

A deuteron projectile has an additional interesting characteristic: since the average separation between the proton and neutron in the deuteron is large, on the order of a few fm, there is a class of events in which only one of the two nucleons participates in the collision. Thus d+Au events can be categorized into "p"+Au or "n"+Au collisions, when only one of the constituent nucleons interacts, and pn+Au, when both nucleons participate in the collision. In such events, the interacting proton or neutron is not a free proton or neutron, so it is not exactly the same as a p+Au or n+Au interaction. For simplicity we will refer to the tagged samples as p+Au and n+Au and collectively N+Au. The selection of p+Au and n+Au collisions in the PHENIX experiment is done by tagging events where the incoming deuteron has a noninteracting neutron or proton. Combined with centrality selection, such event tagging provides better control of the collision geometry and of the number of subsequent inelastic nucleon-nucleon interactions in the gold nucleus.

Very little experimental information has been published about neutron-nucleus collisions at high energy. Tagging allows the direct comparison of pn+Au, p+Au, and n+Au interactions. Results from these collisions are compared with $p+p$ data measured by the PHENIX experiment at the same beam energy to shed light on the Cronin enhancement and other nuclear effects. Further, we have investigated the Cronin effect as a function of the number of collisions per participant nucleon in the deuteron. To estimate the fraction of pions in the charged hadron spectrum, we have looked at hadron to pion ratios as a function of transverse momentum.

The paper is organized as follows. Section II gives a detailed account of the analysis in which we describe the detector, centrality selection, charged particle background rejection, spectra corrections, and systematic errors. In Sec. III, the centrality and p_T dependence of the charged hadron spectra and a comparison with the $p+p$ and the π^0 data are discussed. A summary is given in Sec. IV.

II. EXPERIMENT AND ANALYSIS

A. Detector

The PHENIX detector consists of four spectrometer arms positioned around the vertex of colliding deuteron and gold nuclei—two central arms at midrapidity and two muon arms at forward rapidities—and a set of detectors. A detailed description of the detector can be found elsewhere, see Ref. [15] and references therein. This analysis uses the two central arms and the set of global detectors.

Each central arm covers the pseudorapidity range $|\eta| <$ 0.35, and 90° in azimuth. Charged particles are tracked by drift chambers (DCs) located 2 m from the vertex and layers of pad chambers (PC1 and PC3) positioned at 2.5 and 5 m in the radial direction. The central spectrometer provides axial magnetic fields along the beam pipe. The transverse momentum p_T of each particle is determined by its deflection angle in the azimuthal direction as measured by the DC. The total particle momentum is reconstructed by projecting tracks back to the collision vertex through the magnetic field. The track reconstruction efficiency is approximately 98% and independent of p_T with negligible centrality dependence. The particle momenta are measured with a resolution $\delta p/p = 0.007 \oplus 0.011\,p$, with p in GeV/c. The absolute momentum scale is calibrated to 0.7% from the reconstructed proton mass using the PHENIX time-of-flight system. At high transverse momentum, a substantial background of electrons is produced by photon conversion in the material between the beam pipe and drift chambers. To subtract this background from photon

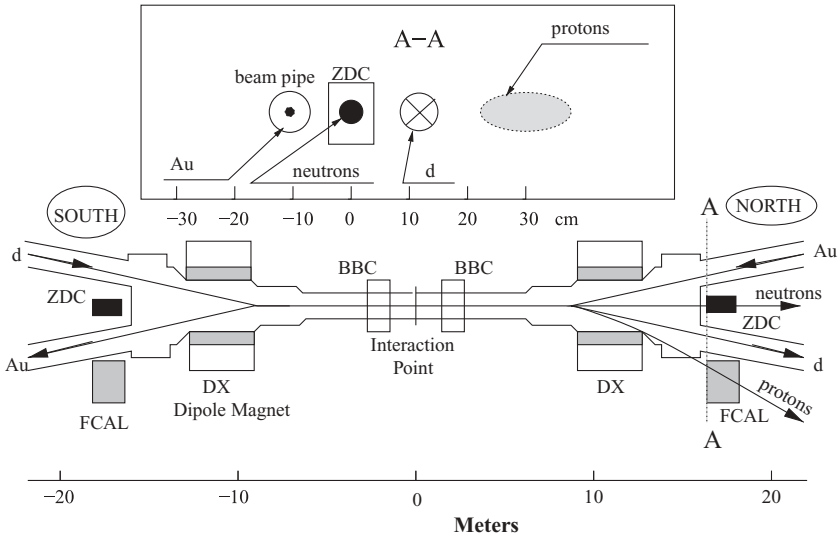

FIG. 1. FCAL, ZDC, and BBC positions relative to the vertex. The vertical scale in the figure is arbitrary. The insert at the top shows the position of primary beam, spectator neutron, and proton spots at the FCAL and ZDC locations; deuteron beam, spectator neutrons, and protons go into the plane, the gold beam is coming out of the plane.

conversion, we use the ring imaging Cherenkov detector (RICH). The RICH is filled with CO_2 gas at atmospheric pressure and has a charged particle threshold $\gamma_{\text{th}} = 35$ for emission of Cherenkov photons.

To characterize the global parameters of the collision and its centrality, the PHENIX experiment uses beam-beam counters (BBCs) covering the pseudorapidity range $3.0 < |\eta| < 3.9$, zero degree calorimeters (ZDCs) and forward calorimeters (FCALs) located at $|\eta| > 6$. The locations of these global detectors are schematically shown in Fig. 1. Each BBC is an array of 64 Cherenkov counters around the beam pipe and is positioned at 1.44 m upstream or downstream of the nominal vertex location. The information from the BBC is used for the event timing, vertex position, and centrality determination. The two ZDCs are hadronic calorimeters which measure spectator neutrons [16]. They are located 18 m from the interaction point. At the top RHIC energy of 100 GeV/nucleon, neutrons evaporated from the spectator remnants of the collision are emitted within 1 mrad from the colliding beam direction. Charged fragments and the noninteracted primary beam are bent by deflecting (DX) magnets to much larger angles. The ZDC measures the total neutron energy within a small cone and with this provides the number of spectator neutrons from the interacting nucleus. The ZDC on the north side measured 100 GeV neutrons from deuteron fragmentation with a resolution of $\sigma = 28$ GeV.

The forward calorimeters were installed before the d+Au run. The FCAL is a hadron calorimeter and consists of lead scintillating fiber modules originally used in BNL Alternating Gradient Synchrotron (AGS) Experiment E864 [17] rearranged into two 9 by 10 arrays. The only difference from the E864 experiment is the readout electronics, which are identical to PHENIX central arm electromagnetic calorimeter electronics. The size of each module is $10 \times 10 \times 117$ cm, the average tower density is 9.6 g/cm^3, and the total length corresponds to 60 nuclear interaction lengths. The two arrays are located 18 m from the interaction point along the beam pipes downstream of the first beam-line deflecting (DX) magnet. The DX magnets work as sweeping magnets for the spectator protons. The FCAL measures the energy of the spectator protons. The resolution of the FCAL on the north side for measuring 100 GeV protons from the deuteron fragmentation was $\sigma = 40$ GeV.

B. Centrality analysis

The present analysis is based on minimum bias events, defined by a coincidence of at least one photomultiplier each in the north and south BBCs. The data were taken for events with vertex position within $|z| < 30$ cm along the beam axis. A total of 6.2×10^7 events were analyzed, which corresponds to 1.6 nb^{-1} of total integrated luminosity. At this vertex cut, the minimum bias trigger cross section measured by BBC is $1.99\,\text{b} \pm 5.2\%$ [18]. Thus at the trigger efficiency [12] of $88.5\% \pm 4\%$ we get the total inelastic d+Au cross section of 2.26 ± 0.1 b. Centrality classes in d+Au events were defined by charged particle multiplicity in the BBC south (BBCS) (the gold fragmentation side). We assume that the number of charged particles firing the BBCS is linearly proportional, on average, to the number of participants from the gold nucleus in the reaction. To check this, the BBCS response was simulated as a superposition of independent N_{targ} nucleon-nucleon type reactions, where N_{targ} is the number of participating nucleons in the struck gold nucleus. As a baseline for the BBCS modeling, we use unbiased data from previous RHIC p+p runs where proton-proton inelastic collisions were selected with a trigger synchronized to fire whenever filled bunches crossed in the PHENIX interaction region. N_{targ} was calculated using a Glauber model [12] with a particular parameter set [19]. The resulting distribution for minimum bias events is plotted in Fig. 2 together with experimental data.

The calculation appears to follow the general features of the data distribution, which supports our assumption that the number of BBCS firings is proportional to N_{targ}. We define four centrality classes for d+Au collisions by slicing the BBCS multiplicity distribution into four regions, A, B, C, and D (Fig. 3). These regions were selected to define in d+Au collisions four centrality classes 0–20%, 20–40%, 40–60%, and 60–88%, respectively. We have taken into account the

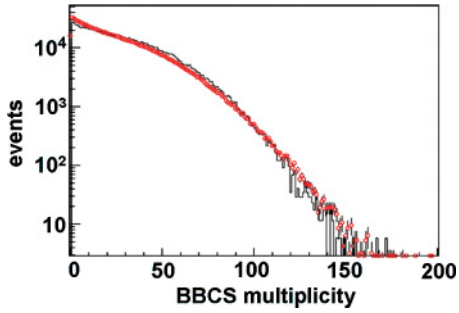

FIG. 2. (Color online) Comparison between the experimental data hit distribution in BBCS in d+Au collisions (open circles) and the calculated BBCS hit distribution (solid line).

limited trigger efficiency for the peripheral collisions. The tagged sample, in which only one nucleon from the deuteron projectile interacts, has a differently shaped BBCS multiplicity distribution than the general data. Nevertheless, for both the tagged sample and the general data, the same BBCS selections were used to define the collision centrality.

In the Glauber model Monte Carlo simulation of d+Au collisions, the deuteron wave function was represented by the Hulthén form [19].[1] The square of this wave function determines the probability distribution for the proton-neutron distance in the deuteron, as shown in Fig. 4. The deuteron is a large system with a mean proton-neutron distance of about 3 fm and a significant probability to be larger. In the left side of Fig. 5, we present the calculated impact parameter distributions of d+Au collisions and the tagged N+Au sample. On the right side of Fig. 5, the corresponding distributions of the number of collisions per participant nucleon from the interacting deuteron, ν, are plotted. The parameter ν is comparable to the number of collisions suffered by the proton in p+A experiments. The impact parameter b is defined as the distance

[1]For the gold nucleus, we use the Woods-Saxon density distribution with radius $R = 6.38$ fm, diffuseness parameter $a = 0.54$ fm, and N-N cross section $\sigma_{NN}^{\text{inel}} = 42$ mb. The deuteron is described by a Hulthén wave function with $\alpha = 0.228\,\text{fm}^{-1}$ and $\beta = 1.18\,\text{fm}^{-1}$, see Ref. [19].

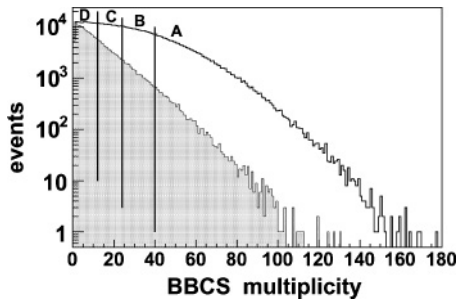

FIG. 3. Multiplicity distribution in BBCS, located on the gold nucleus fragmentation side. Four centrality classes for d+Au collisions are defined by slicing the BBCS distribution, shown with vertical lines. The same multiplicity cuts were used for the tagged sample of p+Au and n+Au events, the summed distribution of which is shown in the lower histogram.

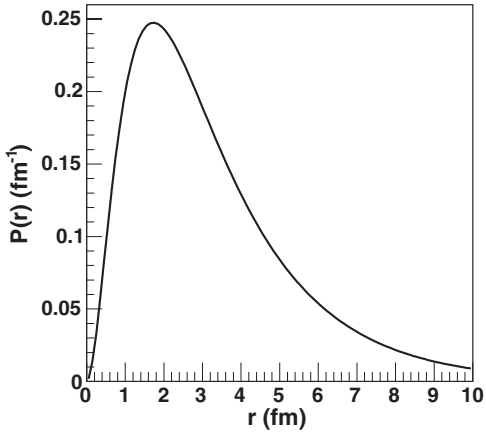

FIG. 4. Probability density distribution for the proton-neutron distance in the deuteron given by the square of the Hulthén wave function [19].

between the centers of the colliding nuclei, Au and d. This means that for the tag sample, the interaction point of participant nucleon from the deuteron is closer to the Au center than the distance b, and the spectator nucleon leaves the interaction region at a distance larger than b. We also did a Monte Carlo simulation with the most recent deuteron wave function parametrization from Ref. [20]. We found that the difference between the calculation with the Hulthén form and the most recent parametrization for the number of nucleon collisions does not exceed 1%.

In Fig. 6, we illustrate our tag selection cuts. A p+Au collision event is tagged by the detection of a spectator neutron in the ZDC north (ZDCN) on the deuteron fragmentation side. Similarly, we use the FCAL north (FCALN) on the deuteron fragmentation side to detect a spectator proton and thereby tag n+Au collision events. The scatter plot in Fig. 6 shows the ZDCN and FCALN signals and has three distinct regions. Region 1 is defined as small or no signal in both the ZDCN and FCALN, which corresponds to the case in which both nucleons from the deuteron interact with the Au nucleus. Region 2 has a small signal in the ZDCN and about 100 GeV amplitude signal in the FCALN. This corresponds to tagged n+Au collisions. Region 3 has a small signal in the FCALN and about 100 GeV energy release in the ZDCN. Events in this region are tagged p+Au events. In Region 3, there is a small (anti) correlation between the ZDCN and FCALN. The reason for this is the close proximity of the FCALN to the ZDCN, see Fig. 1. The ZDCN effectively acts as a secondary target for 100 GeV spectator neutrons. There is some contamination of secondary particles produced in the ZDCN into the large volume FCALN.

The purity of the tag samples from possible background contamination was thoroughly investigated. Figure 7 shows ZDCN and FCALN responses for the most central events. Background may contribute to the tag sample from the left side of the spectrum with low amplitudes. To estimate the background contamination, we fitted the left part of the spectrum using an exponentially falling function and fitted a Gaussian function to the detector response to the spectator nucleon. The thin smooth line in Fig. 7 shows the sum of the

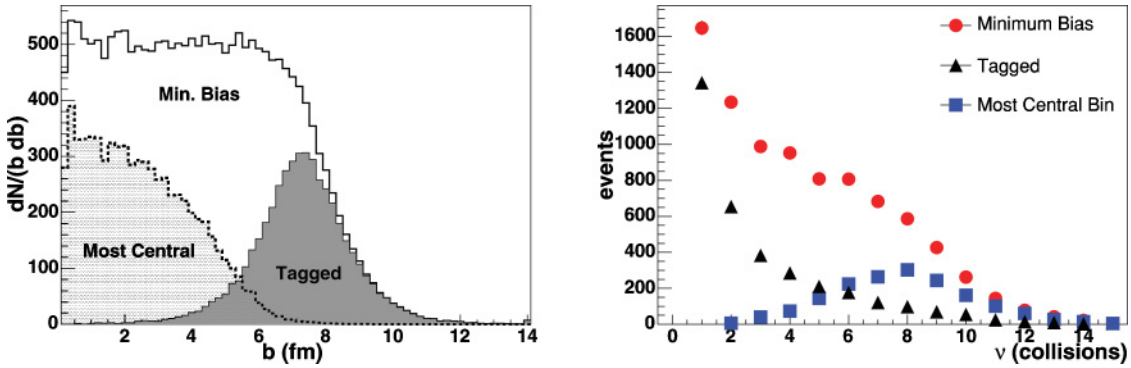

FIG. 5. (Color online) Left: impact parameter distribution for the minimum bias d+Au collisions, for the most central events (centrality bin A), and for the tagged sample. For tagged events, the impact parameter was defined from the center of the deuteron. Right: the corresponding distribution of the number of collisions per participant nucleon from deuteron, ν.

two functions. The background under the Gaussian peak was estimated as the integral of the exponential function above our cut, which is marked by the vertical line and arrow. In central p+Au events, we estimate 2.8% contamination in the ZDCN spectrum. For more peripheral events, this contamination decreases and reaches 1.4% in the most peripheral bin.

The background contamination in the FCALN defined n+Au sample is more complicated. For the most central events, as shown in Fig. 7 on the right, the background contributes 0.4% to the area above our cut. As centrality changes, so too does the shape of the background spectrum. Figure 8 illustrates the problem of background estimation. Attempts to fit the background spectrum with an exponential function, as was done for central events, failed. The sum of the estimated background and the Gauss fit is well above the experimental data, implying that the background spectrum falls much faster than a simple exponential function. However, the relevant question in assessing the background contamination is not its absolute or relative value, but rather how much it could distort our experimental data. The goal of this analysis is to measure the charged hadron spectrum in the PHENIX central arms. Thus, we can estimate the stability of our results measured by the central arms versus different cuts applied to the FCALN. We define the stability of the measurement, S, in a particular FCALN bin (Fig. 9) as the ratio of the number of charged particle tracks per event with $p_T > 0.5\,\mathrm{GeV}/c$ for this cut to a reference cut in which the signal to background ratio is the largest. For the reference cut, we use 100 ± 20 GeV FCALN response (within region 3 as defined above). This is the most probable detector response for a spectator proton, as seen in Fig. 8. We observe that in the region just to the left of our reference cut, where we may expect about equal amount of signal and background events, the parameter S is only 3% smaller than unity, as seen in Fig. 9. Within errors, S does not depend on track momentum. Thus, in the worst case, the background contamination effect is less than 2% for events above our cut in the n+Au tagged sample.

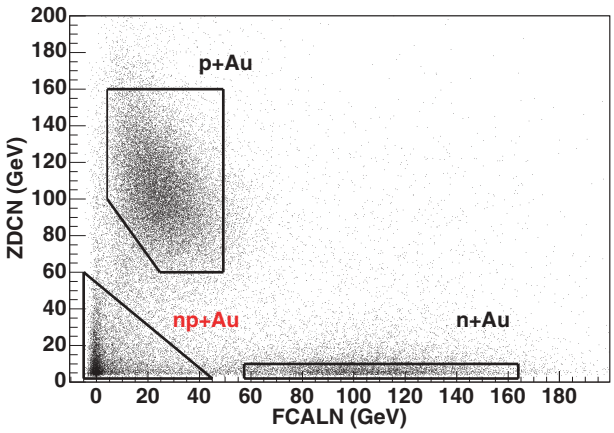

FIG. 6. (Color online) Scatter plot of ZDCN and FCALN signals on the deuteron fragmentation side. Solid lines show cuts which define the p+Au and n+Au collisions.

We do not correct the tagged sample results for any contamination. We average the two tagged samples to form a single nucleon+Au (N+Au) sample.

For each of the four BBCS multiplicity regions shown in Fig. 3, using a Monte Carlo model within the Glauber multiple collision formalism [21], we calculate for the d+Au and the tagged N+Au collisions the average number of participating nucleons N_{part}, the nuclear overlap function T_{AB}, the number of collisions N_{coll}, and number of collisions per participant nucleon from the deuteron ν. The calculated values are presented in Table I. The nuclear overlap function T_{AB} is defined as

$$T_{AB}(b) = \int d^2\,\vec{s}\; T_A(\vec{s})\, T_B(|\vec{b} - \vec{s}|)\,, \tag{1}$$

where the integration is performed over the element of overlapping area $d^2\,\vec{s}$, and $\vec{s} = (x, y)$ is a vector in the transverse plane of interacting nuclei at the impact parameter $\vec{b}$ between the centers of the nuclei. For nucleus A, the nuclear thickness function $T_A(b)$ is defined as

$$T_A(b) = \int dz\, \rho_A(b, z)\,. \tag{2}$$

Normalization of $T_{AB}(b)$ is done by integration over all impact parameters:

$$\int d^2\, b\, T_{AB}(b) = A\, B. \tag{3}$$

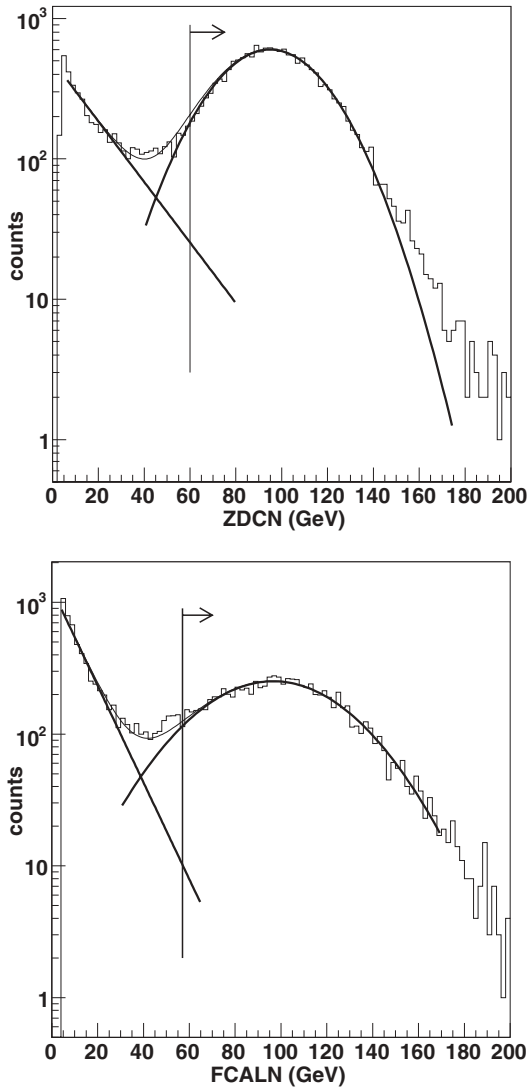

FIG. 7. ZDCN and FCALN spectra for the most central tagged events. Detector response to the spectator nucleon is fit with a Gauss function. Background from the left side of the spectra was fit to an exponential function and extrapolated to the region above our cuts. All events to the right of the cuts, shown by vertical solid lines, were defined as a tag sample.

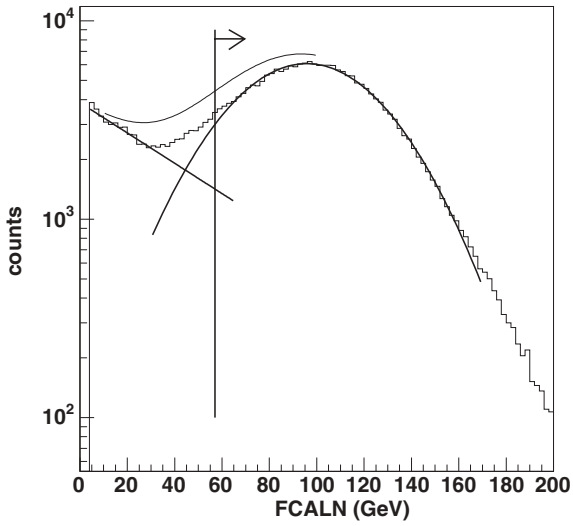

FIG. 8. FCALN spectrum for the most peripheral tagged events, with the same line notation as Fig. 7. The plot illustrates the difficulty of evaluating the background contribution in the most peripheral collisions: background fit with an exponentially falling spectrum significantly overestimates the contribution to the events above our cut.

The average number of binary inelastic nucleon-nucleon collisions at impact parameter b was calculated from $T_{AB}(b)$ as

$$\langle N_{\rm coll}\rangle = \sigma_{NN} T_{AB}(b)\,, \tag{4}$$

where σ_{NN} is the inelastic nucleon-nucleon cross section [19].

An additional multiplicative correction factor, $C_{\rm BBC}$, see Table I, has been applied to the data for different centrality bin selections [22]. This correction addresses two effects, each of which distorts the centrality classification in the opposite direction. Because of natural fluctuations in the number of produced charged particles at a particular impact parameter, the BBCS centrality selections have imperfect resolution. In the case of a steeply falling BBCS multiplicity spectrum, especially for the tagged sample (see Fig. 3), there is a contamination of peripheral collision events into a more central event class. This effectively decreases the actual number of $N_{\rm coll}$ and particle production in the central events. The second

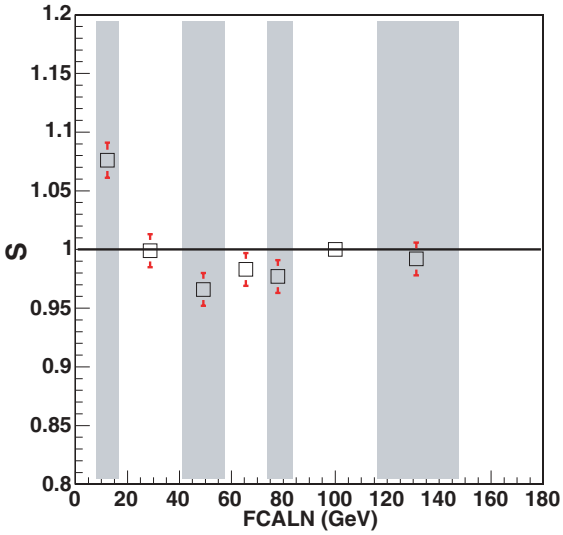

FIG. 9. (Color online) Stability of the results for different FCALN bins, see text for details.

effect is due to the BBC coincidence required for a PHENIX event trigger. In all calculations, we used for the inelastic nucleon-nucleon cross section $\sigma_{NN} = 42$ mb. Actually, this cross section has three components: nondiffractive collisions with 28 mb, single diffractive collisions with 10 mb, and double diffractive collisions with 4 mb cross section [23]. From Monte Carlo simulation of $p+p$ collisions, we found BBC trigger efficiencies of about $(72 \pm 1)\%$, $(7 \pm 1)\%$, and $(32 \pm 1)\%$, for each process, respectively. In the Monte Carlo simulation, we use the PYTHIA 6.2 event generator [23] and the GEANT simulation of the BBC detector. Single and double diffractive collisions produce particles dominantly near the beam rapidity and thus have a small probability for particle production in the BBC acceptance of $3.0 < |\eta| < 3.9$, and an even smaller probability at midrapidity. Therefore, the BBC trigger is biased to the nondiffractive collisions, which have larger particle production at midrapidity. In more central events as the number of nucleon-nucleon collisions increases, the probability that there will be at least one nondiffractive collision approaches 100%; thus the BBC bias becomes negligible in central events.

C. Charged hadron analysis

The present analysis follows the methods of the analysis described in Ref. [3]. The majority of background tracks are particles with low momenta, which in traveling from DC to PC3 undergo multiple scattering and are additionally deflected in the residual magnetic field behind the DC.

To minimize this background, we employ a track matching cut in the PC3 that rejects tracks whose displacement in the ϕ or z direction, D_ϕ and D_z, respectively, is greater than 2.5 standard deviations. In addition, we make a fiducial cut around the z vertex determined by the BBC. Despite these veto cuts, there is still significant background contamination for p_T above $4\,\mathrm{GeV}/c$ which must be subtracted. The main sources of the remaining background are e^+e^- pairs from photon conversions in the material between the collision vertex and the drift chamber, and secondary particles produced by hadron decays.

To distinguish these backgrounds, we use the RICH detector to divide all tracks into two subsets: tracks with an associated RICH signal, N_R, and tracks with no signal in the RICH, N_{NR}. Tracks with at least one hit in the RICH contain high p_T pions and conversion electrons. For reconstructed electrons with momentum above $150\,\mathrm{MeV}/c$, the average number of photomultiplier tube (PMT) hits in the RICH associated with the track is $\langle N_{\mathrm{PMT}} \rangle \approx 4.5$.

The RICH detects more than 99% of all conversion electrons for $N_{\mathrm{PMT}} \geqslant 1$. At this threshold the RICH also detects pions with $p_T \geqslant 4.8\,\mathrm{GeV}/c$, but the number of associated PMTs for pions reaches its asymptotic value well above $10\,\mathrm{GeV}/c$; for a $10\,\mathrm{GeV}/c$ pion $\langle N_{\mathrm{PMT}} \rangle = 3.6$. Therefore we label tracks with $N_{\mathrm{PMT}} \geqslant 5$ as electron tracks, N_e, which compose some fraction, R_e, of conversion electrons. To calculate this fraction, we take advantage of the deflection of conversion electrons in the magnetic field between the DC and PC3. This deflection leads to poor track matching in PC3 which distinguishes electrons from true high p_T pions. We define poor PC3 track matching as a displacement of more than four standard deviations in the ϕ direction. Thus we measure the value of R_e as the fraction of N_R with $4\sigma < |D_\phi| < 10\sigma$. For minimum bias events, we find $R_e = 0.41 \pm 0.01$. The real pion signal S_R in the N_R sample, is calculated for each p_T bin as

$$S_R = N_R - \frac{N_e}{R_e}. \tag{5}$$

The PC3 distribution for the conversion subtraction is shown on the left side of Fig. 10. The conversion subtraction is performed independently in each centrality bin. The definition of N_e (tracks with $N_{\mathrm{PMT}} \geqslant 5$) does not perfectly select electron tracks, as some fraction of pions satisfies the cut. This leads to a fraction of authentic pions, which have $N_{\mathrm{PMT}} \geqslant 5$, being subtracted along with the conversion electrons. This fraction is small below $7\,\mathrm{GeV}/c$, but increases rapidly for higher p_T. We calculate a correction factor to address this over-subtraction, using a Monte Carlo simulation of the detector. The uncertainty associated with this correction, $\delta_{\pi\,\mathrm{loss}}$, is shown later in Table III.

The hadron decay background is of two types: "decay" and "feed down." The decay background is produced by π and K decays far from the source and thus with reconstructed momenta different from their true momenta, whereas the feed-down background is produced by weak decays of short-lived particles, mostly K^0_s and Λ particles near the event vertex with apparent momenta close to their true momenta.

From tracks with no RICH signal, the N_{NR} sample, we define a subsample by selecting tracks with $p_T > 10.5\,\mathrm{GeV}/c$, a p_T region which is almost exclusively background. We expect that its shape in D_ϕ will be the same as the background in the lower p_T region. Within this subsample we calculate the ratio R_{decay} of tracks which pass the PC3 cut ($|D_\phi| < 2.5\sigma$) to those with a poor match ($4\sigma < |D_\phi| < 10\sigma$). For minimum bias events, $R_{\mathrm{decay}} = 0.55 \pm 0.03$. For each momentum bin, the total decay background is then obtained by multiplying

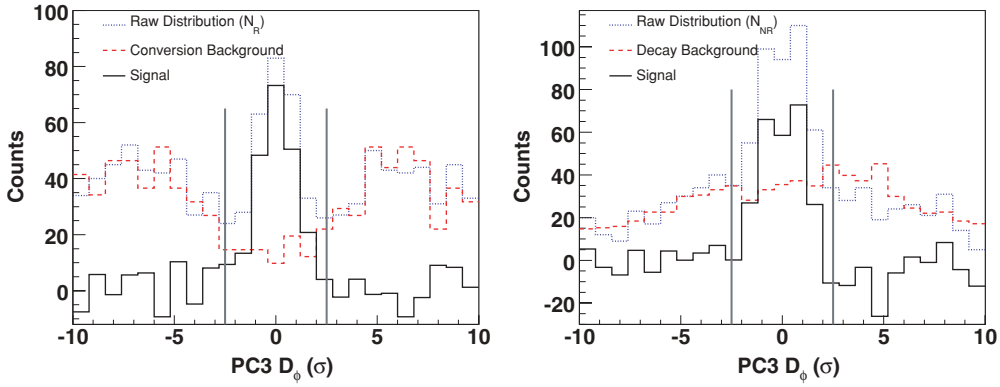

FIG. 10. (Color online) PC3 D_ϕ distributions for the conversion subtraction (left) and the decay subtraction (right) shown for minimum bias with $6 < p_T < 7\,\mathrm{GeV}/c$. The raw distributions, N_R and N_{NR} for conversion and decay, respectively, are shown with dotted lines. The estimated conversion background shown with a dashed line is N_e/R_e. The estimated decay background, shown with a dashed line, was obtained by scaling the PC3 distribution of N_{NR} tracks with $p_T > 10.5\,\mathrm{GeV}/c$ based on the $(4\sigma < |D_\phi| < 10\sigma)$ region. In both plots, the signal is the raw minus the estimated background distributions. The vertical bars show the track matching cuts at $\pm 2.5 D_\phi$.

the N_{NR} tracks with poor PC3 matching $(4\sigma < |D_\phi| < 10\sigma)$ by R_{decay}. The PC3 distribution for the decay subtraction is shown on the right side of Fig. 10. The decay background as a function of p_T is measured and subtracted independently in each centrality bin.

The feed-down subtraction addresses the detected π and p particles that were produced in the decays of K^0_s and Λ particles, so we define the total feed-down contamination as

$$C_{\mathrm{feed}} = \frac{(p+\pi)^{\mathrm{feed}}}{h^{\mathrm{detected}}}, \tag{6}$$

averaging over charged particle and antiparticle yields. For feed-down estimation, we have no statistical recourse and must resort to simulation to find the contamination. We assume that the spectral shapes of the K^0_s and Λ follow the shapes of the charged kaon and proton spectra, respectively. There is good agreement of Monte Carlo simulations in d+Au [24] and minimum bias Au+Au [3] for proton feed down. We therefore use the Au+Au Monte Carlo simulation, which also includes K^0_s to pion processes, to obtain the ratio $(p+\pi)^{\mathrm{feed}}/(p+K)^{\mathrm{detected}} = 0.2$, after the decay background subtraction. To make use of this ratio, we rewrite the contamination as

$$C_{\mathrm{feed}} = \frac{(p+\pi)^{\mathrm{feed}}}{(p+K)^{\mathrm{detected}}} \frac{(p+K)^{\mathrm{detected}}}{h^{\mathrm{detected}}}. \tag{7}$$

To find the contamination, we use the fraction of p+K particles in our measured hadron sample. To do so, for p_T less than $2.5\,\mathrm{GeV}/c$, we use the PHENIX published data on identified hadron production in d+Au [24]. We explicitly calculate the $(p+K)^{\mathrm{detected}}/h^{\mathrm{detected}}$ ratio from those data. At higher p_T assuming π^0 has the same yield as $\pi^\pm$, we subdivide this ratio as

$$\frac{p+K}{h} = \frac{p+K}{\pi}\frac{\pi}{h} = \left(\frac{p}{\pi} + \frac{K}{\pi^0}\right)\frac{\pi^0}{h}, \tag{8}$$

so that the right-hand side consists of all measured quantities. The p/π ratio is taken from STAR measurements [25] scaled to match the PHENIX data [24] in their common p_T region. The K/π^0 ratio is calculated from Refs. [12] and [26]. The ratio of π^0's to hadrons is calculated from the charged hadron measurement of this analysis and π^0 measurements in Ref. [12]. From both the low and high p_T regions, C_{feed} is calculated to be 9.6%. To this factor we assign a 50% systematic uncertainty based on uncertainty of the various particle ratios and the Monte Carlo simulation. C_{feed} is shown in Fig. 11. We correct for the effects of feed-down decay by multiplying the spectra remaining after the conversion and decay subtraction by $1 - C_{\mathrm{feed}}$.

Following the background subtraction, we constructed a single, p_T dependent correction function to correct the hadron spectra for acceptance, decay in flight, reconstruction efficiency, and momentum resolution. The correction is determined by using a Monte Carlo simulation [27] of the PHENIX detector. The correction function is necessarily particle species dependent to take into account multiple

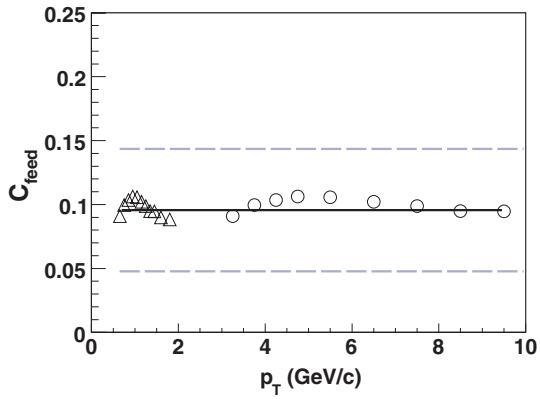

FIG. 11. Feed-down contamination as the ratio of protons and charged pions from feed-down decays to total detected charged hadrons. The low p_T points shown with triangles are calculated using the fraction of p+K particles to hadrons measured in Ref. [24]. The higher p_T points are calculated using the various ratios of Eq. (8). The solid line is a fit to both sets of points and is used as C_{feed}. It is bracketed by dashed lines showing the assigned 50% systematic uncertainty.

scattering and decays, therefore we calculate separate correction functions for $\pi^+, \pi^-, K^+, K^-, p^+$, and p^-. The individual functions are weighted by the particle p_T spectra measured in peripheral Au+Au collisions [28] to form a single correction factor, $C_{\rm MC}(p_T)$, subject to a systematic uncertainty, $\delta_{\rm MC\,weight}$, stemming from uncertainty on the particle mixture [12]. For absolute normalization of the spectra, we match the geometrical acceptance of the Monte Carlo simulation with the actual acceptance of the data. To obtain the charged hadron yield, we multiply the background-subtracted spectra by the correction function. We normalize each centrality bin by dividing by the number of events, and each momentum bin by dividing by its bin width. Each data point is corrected so its value corresponds to the bin center. We define the invariant hadron yield as

$$\frac{1}{N_{\rm evt}}\frac{d^2N}{2\pi p_T\,dp_T\,d\eta} = \left(\frac{d^2N}{2\pi p_T\,dp_T\,d\eta}\right)^{\text{bkg-subtracted}} \times \frac{1}{N_{\rm evt}}(1 - C_{\rm feed})C_{\rm MC}(p_T)C_{\rm BBC}. \quad (9)$$

All of the preceding steps are applied to the tagged N+Au (nucleon+gold) sample as well as to the general d+Au sample.

We further examine the d+Au invariant yields by comparing them with the invariant yield from p+p collisions. Previous experiments have demonstrated the suppression of charged hadron and pion yields in Au+Au collisions [3]; such suppression can be quantified by the nuclear modification factor R_{AB}. For any collision of nuclei A+B, R_{AB} is calculated for each centrality class as the ratio of the yield in A+B collision to the cross section in p+p collisions scaled by the nuclear overlap function $\langle T_{AB}\rangle$, that is,

$$R_{AB}(p_T) = \frac{(1/N_{\rm evt})\,d^2N^{A+B}/dp_T\,d\eta}{\langle T_{AB}\rangle\,d^2\sigma^{p+p}/dp_T\,d\eta}. \quad (10)$$

$\langle T_{AB}\rangle$ is determined by the density distribution in the nuclei A and B and is averaged over the impact parameter range within a particular centrality class. In our case, nucleus A refers to the deuteron (or the single nucleon in tagged events), and nucleus B refers to the gold nucleus. $\langle T_{AB}\rangle$ values are presented in Table I. Using the PHENIX p+p spectra [29], we thus calculate $R_{d\rm Au}$ and $R_{N\rm Au}$.

We estimate systematic uncertainties in the methods and assumptions of our analysis as displayed in Tables II and III. Table II shows uncertainties in the spectra that do not vary with p_T, and Table III shows uncertainties that vary with p_T. All the uncertainties listed in Table II propagate into the R_{AB} and the hadron/π^0 ratio, although the uncertainty from the feed-down correction partially cancels in the R_{AB} because of an analogous uncertainty in the p+p reference spectrum. The background subtraction and momentum scale uncertainties only partially cancel in the R_{AB}; the momentum resolution uncertainty and $\delta_{\pi\,\rm loss}$ fully cancel. The p+p reference spectrum also introduces an uncertainty that ranges from 10.7% in the low p_T bins to 11.3% at $p_T > 2\,{\rm GeV}/c$. The π^0 analysis [13] we used in the hadron/π^0 ratios applies the same BBC bias correction factors as the present analysis, and therefore the uncertainty stemming from this correction factor is canceled.

TABLE II. Systematic uncertainties that are constant for all values of transverse momentum p_T.

Source	Uncertainty (%)
Geometric acceptance correction	2.9
Track matching	2.2
Run-by-run variation	5
Feed-down correction	4.8
$\delta_{\rm MC\,weight}$	3.7
Total	8.7

TABLE III. Systematic uncertainties that vary with p_T. Background subtraction (Bckg. sub.) uncertainties refers to the 0–88% d+Au spectra; the uncertainties are greater in the more peripheral d+Au and more central N+Au spectra.

p_T (GeV/c)	Mom. res. (%)	Mom. scale (%)	Bckg. sub. (%)	$\delta_{\pi\,\rm loss}$ (%)	Total (%)
<4.5	<0.5	<3.2	<0.1	<0.3	<3.3
4.5–5.5	<0.6	3.3	0.5	0.5	3.4
5.5–6.5	0.8	3.5	1.4	1.1	4.0
6.5–7.5	1.0	3.6	2.0	3.6	5.6
7.5–8.5	1.4	3.7	4.9	6.9	9.3
8.5–9.5	1.8	3.8	11.9	13.9	18.8

III. RESULTS

The fully corrected p_T distributions of $(h^+ + h^-)/2$ for d+Au and N+Au collisions for minimum bias and four centrality classes are shown in Fig. 12. The d+Au data are in good agreement with the sum of identified hadrons published in Ref. [24].

The N+Au sample is averaged over p+Au and n+Au events. This is based on the good agreement between the yields of the two tagged samples, as shown in Fig. 13.

Figure 14 shows $R_{d\rm Au}$ and $R_{N\rm Au}$. As expected, in the most peripheral N+Au bin, with $N_{\rm coll} = 2.1$, $R_{N\rm Au}$ is consistent with unity. $R_{d\rm Au}$ and $R_{N\rm Au}$ are in agreement within our uncertainty bounds.

The enhancement of the hadron yield relative to p+p collisions has previously been observed in lower energy p+A collisions [10,11], and is called the Cronin effect. We observe that $R_{d\rm Au}$ and $R_{N\rm Au}$ are systematically larger than unity in the momentum range between 1.5 and 5 GeV/c with maximum amplitude around 1.3.

There are many theoretical models with very different assumptions about initial state effects, which describe the Cronin effect [30–32]. All the models agree that there is at least one additional scattering of the initial nucleon or parton while propagating though the target nucleus. This scattering increases the intrinsic transverse momentum of the colliding parton and leads to a broadening of the parton p_T distribution. We can parametrize the effect of this broadening by writing the mean value of parton intrinsic momentum k_T as

$$\langle k_T^2\rangle_{pA} = \langle k_T^2\rangle_{pp} + \langle k_T^2\rangle_A, \quad (11)$$

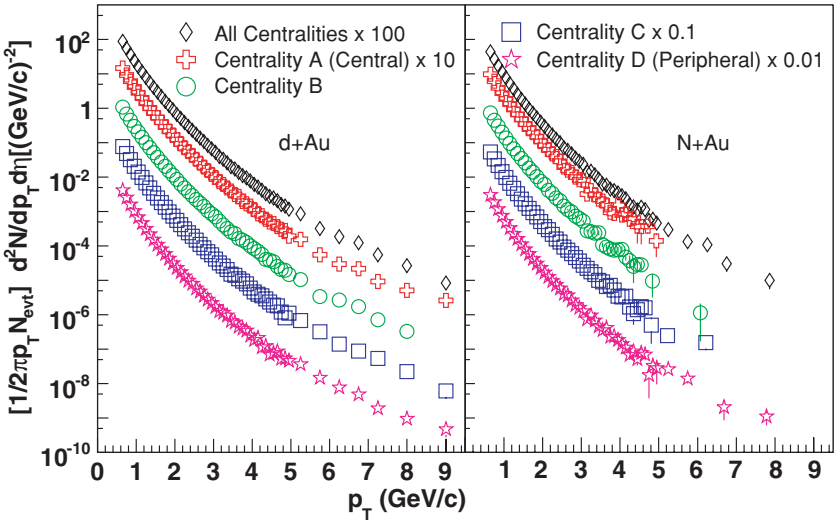

FIG. 12. (Color online) Charged hadron spectra for centrality selected d+Au and N+Au collisions. The error bars represent statistical uncertainties only, although they are generally smaller than the data point symbols. Points from different centrality bins are scaled sequentially by a factor of 10. (See Table I for centrality class definitions.)

where $\langle k_T^2 \rangle_{pp}$ is the square of the initial parton transverse momentum in the proton, $\langle k_T^2 \rangle_A$ is an additional momentum squared after rescattering, and $\langle k_T^2 \rangle_{pA}$ is the final broadened width. Most of the models differ on the assumption they use to describe $\langle k_T^2 \rangle_A$: whether there is a single hard scattering [31] or a sum of small sequential rescatterings [30] that produces the additional k_T.

Common to the models is that $\langle k_T^2 \rangle_A$ is a function of the number of sequential nucleon-nucleon collisions, ν. For impact parameter b, $\langle k_T^2 \rangle_A$ can be written as

$$\langle k_T^2 \rangle_A(b) = H(\nu(b) - 1), \tag{12}$$

where H is the square of the average momentum acquired in $\nu - 1$ rescatterings. For a single hard scattering model, $\langle k_T^2 \rangle_A$ should saturate at $\nu = 2$. We therefore investigate the shape of $R_{d\mathrm{Au}}$ as a function of ν to illuminate the underlying process. The centrality selection of our data and the tagged N+Au sample allow us to investigate precisely the effect of the collision geometry. We use $\nu = \langle N_{\mathrm{coll}}/N_{\mathrm{part}}^{\mathrm{deutron}} \rangle$ (in N+Au collisions, $\nu = \langle N_{\mathrm{coll}} \rangle$) to look explicitly at the impact parameter dependence of the nuclear modification factor.

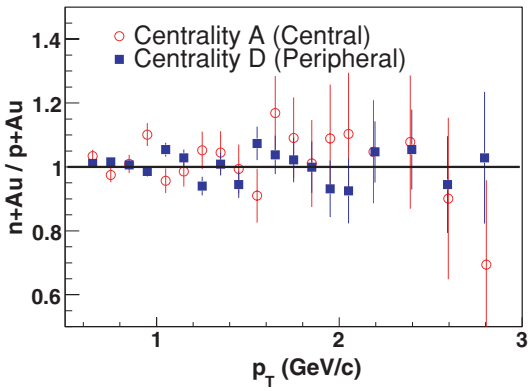

FIG. 13. (Color online) Ratio of n+Au to p+Au invariant yield per event shown in the most central and peripheral bins. The error bars are statistical only, as all systematic uncertainties cancel in the ratio. (See Table I for centrality class definitions.)

In Fig. 15, we plot $R_{d\mathrm{Au}}$ and $R_{N\mathrm{Au}}$ as a function of $(\nu - 1)$. The values of ν are presented in Table I.

Three transverse momentum regions were selected to study the dependence of R_{AB} on ν: $2.8 \leqslant p_T \leqslant 6.0$, $1.5 \leqslant p_T \leqslant 2.7$, and $0.6 \leqslant p_T \leqslant 1.0\,\mathrm{GeV}/c$. In the low p_T region, we expect scaling with the number of participating nucleons rather than with the number of binary collisions; therefore R_{AB} is less than unity. The Cronin effect is observed in the $2.8 \leqslant p_T \leqslant 6.0\,\mathrm{GeV}/c$ region, where within the limits of our uncertainties, it is independent of the number of additional scatterings $(\nu - 1)$. In the intermediate p_T region, the data show little to no Cronin enhancement, thus confirming scaling with the number of binary collisions. Just as $R_{d\mathrm{Au}}(p_T)$ and $R_{N\mathrm{Au}}(p_T)$ matched very closely, so do $R_{d\mathrm{Au}}(\nu)$ and $R_{N\mathrm{Au}}(\nu)$.

As discussed above, previous experiments found a larger Cronin enhancement for protons than pions [11]. Recently the PHENIX Collaboration published identified pion, kaon, and proton production data from $\sqrt{s_{NN}} = 200$ GeV d+Au collisions [24], in which a similar Cronin behavior was observed. $R_{d\mathrm{Au}}$ for protons reaches about 1.8 at $p_T \approx 3\,\mathrm{GeV}/c$, whereas pion $R_{d\mathrm{Au}}$ is measured to be about 1.1 for transverse momentum between 2 and $2.6\,\mathrm{GeV}/c$.

At the time these data were taken, the PHENIX experiment did not have the capability to measure identified charged pions and protons at momenta above 2.6 and $4\,\mathrm{GeV}/c$, respectively. To extend the trends observed in these low momentum regions [24], we calculate the ratio of the charged hadrons measured in the present analysis to the π^0 spectra from Ref. [13], alongside the ratio of $(p^{\pm} + K^{\pm} + \pi^{\pm})/\pi^{\pm}$ from Ref. [24]. These ratios are presented in Fig. 16.

In the transverse momentum region common to the two presented ratios, there is strong agreement between the analyses. The $(h^+ + h^-)/2\pi^0$ ratio is independent of p_T above $2\,\mathrm{GeV}/c$ where the identified particle data end, implying that the $R_{d\mathrm{Au}}$ and particle ratio trends observed at low transverse momentum continue at higher transverse momentum. The average value of 1.58 ± 0.03 of the $(h^+ + h^-)/2\pi^0$ ratio for p_T above $2\,\mathrm{GeV}/c$ in the peripheral D centrality bin agrees well with the value of 1.59 obtained from lower energy collisions in

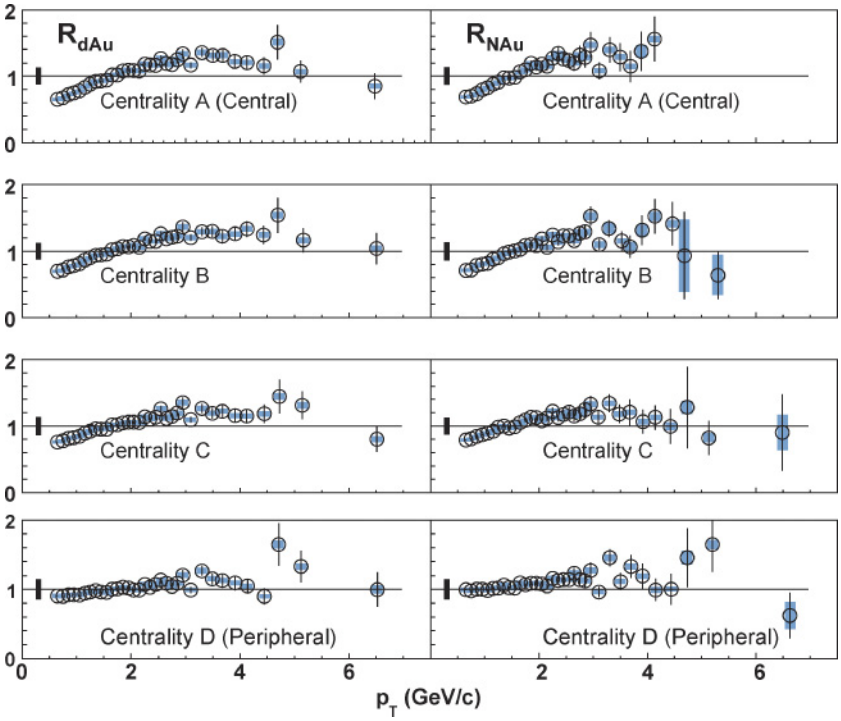

FIG. 14. (Color online) $R_{d\mathrm{Au}}$ and $R_{N\mathrm{Au}}$ as functions of p_T. The bars represent statistical uncertainty (often smaller than the data point symbols), the shaded boxes on each point represent systematic uncertainties that change with p_T, and the black boxes on the left show systematic uncertainties that do not change with p_T. (See Table I for centrality class definitions.)

the CERN Intersecting Storage Rings (ISR) [33]. As found in Ref. [1] for Au+Au collisions, this value rises for more central events: we find average values of 1.78 ± 0.02, 1.77 ± 0.03, and 1.72 ± 0.03 for centrality bins A, B, and C, respectively. There is an additional 11% systematic uncertainty common to all four values. The centrality dependence implies moderate medium modification effects in central $\sqrt{s_{NN}} = 200$ GeV collisions, even in the d+Au system, that increase the production of protons and kaons relative to pions. The PHENIX measurement of particle species dependent $R_{d\mathrm{Au}}$ in Ref. [24] at lower p_T suggests that the increased particle production relative to pions is dominantly proton and not kaon production.

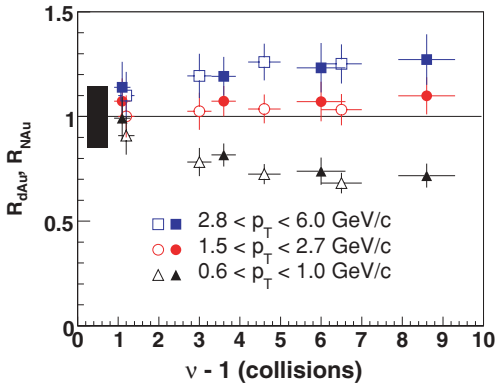

FIG. 15. (Color online) $R_{d\mathrm{Au}}$ (open symbols) and $R_{N\mathrm{Au}}$ (closed symbols) values averaged in three momentum ranges as functions of $\nu - 1$. Point-by-point uncertainty bars show the quadratic sum of the statistical uncertainty in R_{AB} and the systematic uncertainties that change with ν. The box on the far left represents the size of the systematic uncertainty that does not change with ν. Horizontal bars show the uncertainty in the value of ν for each centrality class.

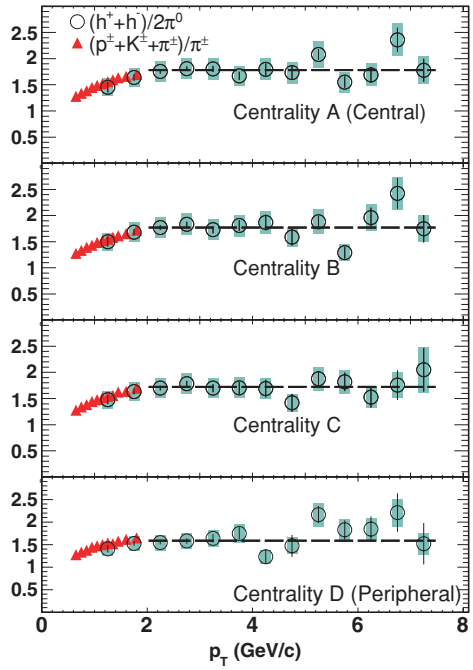

FIG. 16. (Color online) $(h^+ + h^-)/2\pi^0$ ratios as functions of transverse momentum from d+Au collisions in four centrality bins. Open circles are the charged hadron spectra from the present analysis divided by π^0 data from Ref. [13]. Bars indicate statistical uncertainties, and the shaded boxes systematic uncertainties. Triangles are the $(p^{\pm} + K^{\pm} + \pi^{\pm})/\pi^{\pm}$ ratios from Ref. [24], with statistical uncertainties roughly the size of the symbols. (See Table I for centrality class definitions.)

IV. SUMMARY

We have measured the centrality dependence of charged hadron production at midrapidity in d+Au collisions, as well as in p+Au and n+Au collisions that are tagged by a spectator nucleon from the deuteron nucleus. The hadron yields in p+Au and n+Au collisions are identical within our experimental uncertainty. Using the $p+p$ data from same energy, we calculated the nuclear modification factors $R_{d\mathrm{Au}}$ and $R_{N\mathrm{Au}}$ for various centrality selections. Within this analysis and its experimental uncertainty, there is no difference between $R_{d\mathrm{Au}}$ and $R_{N\mathrm{Au}}$. Instead of a strong suppression as predicted by some color glass condensate models [9], an excess of hadron production is seen at $p_T > 2\,\mathrm{GeV}/c$, consistent with enhancement due to the Cronin effect. The magnitude of the Cronin effect is independent of the number of additional scatterings $(\nu - 1)$ within the limits of our uncertainties. We also studied the ratio of charged hadron yield to pion yield. We found that the charged pions account for about 60% of the charged hadrons at $p_T > 3\,\mathrm{GeV}/c$, with a slightly larger value in central d+Au collisions. This implies that $R_{d\mathrm{Au}}$ for protons and kaons remains close to one at higher p_T.

ACKNOWLEDGMENTS

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions. We acknowledge support from the Office of Nuclear Physics in the Office of Science of the Department of Energy, the National Science Foundation, Abilene Christian University Research Council, Research Foundation of SUNY, and Dean of the College of Arts and Sciences, Vanderbilt University (U.S.A.); Ministry of Education, Culture, Sports, Science, and Technology and the Japan Society for the Promotion of Science (Japan); Conselho Nacional de Desenvolvimento Científico e Tecnológico and Fundação de Amparo à Pesquisa do Estado de São Paulo (Brazil); Natural Science Foundation of China (People's Republic of China); Centre National de la Recherche Scientifique, Commissariat à l'Énergie Atomique, and Institut National de Physique Nucléaire et de Physique des Particules (France); Ministry of Industry, Science and Tekhnologies, Bundesministerium für Bildung und Forschung, Deutscher Akademischer Austausch Dienst, and Alexander von Humboldt Stiftung (Germany); Hungarian National Science Fund, OTKA (Hungary); Department of Atomic Energy (India); Israel Science Foundation (Israel); Korea Research Foundation and Korea Science and Engineering Foundation (Korea); Ministry of Education and Science, Russia Academy of Sciences, Federal Agency of Atomic Energy (Russia); VR and the Wallenberg Foundation (Sweden); the U.S. Civilian Research and Development Foundation for the Independent States of the Former Soviet Union; the U.S.-Hungarian NSF-OTKA-MTA; and the U.S.-Israel Binational Science Foundation.

(Dated: February 1, 2008)

The PHENIX experiment has measured the dielectron continuum in $\sqrt{s_{NN}}$=200 GeV Au+Au collisions. In minimum bias collisions the dielectron yield in the mass range between 150 and 750 MeV/c^2 is enhanced by a factor of 3.4±0.2(stat.)±1.3(syst.)±0.7(model) compared to the expectation from our model of hadron decays. The integrated yield increases faster with the centrality of the collisions than the number of participating nucleons, suggesting emission from scattering processes in the hot and dense medium. The continuum yield between the masses of the ϕ and the J/ψ mesons is consistent with expectations from correlated $c\bar{c}$ production, though other mechanisms are not ruled out.

PACS numbers: 25.75.Dw

Electron-positron pairs, or dileptons in general, have proven to be an excellent tool to study collisions of heavy ions at ultra-relativistic energies. Because leptons do not interact strongly, emission of dileptons from the hot matter created at RHIC should leave an imprint on the observed dilepton distributions. Emission from the hot matter may include thermal radiation and in-medium decays of mesons with short lifetimes, like the ρ meson, while their spectral functions may be strongly modified. However, below the mass of the ϕ meson, these sources compete with a large contribution of e^+e^-–pairs from Dalitz decays of pseudoscalar mesons (π^0, η, η') and decays of vector mesons (ρ, ω, ϕ). Above the ϕ meson mass up to 4.5 GeV/c^2, competing sources are dilepton decays of charmonia ($J/\psi, \psi'$) and semileptonic decays of D and $\bar{D}$ mesons, correlated through flavor conservation, which lead to a continuum of masses. In addition to thermal radiation, energy loss of charm quarks in the medium might modify the continuum yield in this mass region.

The discovery of a large enhancement of the dilepton yield at masses below the ϕ meson mass in ion-ion collisions at the CERN SPS [1] has triggered a broad theoretical investigation of modifications of properties of hadrons in a dense medium and of how these modifications relate to chiral symmetry restoration [2]. These theoretical studies will benefit from the availability of more precise data from CERN [3, 4] and GSI [5]. An enhanced yield was also observed at higher masses, above the ϕ meson mass [6]. Recent NA60 data suggest that the enhancement can not be attributed to decays of D-mesons but may result from prompt production, as expected for thermal radiation [7].

The PHENIX experiment at the Relativistic Heavy Ion Collider (RHIC) extends these measurements in a new energy regime by exploring Au+Au collisions at a center of mass energy of $\sqrt{s_{NN}}$=200 GeV. In this paper we present results from minimum bias data taken in 2004. Collisions were triggered and selected by centrality using beam-beam counters (BBC) and zero degree calorimeters (ZDC). We analyzed a sample of 8×10^8 minimum bias events.

Electrons and positrons are reconstructed in the two central arm spectrometers of PHENIX [8] using Drift Chambers (DC), located outside an axial magnetic field, which measure their momenta with an accuracy of $\sigma_p/p = 0.7\% \oplus 1\% p/(\mathrm{GeV/c})$. They are identified by hits in the Ring Imaging Cherenkov detector (RICH) and by matching the momentum with the energy measured in an electromagnetic calorimeter (EMCal) [9]. Electrons are reconstructed with an efficiency of ∼90%, while a hadron contamination of ∼20% remains.

Each central arm covers $|\Delta\eta| \leq 0.35$ in pseudorapidity and $\pi/2$ in azimuthal angle. Because charged particles are deflected in the azimuthal direction by the magnetic field, the acceptance depends on the momentum and the charge of the particle, and also on the radial location of the detector component (DC, EMCal and RICH). The acceptance for a track with charge q, transverse momentum p_T and azimuthal emission angle ϕ can be described by:

$$\phi_{\min} \leq \phi + q\frac{k_{\mathrm{DC,RICH}}}{p_\mathrm{T}} \leq \phi_{\max} \qquad (1)$$

where k_DC and k_RICH represent the effective azimuthal bend to DC and RICH ($k_{DC} = 0.206$ rad GeV/c and $k_{RICH} = 0.309$ rad GeV/c). One arm has $\phi_{\min} = \frac{-3}{16}\pi$ and $\phi_{\max} = \frac{5}{16}\pi$, the other arm $\phi_{min} = \frac{11}{16}\pi$ and $\phi_{max} = \frac{19}{16}\pi$. Only electrons with $p_\mathrm{T} \geq 200$ MeV/c are used in the analysis. The photon conversion probability was minimized by installing a helium bag between the beam pipe and the DC, reducing the material to ∼0.4% of a radiation length.

In an event the source of any electron or positron is unknown and therefore all electrons and positrons are combined to pairs, like-sign and unlike-sign. This results in a large combinatorial background which must be removed. The background is computed with a mixed event technique, which combines tracks from different events that have similar topology (centrality, collision vertex, reaction plane).

In order to achieve the necessary accuracy, all unphysical correlations that arise from overlapping tracks or hits in the detectors, mostly in the RICH, must be eliminated, because they can not be reproduced by mixed events. If hits of both tracks of a pair overlap in any detector, the event is rejected. About 4% of all pairs are removed by this event rejection. Comparing measured like-sign pairs with the mixed combinatorial background shows that the mixing technique reproduces the shape within the statistical accuracy of the data.

The absolute normalization of the unlike-sign combinatorial background is given by the geometrical mean of the observed positive and negative like-sign pairs $2\sqrt{N_{--}N_{++}}$, where, in principle, N_{--} and N_{++} are the measured number of like-sign pairs. There is a small correlated signal also in the observed like-sign pairs, which can occur if there are two e^+e^-–pairs in the final state of a meson, e.g. double Dalitz decays, Dalitz decays followed by a conversion of the decay photon or two photon decays followed by conversion of both photons. These "cross" pairs have small masses, typically less than the η mass (550 MeV/c^2).

We therefore determine N_{--} and N_{++} by integrating the mixed event distributions after they were normalized to the 7.5×10^6 like-sign pairs measured above 700 MeV/c^2. N_{--} and N_{++} are determined with an accuracy of 0.12%. The normalization is multiplied by 1.004 to account for the fact that the event rejection removes 10% more like-sign than unlike-sign pairs. This correction factor was estimated, using mixed events, with an accuracy better than 50%. Adding the statistical error

and the uncertainty due to the event rejection in quadrature gives an accuracy of 0.25% on the normalization.

After subtraction of the combinatorial background, physical background from photon conversions and cross pairs is removed. Because the tracking assumes that the e^+e^-–pair originates at the collision vertex, pairs from photons that convert in or outside of the beampipe are reconstructed with finite mass and opening angle, which is oriented perpendicular to the magnetic field. A cut on the orientation of the opening angle in the field removes more than 98% of the conversion pairs.

Cross pairs occur as like and unlike-sign pairs. Monte Carlo simulations show that the rate of unlike-sign cross pairs accepted in PHENIX is 44% of the rate for like-sign cross pairs. To deterime the rate of unlike-sign cross pairs, we scale the simulated like-sign cross pair distribution to the observed like-sign signal, obtained by subtraction of the mixed event background normalized above 700 MeV/c^2. We note that the like-sign signal is well described by the Monte Carlo simulation. The simulated unlike-sign cross pair distribution is scaled by the same factor and subtracted from the unlike-sign signal. The uncertainty of this subtraction depends on mass, but is $\leq 9\%$ of the final yield.

Figure 1 shows the mass distribution of e^+e^-–pairs, the normalized mixed event background (B), and the signal yield (S) obtained by subtracting the mixed event background, the cross pairs and the conversion pairs. The insert shows the signal-to-background ratio (S/B). The systematic errors (boxes) reflect the error on the background subtraction, which is given by $\delta_S/S = 0.25\% \cdot B/S$, added in quadrature to the uncertainty due to the cross pair subtraction, assumed to be $9\%S$ below 600 MeV/c^2. Despite the small S/B ratio, the vector meson resonances ω, ϕ and J/ψ which decay directly to e^+e^-, and an e^+e^-–pair continuum is visible up to 4.5 GeV/c^2.

In order to check the background subtraction, a subset of data (5×10^7 events), taken with additional material wrapped around the beam pipe to increase the number of photon conversions [9], was analyzed. In this data set the combinatorial background and the cross pair contribution is larger by a factor of $\sim$2.5. As shown in Fig. 1, the results from both data sets agree well within statistical errors, which are 30% in the range from 150 to 750 MeV/c^2 and much less below. Considering the decreased S/B ratio for the data with the converter we can estimate a 0.1% scale uncertainty of the background normalization, well within the 0.25% systematic uncertainty assigned.

The spectra are corrected to represent the invariant yield of e^+e^-–pairs, with both the e^+ and e^- in the detector acceptance as specified in Eq. 1. The correction is determined using a GEANT simulation [10] of the PHENIX detector that includes the details of the detector response. Simulated e^+e^-–pairs are reconstructed with the same analysis chain and all cuts applied. The correction is determined double differentially in p_T and mass of the e^+e^-–pair. The reduction of the electron reconstruction efficiency (0.92+/-0.03) due to detector occupancy is corrected for. Systematic uncertainties on the correction can be summarized as: (i) 13.4% on di-electron reconstruction, which is twice the uncertainty on the electron reconstruction efficiency [9], (ii) 6% conversion rejection cut, (iii) 5% event rejection and (iv) 3% occupancy. These uncertainties are included in the final systematic error on the invariant e^+e^-–pair yield.

Figure 2 compares the invariant yeild to the expected yield from meson decays and correlated decays of charmed mesons. The cocktail of hadron decay contributions was estimated using PHENIX data for meson production when available. As input distributions we use the measured $\pi, \eta, \phi, J/\psi$ yield and spectra [11, 12, 13, 14, 15]. For other mesons we use the m_T scaling procedure outlined in [9]. The systematic uncertainties depend on mass and range from 10 to 25%.

For the continuum below the J/ψ the dynamic correlation of c and $\bar{c}$ is essential, but unknown. We make two assumptions: (i) the correlation is unchanged by the medium and equal to what is known from p+p collisions. In this case we use PYTHIA [16] scaled from the p+p equivalent $c\bar{c}$ cross section of $567\pm57\pm193$ μbarn [17] to minimum bias Au+Au collisions proportional to the number of binary collisions (258 ± 25) [12]. We note that the p_T distribution for electrons generated by PYTHIA is softer than the spectra measured in p+p data but coincides with those observed in Au+Au [9]. As a second assumption (ii) there is no dynamical correlation, i.e. the direction of c and $\bar{c}$ quarks are uncorrelated. We keep the overall cross section and the p_T distributions fixed to experimental data [9]. Other contributions from bottom and Drell-Yan are expected to be small in the mass region below the J/ψ peak. Each e^+ and e^- must fall in the PHENIX acceptance, given by Eq. 1.

The data below 150 MeV/c^2 are well described by the cocktail of hadronic sources. The vector mesons ω, ϕ and J/ψ are reproduced within the uncertainties. However, the yield is substantially enhanced above the expected yield in the continuum region from 150 to 750 MeV/c^2. The enhancement in this mass range is a factor of 3.4 $\pm$ 0.2(stat.) $\pm$ 1.3(syst.) $\pm$ 0.7(model), where the first error is the statistical error, the second the systematic uncertainty of the data, and the last error is an estimate of the uncertainty of the expected yield. Above the ϕ meson mass the data seem to be well described by the continuum calculation based on PYTHIA. This is somewhat surprising, since single electron distributions from charm show substantial medium modifications [9], and thus it is hard to understand how the dynamic correlation at production of the $c\bar{c}$ remains unaffected by the medium. A complete randomization of that correlation (see Fig.2) leads to a much softer mass spectrum and

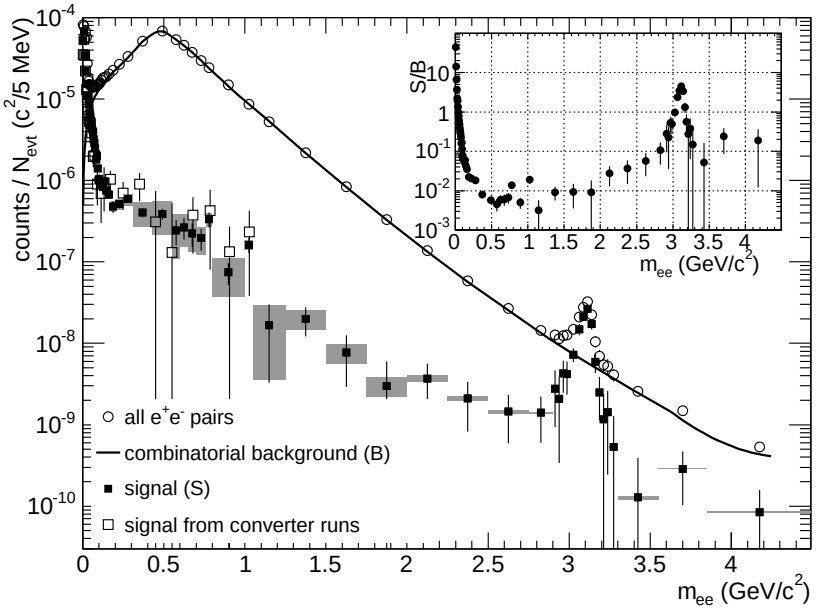

FIG. 1: Uncorrected mass spectra of all e^+e^- pairs, mixed events background (B) and signal (S) with statistical (bars) and systematic (boxes) uncertainties shown separately. The signal from the runs with additional converter is shown with statistical errors only. The insert shows the S/B ratio. The mass range covered by each data point is given by horizontal bars.

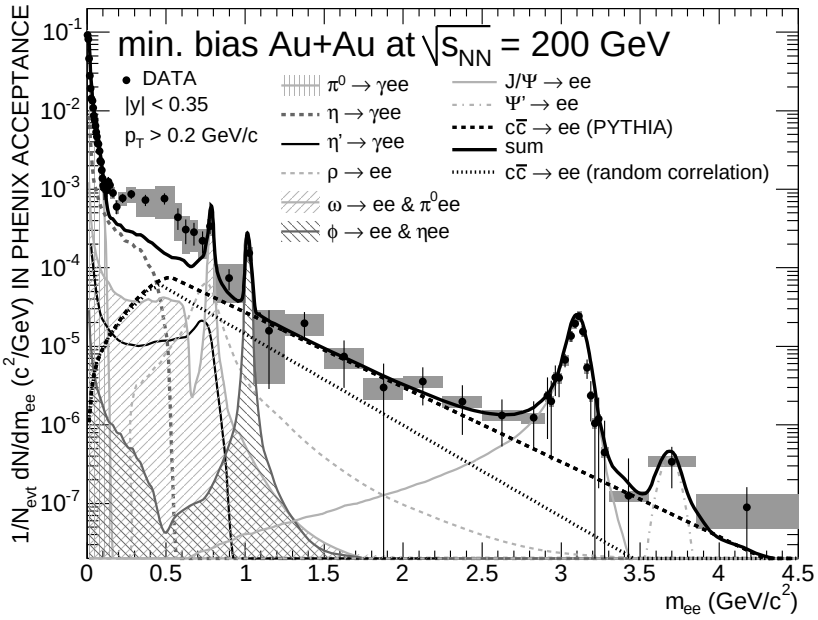

FIG. 2: Invariant e^+e^-–pair yield compared to the yield from the model of hadron decays. The charmed meson decay contribution based on PYTHIA is included in the sum of sources (solid black line). The charm contribution expected if the dynamic correlation of c and $\bar{c}$ is removed is shown separately. Statistical (bars) and systematic (boxes) uncertainties are shown separately; the mass range covered by each data point is given by horizontal bars. The systematic uncertainty on the cocktail is not shown.

would leave significant room for other contributions, e.g. thermal radiation.

To shed more light on the continuum yield we have studied the centrality dependence of the yield in three mass windows, below 100 MeV/c^2, from 150 to 750 MeV/c^2 and 1.2 to 2.8 GeV/c^2. The top panel of Fig. 3 shows the centrality dependence of the yield in the mass region 150–750 MeV/c^2 divided by the number of participating nucleon pairs ($N_{\rm part}/2$). For comparison the yield below 100 MeV/c^2, which is dominated by low p_T

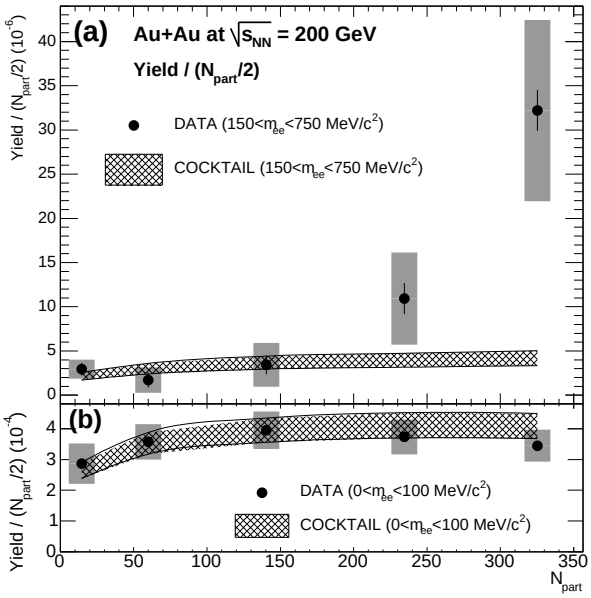

FIG. 3: Dielectron yield per participating nucleon pairs ($N_{\rm part}/2$) as function of N_{part} for two different mass ranges compared to the expected yield from the hadron decay model. The two lines give $\pm 1\sigma$ systematic uncertainty. For the data statistical and systematic uncertainties are shown separately.

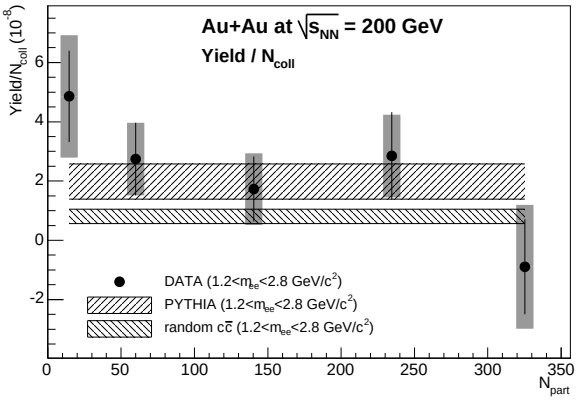

FIG. 4: Dielectron yield per number of collisions N_{coll} in the mass range 1.2 to 2.8 GeV/c^2 as function of $N_{\rm part}$. Statistical and systematic errors are shown separately. Also shown are two bands corresponding to the two different estimates of the contribution from charmed meson decays. The width of the band reflect the uncertainty of the charm cross-section only.

pion decays, is shown in the lower panel. For both intervals the yield is compared to the same yield calculated from the hadron cocktail. In the lower mass range the yield agrees with the expectation, i.e. is proportional to the pion yield. In contrast, in the range from 150 to 750 MeV/c^2, the observed yield rises significantly compared to the expectation, reaching a factor of 7.7 $\pm$ 0.6(stat.) $\pm$ 2.5(syst.) $\pm$ 1.5(model) for most central collisions. The increase is qualitatively consistent with the conjecture that an in-medium enhancement of the dielectron continuum yield arises from scattering processes like $\pi\pi$ or $q\bar{q}$ annihilation, which would result in a yield rising faster than proportional to N_{part}.

We normalize the yield in the mass region 1.2 to 2.8 GeV/c^2 to the number of binary collisions (Fig. 4), which is the correct scaling for pairs from charmed meson decays [9]. The normalized yield shows no significant centrality dependence and is consistent with the expectation based on PYTHIA. It is also likely that a scenario where the correlation between the c and $\bar{c}$ is randomized will require an additional source, e.g. a contribution from thermal radiation. This contribution could increase faster than linear with $N_{\rm part}$ and therefore the apparent scaling with N_{coll} may be a mere coincidence. We note that this coincidence may have been observed in this mass region at the CERN SPS [6], where a major prompt component has now been suggested by NA60 data [7].

In conclusion, measurements of Au+Au collisions at $\sqrt{s_{NN}}$=200 GeV in the mass range 150–750 MeV/c^2 show a significant enhancement of the dielectron continuum and exhibit a clear increase with centrality of the collision. The observed yield between ϕ and J/ψ is consistent with the expectation from correlated $c\bar{c}$ production, but does not exclude other mechanisms.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 22 May 2007; published 7 January 2008)

Azimuthal angle ($\Delta\phi$) correlations are presented for charged hadrons from dijets for $0.4 < p_T < 10$ GeV/c in Au+Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV. With increasing p_T, the away-side distribution evolves from a broad and relatively flat shape to a concave shape, then to a convex shape. Comparisons to $p+p$ data suggest that the away-side can be divided into a partially suppressed "head" region centered at $\Delta\phi \sim \pi$ and an enhanced "shoulder" region centered at $\Delta\phi \sim \pi \pm 1.1$. The p_T spectrum for the head region softens toward central collisions, consistent with the onset of jet quenching. The spectral slope for the shoulder region is independent of centrality and trigger p_T, which offers constraints on energy transport mechanisms and suggests that it contains the medium response to energetic jets.

DOI: 10.1103/PhysRevC.77.011901 PACS number(s): 25.75.Dw

High transverse momentum (p_T) partons are valuable probes of the high energy density matter created at the Relativistic Heavy-Ion Collider (RHIC). These partons lose a large fraction of their energy in the matter prior to forming hadrons, a phenomenon known as jet quenching. Such energy loss is predicted to lead to strong suppression of both single and correlated away-side dihadron yields at high p_T [1], consistent with experimental findings [2,3]. The exact mechanism for energy loss is not yet understood. Recent results of dihadron azimuthal angle ($\Delta\phi$) correlations have indicated strong modification of the away-side jet [3–6]. For high p_T hadron pairs, such modification is manifested by a partially suppressed away-side peak at $\Delta\phi \sim \pi$ [3]. This has been interpreted as evidence for the fragmentation of jets that survive their passage through the medium.

For intermediate p_T charged hadron pairs, the away-side jet was observed to peak at $\Delta\phi \sim \pi \pm 1.1$ [4,5], suggesting that the energy lost by high p_T partons is transported to lower p_T hadrons at angles away from $\Delta\phi \sim \pi$. The mechanisms for such energy transport include medium deflection of hard [7] or shower partons [8], large-angle gluon radiation [9], Cherenkov gluon radiation [10], and mach-shock medium excitations [11].

In this brief report we present a detailed "mapping" of the p_T and centrality dependence of away-side jet shapes and yields. These measurements allow a detailed investigation of the jet distributions centered around $\Delta\phi \sim \pi \pm 1.1$ and $\Delta\phi \sim \pi$, provide new insight on the interplay between jet quenching and the response of the medium to the lost energy, and provide new constraints for distinguishing the competing mechanisms for energy transport.

The results presented here are based on minimum-bias (MB) Au+Au and $p+p$ datasets as well as a photon level-1 triggered (PT) $p+p$ dataset collected with the PHENIX detector [12] at $\sqrt{s_{\rm NN}} = 200$ GeV, during the 2004–2005 RHIC run. The PT trigger requires a minimum energy of 1.4 GeV in 4×4 electromagnetic calorimeter (EMC) towers in coincidence with the Beam Beam Counters (BBC) [13]. The event centrality was determined via the method in Ref. [12]. A total of 840 million Au+Au events in the vertex range $|z| < 30$ cm was analyzed. Charged particles were reconstructed in the two central arms of PHENIX, each covering -0.35 to 0.35 in pseudorapidity and 90° in azimuth. The tracking system consisted of the drift chambers and two layers of multiwire proportional chambers with pad readout (PC1 and PC3), achieving a momentum resolution of $0.7\% \bigoplus 1.0\%\ p$ (GeV/c) [2].

Dihadron $\Delta\phi$ correlations were obtained by correlating trigger (type A) hadrons with partner (type B) hadrons. The MB and PT $p+p$ datasets were used for trigger $p_T < 5$GeV/c and $p_T > 5$ GeV/c, respectively. To reduce background from decays and conversions, tracks were required to have a matching hit within a $\pm 2.3\sigma$ window in PC3. For $p_T > 4$GeV/c, an additional matching hit at the EMC was required. For triggers with $p_T > 5$ GeV/c, a p_T dependent energy cut in the EMC and a tight $\pm 1.5\sigma$ matching cut at the PC3 were applied to reduce the background to <10% [14]. This energy cut greatly reduces PT trigger bias effects. The PT $p+p$ results are consistent with the MB $p+p$ data for trigger $p_T > 5$ GeV/c.

The jet associated partner yield per trigger, $Y_{\rm jet}(\Delta\phi)$, is obtained by assuming independent contributions from jets and elliptic flow to the $\Delta\phi$ distribution as [4,14]

$$Y_{\rm jet} = \left[\frac{N^s(\Delta\phi)}{N^m(\Delta\phi)} - b_0\left(1 + 2v_2^A v_2^B \cos 2\Delta\phi\right)\right] \times \frac{\int d\Delta\phi N^m(\Delta\phi)}{2\pi N_A \varepsilon_B}, \quad (1)$$

where N_A is the number of triggers, ε_B is the single-particle efficiency for partners in the full azimuth and $|\eta| < 0.35$; $N^s(\Delta\phi)$ and $N^m(\Delta\phi)$ are pair distributions from the same- and mixed-events, respectively. Mixed-event pairs are obtained by selecting partners from different events with similar centrality and vertex. The ε_B values include detector acceptance and reconstruction efficiency, with an uncertainty of ~10% [2,15]. The harmonic term, $2v_2^A v_2^B \cos 2\Delta\phi$, reflects the elliptic flow modulation of the combinatoric pairs in Au+Au [4], where we have assumed $\langle v_2^A v_2^B\rangle$ is factorizable. v_2^A and v_2^B are measured via the reaction plane method [16] using BBC at $3 < |\eta| < 4$. The large rapidity gap between the BBC and the central arm reduces the nonflow contributions, especially those from dijets [17]. The systematic errors on v_2 are estimated to be ~6% for central and midcentral collisions and ~10% for the peripheral collisions [4].

To fix the value of b_0, we followed the subtraction procedure of Refs. [4] and [18] and assumed that $Y_{\rm jet}$ has zero yield at its minimum $\Delta\phi_{\rm min}$ (ZYAM). To estimate the possible oversubtraction at $\Delta\phi_{\rm min}$, we calculate b_0 values independently by fitting $Y_{\rm jet}(\Delta\phi)$ to a function consisting of one near-side and two symmetric away-side Gaussians. The fitting procedure is similar to that used in Ref. [5], except that $|\Delta\phi - \pi| < 1$ is

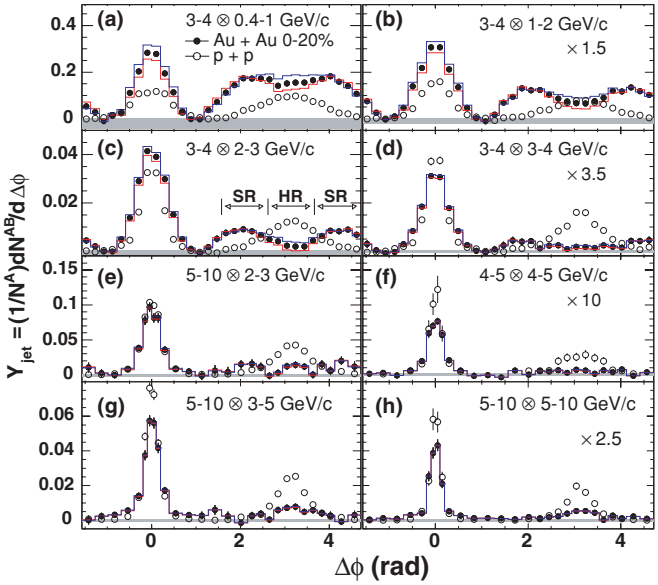

FIG. 1. (Color online) Per-trigger yield versus $\Delta\phi$ for various trigger and partner p_T ($p_T^A \otimes p_T^B$), arranged by increasing pair momentum ($p_T^A + p_T^B$), in $p+p$ and 0–20% Au+Au collisions. The data in some panels are scaled as indicated. Solid histograms (shaded bands) indicate elliptic flow (ZYAM) uncertainties. Arrows in Panel (c) indicate "head" (HR) and "shoulder" (SR) regions. The difference in near-side yield between Au+Au and $p+p$ for Panels (d)–(h) is within the 14% combined uncertainty of the single-particle efficiency.

excluded to avoid punch-through jets around π (see Fig. 1). This fit accounts for the overlap of the near- and away-side Gaussians at $\Delta\phi_{\rm min}$ and thus gives b_0 values systematically lower than that for ZYAM. We assign the differences as one-sided systematic errors on b_0. This oversubtraction error is only significant in central collisions and at $p_{\rm T}^{A,B} < 3$ GeV/c.

The per-trigger yield distributions for $p+p$ and 0–20% central Au+Au collisions are compared in Fig. 1 for various combinations of trigger and partner p_T ranges ($p_T^A \otimes p_T^B$) as indicated. The $p+p$ data show essentially Gaussian away-side peaks centered at $\Delta\phi \sim \pi$ for all p_T^A and p_T^B. In contrast, the Au+Au data show substantial shape modifications dependent on p_T^A and p_T. For a fixed value of p_T^A, Figs. 1(a)–1(d) reveal a striking evolution from a broad, roughly flat peak to a local minimum at $\Delta\phi \sim \pi$ with side peaks at $\Delta\phi \sim \pi \pm 1.1$. Interestingly, the location of the side peaks in $\Delta\phi$ is roughly constant with increasing p_T^B (see also Ref. [5]). Such p_T independence is compatible with the away-side jet modification expected from a medium-induced mach-shock [11] but disfavors models that incorporate large angle gluon radiation [9], Cherenkov gluon radiation [10], or deflected jets [7,8].

For relatively high values of $p_T^A \otimes p_T^B$, Figs. 1(e)–1(h) show that the away-side jet shape for Au+Au gradually becomes peaked as for $p+p$, albeit suppressed. This "reappearance" of the away-side peak seems due to a reduction of the yield centered at $\Delta\phi \sim \pi \pm 1.1$ relative to that at $\Delta\phi \sim \pi$, rather than to a merging of the peaks centered at $\Delta\phi \sim \pi \pm 1.1$. This is consistent with the dominance of dijet fragmentation at large $p_T^A \otimes p_T^B$, possibly due to jets that punch-through the medium [19] or to those emitted tangentially to the medium's surface [20].

The evolution of the away-side jet shape with p_T! (cf. Fig. 1) suggests separate contributions from a medium-induced component centered at $\Delta\phi \sim \pi \pm 1.1$ and a fragmentation component centered at $\Delta\phi \sim \pi$. A model independent study of these contributions can be made by dividing the away-side jet function into equal-sized head ($|\Delta\phi - \pi| < \pi/6$, HR) and shoulder ($\pi/6 < |\Delta\phi - \pi| < \pi/2$, SR) regions, as indicated in Fig. 1(c). We characterize the relative amplitude of these two regions with the ratio, $R_{\rm HS} = \frac{\int_{\Delta\phi\in{\rm HR}} d\Delta\phi Y_{\rm jet}(\Delta\phi)}{\int_{\Delta\phi\in{\rm HR}} d\Delta\phi} / \frac{\int_{\Delta\phi\in{\rm SR}} d\Delta\phi Y_{\rm jet}(\Delta\phi)}{\int_{\Delta\phi\in{\rm SR}} d\Delta\phi}$. Because $N_{\rm A}$ in Eq. (1) cancels in the ratio, $R_{\rm HS}$ is a pure pair variable and is symmetric *w.r.t.* p_T^A and p_T^B: $R_{\rm HS}(p_T^A, p_T^B) = R_{\rm HS}(p_T^B, p_T^A)$. For concave and convex shapes, one expects $R_{\rm HS} < 1$ and $R_{\rm HS} > 1$, respectively.

Figure 2 summarizes the p_T^B dependence of $R_{\rm HS}$ for both $p+p$ and central Au+Au collisions in four p_T^A bins. The ratios for $p+p$ are always above one and increase with p_T^B. This reflects the narrowing of a peaked jet shape with increasing p_T^B [14]. In contrast, the ratios for Au+Au show a nonmonotonic dependence on $p_T^{A,B}$. They evolve from $R_{\rm HS} \sim 1$ for $p_T^{A,B} \lesssim 1$ GeV/c through $R_{\rm HS} < 1$ for $1 \lesssim p_T^{A,B} \lesssim 4$ GeV/c, followed by $R_{\rm HS} > 1$ for $p_T^{A,B} \gtrsim 5$ GeV/c. These trends reflect the competition between medium-induced modification and jet fragmentation and suggest that the latter dominates at $p_T^{A,B} \gtrsim 5$ GeV/c. The results shown in Fig. 1 indicate that, relative to $p+p$, the Au+Au yield is suppressed in the HR but is enhanced in the SR. We quantify this suppression/enhancement via $I_{\rm AA}$, the ratio of jet yield $Y_{\rm jet}$ between Au+Au and $p+p$ collisions over a $\Delta\phi$ region, W, $I_{\rm AA}^W = \int_{\Delta\phi\in W} d\Delta\phi Y_{\rm jet}^{\rm Au+Au} / \int_{\Delta\phi\in W} d\Delta\phi Y_{\rm jet}^{p+p}$.

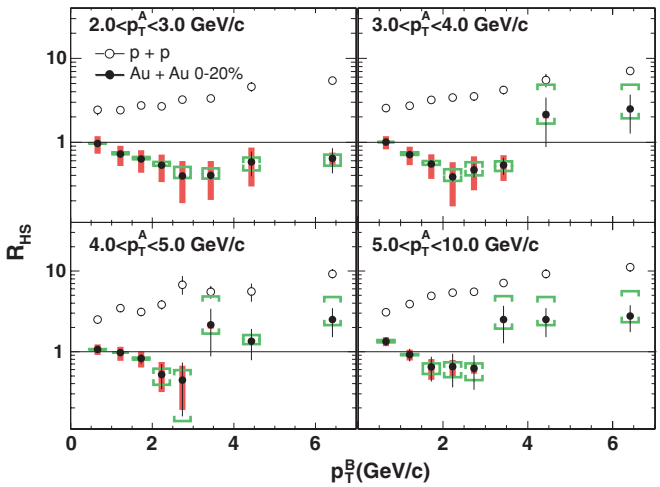

FIG. 2. (Color online) $R_{\rm HS}$ vs p_T^B for $p+p$ (open) and Au+Au (filled) collisions for four trigger selections. Because $R_{\rm HS}$ is purely hadron pair variable, the result is unchanged by swapping p_T^A and p_T^B. Shaded bars (brackets) represent p_T-correlated uncertainties due to elliptic flow (ZYAM procedure).

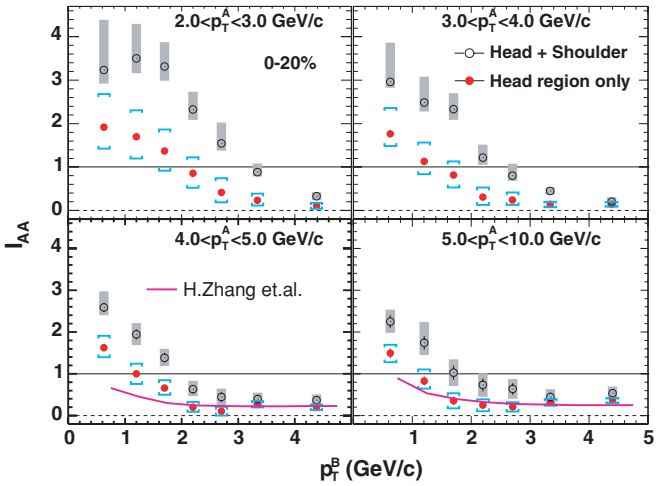

FIG. 3. (Color online) $I_{\rm AA}$ vs p_T^B for four trigger p_T bins in HR+SR ($|\Delta\phi - \pi| < \pi/2$) and HR ($|\Delta\phi - \pi| < \pi/6$). The systematic errors for the two regions, represented by shaded bars and brackets, respectively, include elliptic flow and ZYAM uncertainties and hence are strongly correlated. Grey bands around $I_{\rm AA} = 1$ represent 14% combined uncertainty on the single-particle efficiency in Au+Au and $p+p$. The thick curves are energy loss calculation from Ref. [21] for pairs in $|\Delta\phi - \pi| < 0.64$.

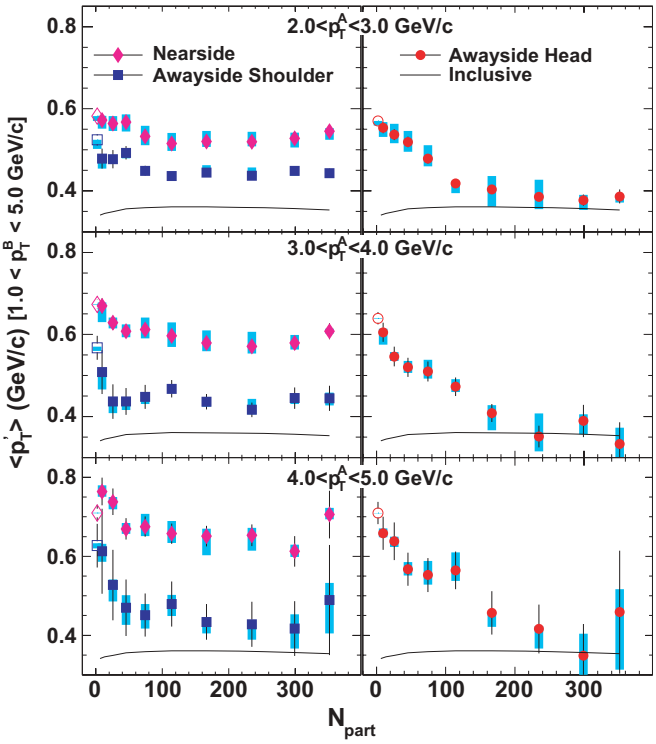

FIG. 4. (Color online) Truncated mean $\langle p'_T \rangle$ in $1 < p_T^B < 5$ GeV/c versus $N_{\rm part}$ for the near-side (diamonds), away-side shoulder (circles), and head (squares) regions for Au+Au (filled) and $p+p$ (open) for three trigger p_T bins. Solid curves represent values for inclusive charged hadrons (~0.36 GeV/c) [2]. Error bars represent the statistical errors. Shaded bars represent the sum of $N_{\rm part}$-correlated elliptic flow and ZYAM error.

Figure 3 shows $I_{\rm AA}$ as a function of p_T^B for the HR and the HR+SR, respectively, in four p_T^A bins. For triggers of $2 < p_{\rm T}^{\rm A} < 3$ GeV/c, $I_{\rm AA}$ for HR+SR exceeds one at low p_T^B, but falls and crosses one at ~3.5 GeV/c. A similar trend is observed for the higher p_T triggers, but the enhancement (at low p_T^B) is smaller and the suppression (at high p_T^B) is stronger. The $I_{\rm AA}$ values in HR are lower relative to HR+SR for all $p_T^{A,B}$. For the low p_T triggers, the suppression sets in around $1 \lesssim p_T^B \lesssim 3$ GeV/c, followed by a fall-off for $p_T^B \gtrsim 4$ GeV/c. For higher p_T triggers, a constant level of ~0.2–0.3 is observed above ~2 GeV/c. The suppression level is similar to the $R_{\rm AA}$ of inclusive hadrons [2] and agrees well with an energy loss model calculation [21] as indicated by the thick solid curves in Fig. 3. These results provide clear evidence for significant yield enhancement in the SR and suppression in the HR. The former reflects the dissipative processes that redistribute the energy lost in the medium, while the latter is consistent with jet quenching. However, we note that the $I_{\rm AA}$ values for the HR are upper limit estimates for the jet fragmentation component. This is because the HR yield includes possible contributions from the tails of the SR, as well as from bremsstrahlung gluon radiations [9].

To further contrast the HR and the SR, we focus on the p_T region of $1 < p_T^B < 5$ GeV/c, where the medium-induced component dominates the away-side. We characterize the inverse local slope of the partner yield in this p_T range via a truncated mean p_T, $\langle p'_T \rangle \equiv \langle p_T^B \rangle|_{1<p_T^B<5{\rm GeV}/c} - 1$ GeV/c. $\langle p'_T \rangle$ is calculated from the jet yields used to make $I_{\rm AA}$ in Fig. 3. Figure 4 shows the $\langle p'_T \rangle$ values for the HR, the SR, and a near-side region ($|\Delta\phi| < \pi/3$, NR) versus the number of participating nucleons, $N_{\rm part}$. The $\langle p'_T \rangle$ values for NR have a weak centrality dependence. Their overall levels for $N_{\rm part} > 100$ are 0.533 ± 0.024, 0.605 ± 0.032, and 0.698 ± 0.040 GeV/c for the p_T^A ranges 2–3, 3–4, and 4–5 GeV/c, respectively [22]. This is consistent with the dominance of jet fragmentation on the near-side, i.e., a harder spectrum for partner hadrons is expected for higher p_T trigger hadrons.

A very weak centrality dependence is observed for the SR for $N_{\rm part} \gtrsim 100$. In this case, the values for $\langle p'_T \rangle$ are lower (≈0.45 GeV/c) and do not depend on p_T^A. They are, however, larger than the values for inclusive charged hadrons [2]. The relatively sharp increase in $\langle p'_T \rangle$ for $N_{\rm part} \lesssim 100$ may reflect a significant jet fragmentation contribution in peripheral collisions. In contrast, the $\langle p'_T \rangle$ values for the HR show a gradual decrease with $N_{\rm part}$, starting close to that for the near-side jet, and approach the value for the inclusive spectrum for $N_{\rm part} \gtrsim 150$.

The different patterns observed for the yields in the HR and SR suggest a different origin for these yields. The suppression of the HR yield and the softening of its spectrum are consistent with a depletion of yield due to jet quenching. Further evidence is given by high p_T pairs, for which the HR yield agrees with energy loss calculations [21] and the HR shape becomes jet like. This suggests that these pairs come mainly from the fragmentation of partons that suffer small energy loss due to tangential or punch-through jet emissions. By contrast, the enhancement of the SR yield reflects a remnant of the lost energy from quenched jets. This enhancement is limited to

$p_T^{A,B} \lesssim 4$ GeV/c, the same p_T region where the soft processes such as hydrodynamical flow and recombination are important. The spectra slope of the SR is almost independent of p_T^A and centrality (for $N_{\rm part} \gtrsim 100$), reflecting an intrinsic property of the response of the medium to the energetic jets. These observations provide separate constraints on geometrical bias at high p_T [19–21] and on the energy transport at low p_T [7–11,23]. However, a model framework including both jet quenching and medium response, which can describe the full p_T evolution of the away-side jet shape and yield, is required to understand the parton-medium interactions.

In conclusion, we have observed strong medium modification of away-side shapes and yields for jet-induced pairs in Au+Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV. The detailed dependence of these results on p_T and centrality gives strong evidence for two distinct contributions from the regions of $\Delta\phi \sim \pi$ and $\Delta\phi \sim \pi \pm 1.1$. The former shows a strong yield suppression, with a level consistent with a jet quenching calculation at high p_T. The latter exhibits p_T and centrality independent shape and mean p_T, possibly reflecting an intrinsic property of the medium response to energetic jets.

The PHENIX experiment presents results from the Relativistic Heavy Ion Collider 2005 run with polarized proton collisions at $\sqrt{s} = 200$ GeV, for inclusive π^0 production at midrapidity. Unpolarized cross section results are given for transverse momenta $p_T = 0.5$ to 20 GeV/c, extending the range of published data to both lower and higher p_T. The cross section is described well for $p_T < 1$ GeV/c by an exponential in p_T, and, for $p_T > 2$ GeV/c, by perturbative QCD. Double helicity asymmetries A_{LL} are presented based on a factor of 5 improvement in uncertainties as compared to previously published results, due to both an improved beam polarization of 50%, and to higher integrated luminosity. These measurements are sensitive to the gluon polarization in the proton. Using one representative model of gluon polarization it is demonstrated that the gluon spin contribution to the proton spin is significantly constrained.

DOI: 10.1103/PhysRevD.76.051106 PACS numbers: 13.85.Ni, 13.88.+e, 21.10.Hw, 25.40.Ep

A principal goal of the spin program at the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory is to determine the gluon spin contribution to a longitudinally polarized proton (ΔG), taking advantage of the strongly interacting probes available in proton-proton collisions [1]. Previous measurements have established the validity of the perturbative quantum chromodynamics (pQCD) description for inclusive midrapidity π^0 [2] and forward π^0 production [3], and for midrapidity jet [4] and direct photon production [5], at $\sqrt{s} = 200$ GeV. The double helicity asymmetries for the production of these particles involve gluons in the hard scattering processes in this pQCD description, and the first measurements for π^0 [6,7] and for jets [4] have begun to probe ΔG.

The RHIC beam polarization and luminosity have significantly improved [8]. The statistical uncertainty for a double helicity asymmetry measurement is proportional to the inverse of $P^2 \times \sqrt{\mathcal{L}}$ for beam polarizations P and integrated luminosity $\mathcal{L}$, and decreased by a factor of 5 from the previously published data from PHENIX [6,7].

In this paper, we first present the cross section for midrapidity π^0 production for unpolarized proton-proton collisions at $\sqrt{s} = 200$ GeV. These results extend to lower and higher p_T than in previous publications, and we discuss an apparent transition region between soft and hard scattering; the inclusive cross section is dominated by hard scattering, described by pQCD, for $p_T > 2$ GeV/c. We then present the double helicity asymmetry, A_{LL}, for midrapidity π^0 production. We also include measurements of A_{LL} at low p_T, below the hard scattering region. Finally, our results for $p_T > 2$ GeV/c are compared to a pQCD calculation that incorporates a model of gluon polarization. We present the range that we probe in the gluon momentum fraction (x_g) and discuss the constraint from these data on ΔG.

The PHENIX experiment at RHIC measured π^0's via $\pi^0 \rightarrow \gamma\gamma$ decays using a highly segmented ($\Delta\eta \times \Delta\phi \sim 0.01 \times 0.01$) electromagnetic calorimeter (EMCal) [9], covering a pseudorapidity range of $|\eta| < 0.35$ and azimuthal angle range of $\Delta\phi = \pi$. The π^0 data in this analysis were collected using two different trigger conditions. A minimum bias (MB) trigger was defined by the coincidence of signals in two beam-beam counters (BBC) with full azimuthal coverage located at pseudorapidities $\pm(3.0 - 3.9)$ [10]. The cross section for events selected by the MB trigger was 23.0 mb (about half of $\sigma_{pp}^{\text{inel}}$) with a systematic uncertainty of $\pm 9.7\%$, derived from vernier scan results [2] and the variation of MB trigger efficiency for subsequent years. Higher p_T data were collected using the coincidence of the MB trigger and an EMCal-based high p_T photon trigger [2,11], with efficiency $\sim 5\%$ at $p_T(\pi^0) \sim 1$ GeV/c and $\sim 90\%$ for $p_T(\pi^0) > 3.5$ GeV/c. The collision vertex was required to be within $|z| < 30$ cm along the beam axis, based on the time difference between the two BBC detectors. The π^0 acceptance is uniform over this interval. The analyzed data sample of the 2005 run corresponds to an integrated luminosity of 2.5 pb^{-1}.

Details of the unpolarized cross section analysis technique are described in [2,11]. The background contribution under the π^0 peak in the two-photon invariant mass distribution varied from 80% in the lowest 0.5–0.75 GeV/c p_T bin to less than 8% for $p_T > 4$ GeV/c. The π^0 spectrum was corrected for overlapping decay photon showers in the EMCal, based on Monte Carlo simulations confirmed with test beam data [12]. Below a $p_T(\pi^0)$ of 12 GeV/c the correction is less than 4%, and for $p_T(\pi^0) = 20$ GeV/c the correction is $\sim 25\%$ and $\sim 70\%$, for two different EMCal subsystems [9]. The systematic uncertainty of the measurement (excluding the 9.7% uncertainty from the MB trigger cross section) varied from $\sim 7\%$ at $p_T \sim 1$ GeV/c to $\sim 16\%$ for the highest p_T bin.

Figure 1 presents the cross section results for midrapidity π^0 production at $\sqrt{s} = 200$ GeV, versus p_T, from $p_T = 0.5$ GeV/c to $p_T = 20$ GeV [13]. Points are plotted at the average p_T for each bin. The pQCD prediction, at next-to-leading order (NLO), is shown for theory scales $\mu = p_T/2$, p_T and $2p_T$, where μ represents equal factorization, renormalization, and fragmentation scales [14,15]. The Coordinated Theoretical-Experimental Project on QCD (CTEQ6M) parton distribution functions [16] and Kniehl-Kramer-Pötter set of fragmentation functions [17] are used. These data extend the published cross section data at both low and high p_T, and are consistent with previously published results [2,11]. From $p_T = 2$ GeV/c to 20 GeV/c, the NLO pQCD calculation describes the data over a change in cross section of 7 orders of magni-

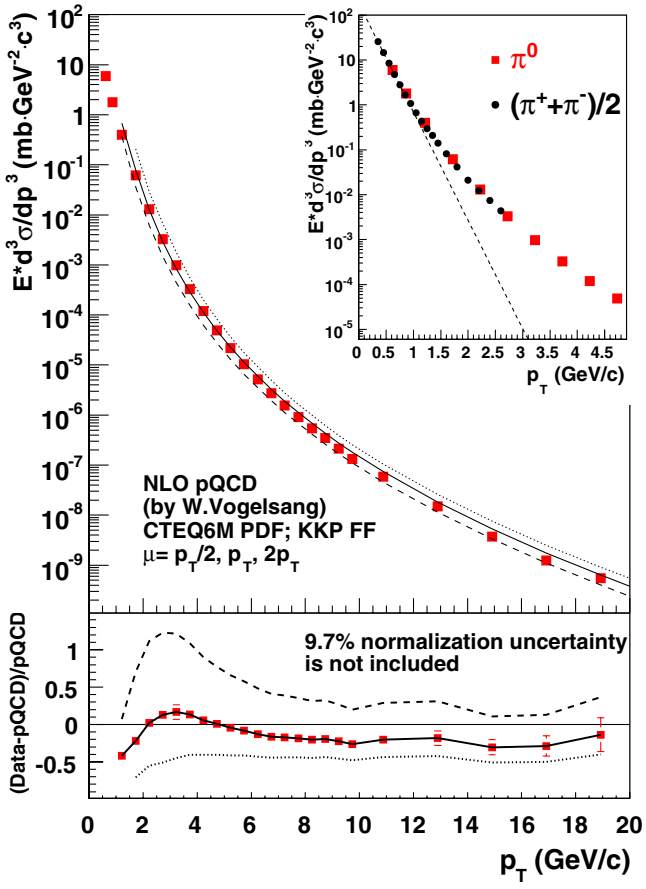

FIG. 1 (color online). The neutral pion production cross section at $\sqrt{s} = 200$ GeV as a function of p_T (squares) and the results of NLO pQCD calculations for theory scales $\mu = p_T/2$ (dotted line), p_T (solid line) and $2p_T$ (dashed line), see text for details; note that the error bars are smaller than the points. The inset shows, in addition to π^0 (squares), data for $(\pi^+ + \pi^-)/2$ (solid circles), and a fit of charged pion data to an exponential function for $p_T < 0.8$ GeV/c (dashed line). The bottom panel shows the relative difference between the data and theory for the three theory scales. Experimental uncertainties (excluding the 9.7% normalization uncertainty) are shown for the $\mu = p_T$ curve.

tude. We note also more recent theoretical work which describes the RHIC midrapidity π^0 data, and which introduces an intrinsic k_T dependence into the parton distribution and fragmentation functions [18], or which includes soft gluon emission in the interaction [19]. Both new approaches improve agreement with data at lower energies and have a smaller effect on the $\sqrt{s} = 200$ GeV midrapidity cross sections.

The inset of Fig. 1 shows the lower p_T region in more detail including high precision data for the charged pion cross section from [20]. The data show a transition in the p_T dependence of the cross section, from exponential to a power law dependence, in the region $p_T \approx 1$–2 GeV/c. In order to estimate possible contamination from nonperturbative physics in the higher p_T data, an exponential function ($\sim e^{-\alpha p_T}$) representing a nonperturbative component is fit to the charged pion spectrum in the region $p_T = 0.3$ to 0.8 GeV/c (only the lowest p_T π^0 data point is in this range) and extrapolated to the higher p_T region. The exponential fit for the low p_T region gives $\alpha = 5.56 \pm 0.02$ $(\mathrm{GeV}/c)^{-1}$, with $\chi^2/NDF = 6.2/3$. Only statistical uncertainties for the charged pion data were used in the fit. The dominant systematic uncertainty for the points in the fitted p_T range is a ~12% normalization uncertainty (excluding the normalization uncertainty from the MB trigger cross section). Beyond about $p_T = 1$ GeV/c, the data lie above this single exponential. The fraction of the exponential contribution to the data for the 2–2.5 GeV/c p_T bin is found to be less than 10%, with a negligible contribution for higher p_T. This is the basis for applying the pQCD formalism to the double helicity asymmetry data with $p_T > 2$ GeV/c.

For the 2005 run, each collider ring of RHIC was filled with up to 111 bunches in a 120 bunch pattern, spaced 106 ns apart, with predetermined patterns of polarization signs for the bunches. Spin rotators, sets of four helical dipole magnets on each side of PHENIX, rotate the polarization orientation from vertical, the stable spin direction in the RHIC arcs, to longitudinal at the interaction point [21]. Beam helicity asymmetries are obtained by tagging the polarization signs of the bunches for each event. The bunches for one beam alternate in polarization sign, and pairs of bunches alternate in sign for the other beam. In this way data for all combinations of beam helicity are collected at the same time, and the possibility of false asymmetries due to changing detector response versus spin state is greatly reduced. Each RHIC fill, typically lasting 8 h, used one of four bunch spin patterns.

The beam polarizations for 2005 were measured using fast carbon target polarimeters [22], normalized by absolute polarization measurements made during 2005 by a separate polarized atomic hydrogen jet polarimeter [23]. The beam polarizations, from luminosity-weighted averages over 104 RHIC fills used in the analysis, were $\langle P^B \rangle = 0.50 \pm 0.002(\mathrm{stat}) \pm 0.025(\mathrm{systB}) \pm 0.015(\mathrm{systG})$ and $\langle P^Y \rangle = 0.49 \pm 0.002(\mathrm{stat}) \pm 0.025(\mathrm{systY}) \pm 0.015(\mathrm{systG})$, for blue ($B$) and yellow ($Y$) RHIC beams, respectively, for the bunches colliding at PHENIX. The systematic uncertainties have been separated into uncorrelated uncertainties for each beam, "systB" and "systY," and a global systematic uncertainty "systG," which is common for both beams and comes from systematic uncertainty in jet polarimeter measurements [24]. For comparison, the polarizations in the 2004 run were $0.44 \pm 0.08(\mathrm{syst})$.

Local polarimeters based on very forward neutron production (production angle 0.3–2.5 mrad) [6,25] were used to set up and monitor the beam polarization orientation at PHENIX. The polarimeters monitor the transverse polarization of each beam at PHENIX, which can be compared to the beam polarization measured by the RHIC polar-

imeters where the polarization direction is vertical. The local polarimeters were calibrated by turning off the spin rotators around PHENIX, and measuring the response of the local polarimeters with the beams vertically polarized. For the longitudinal polarization data, the beams showed a measurable transverse polarization, with $(P_T/P)^B = 0.10 \pm 0.02$ and $(P_T/P)^Y = 0.14 \pm 0.02$, with P_T/P referring to the fraction of transverse polarization of each beam. The polarization directions, as determined by the spin rotator settings and as measured by the local polarimeters, remained constant over the run. The product of the beam polarizations $P^B \cdot P^Y$ is required for the double helicity asymmetry measurement. The average transverse component of the product was $\langle P_T^B \cdot P_T^Y \rangle / \langle P^B \cdot P^Y \rangle < (P_T/P)^B \cdot (P_T/P)^Y = 0.014 \pm 0.003$; the average of the polarization product over the run was $\langle P^B \cdot P^Y \rangle = 0.24$ with a systematic uncertainty of $\pm 9.4\%$.

The double helicity asymmetry A_{LL} is the difference of cross sections for the same versus opposite beam helicities, divided by the sum. Experimentally, for inclusive π^0 production, it can be determined as

$$A_{LL}^{\pi^0} = \frac{1}{|P^B \cdot P^Y|} \cdot \frac{N_{++} - R \cdot N_{+-}}{N_{++} + R \cdot N_{+-}}; \qquad R = \frac{L_{++}}{L_{+-}}, \quad (1)$$

where N is the number of π^0's measured in PHENIX from the colliding bunches with the same $(++)$ and opposite $(+-)$ helicities, and R is the relative luminosity between bunches with the same and opposite helicities. Here we neglect the parity-violating difference in cross section between $(++) \leftrightarrow (--)$ and $(+-) \leftrightarrow (-+)$ beam helicity configurations [26]. A_{LL} was calculated for each fill in order to reduce systematics from variation in beam polarizations and in R for different fills. Even and odd crossings were handled by separate high p_T photon trigger electronics chains. To avoid possible detector bias, A_{LL} was also determined separately for the even and odd crossings. Final asymmetries were averaged, and corrected for the asymmetry of the background under the π^0 peak in the two-photon mass distribution A_{LL}^{BG}, measured from the data outside the π^0 peak region (50 MeV/c^2 wide bands on either side of the π^0 peak) [6]. A_{LL}^{BG} was consistent with zero in all p_T bins.

The relative luminosity ratio R is obtained from the MB triggers discussed above. Scalers keep track of the number of live triggers for each bunch crossing. Single beam background was $<0.05\%$, as measured from noncolliding bunches, and contributes negligible systematic uncertainty to the measured R. We also measured the double helicity asymmetry of the relative luminosity scaler counts, by normalizing using zero degree neutral particle production as measured by zero degree calorimeters (ZDC) [27]. No asymmetry was observed. This gave a limit on an asymmetry bias in the measurement of $\delta A_{LL}^{\pi^0}|_{\text{bias}} < 2 \times 10^{-4}$, and a limit on the systematic uncertainty for the measurement of relative luminosity giving $\delta A_{LL}^{\pi^0}|_R < 2 \times 10^{-4}$. These limits also include the effects from the pileup of two or more collisions in a crossing, calculated at $\lesssim 4\%$ of the crossings. The BBC and ZDC monitors observe the pileup at significantly different rates, and therefore the limits above, from comparing BBC and ZDC counts, include these uncertainties.

A transverse double spin asymmetry A_{TT}, the transverse equivalent to Eq. (1), can contribute to A_{LL} through the 1.4% transverse component of the product of the beam polarizations discussed above. Although A_{TT} has been postulated to be extremely small, $\sim 10^{-4}$ [28], it has not been previously measured. We measured A_{TT} in a short run with transverse polarization. $A_{TT}(p_T)$ was consistent with zero within statistical errors [13]; the errors were 5 times larger than the uncertainties for A_{LL}, $\delta^{\text{stat}} A_{LL}$. Therefore, a limit was determined for the A_{TT} contribution to A_{LL} of $0.07 \cdot \delta^{\text{stat}} A_{LL}$.

Figure 2 presents the measured double helicity asymmetry in π^0 production [13]. A scale uncertainty of 9.4% in $A_{LL}^{\pi^0}$ due to the uncertainty in beam polarization is not shown. The other systematic uncertainties are negligible, as discussed above, and checked using a bunch polarization sign randomization technique, and by varying the π^0 identification criteria [6]. Data for $p_T > 1$ GeV/c were obtained from the high p_T photon triggered sample. For p_T below 1 GeV/c, due to low efficiency for the high p_T photon trigger, we used the MB data sample. In the low p_T region, where the cross section shows an exponential

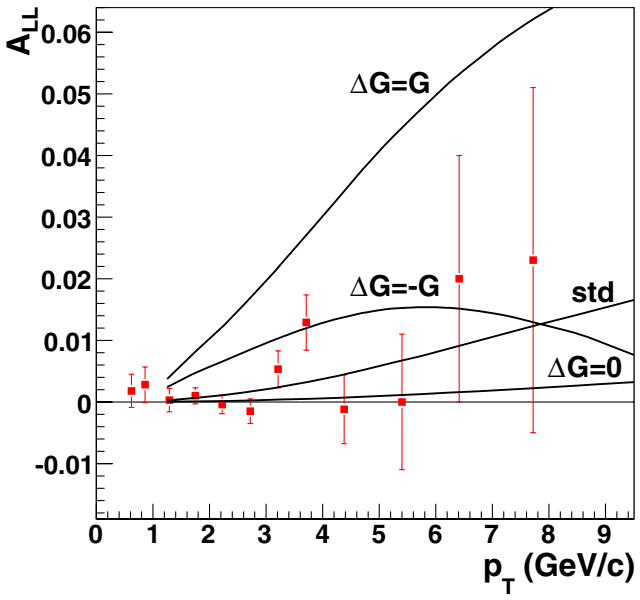

FIG. 2 (color online). The double helicity asymmetry for neutral pion production at $\sqrt{s} = 200$ GeV as a function of p_T (GeV/c). Error bars are statistical uncertainties, with the 9.4% scale uncertainty not shown; other experimental systematic uncertainties are negligible. Four GRSV theoretical calculations based on NLO pQCD are also shown for comparison with the data (see text for details).

behavior, the helicity asymmetry is $A_{LL}^{\pi^0} = 0.002 \pm 0.002$, for the data in the range $p_T = 0.5 - 1$ GeV/c. For the higher p_T region, the four curves in Fig. 2 show calculations of $A_{LL}^{\pi^0}$, using NLO pQCD with $\mu = p_T(\pi^0)$, that reflect the range of gluon polarizations allowed by inclusive deep inelastic scattering (DIS) data. The calculations are based on the Glück-Reya-Stratmann-Vogelsang (GRSV) model, where "standard" (std) was the best fit to inclusive DIS data [29]. For momentum fraction x, $\Delta G(x) = G^+(x) - G^-(x)$ refers to the gluon helicity distribution, and $G^+(x)$ and $G^-(x)$ refer to the gluon densities for + and − helicities in a + helicity proton. The first moment of the gluon helicity distribution, $\int_0^1 \Delta G(x)dx$, for the std parameterization is $\Delta G = 0.4$, at the scale $Q^2 = 1$ GeV^2. The other three curves are calculations based on this best fit, but use at $Q^2 = 0.4$ GeV^2 the function $\Delta G(x) = G(x)$, 0, $-G(x)$, where $G(x)$ is the unpolarized gluon distribution. The gluon distribution at the input scale is evolved to the scale $Q^2 = p_T^2(\pi^0)$.

In order to explore the impact of the new data on the sensitivity to the polarized gluon distribution, we have compared the data with a set of $A_{LL}(p_T)$ curves corresponding to different $\Delta G(x)$ between $\Delta G(x) = -G(x)$ and $\Delta G(x) = G(x)$ at $Q^2 = 0.4$ GeV^2. We used the data for $p_T > 2$ GeV/c, which appear to have little contamination from soft physics as discussed earlier.

Combining the estimate of the soft physics fraction in the $p_T = 2$–2.5 GeV/c bin of $<10\%$, with the soft physics asymmetry as measured for $p_T < 1$ GeV/c, a soft physics contribution to the asymmetry in the $p_T = 2 - 2.5$ GeV/c bin would be $\lesssim 2 \cdot 10^{-4}$, and negligible for higher p_T bins. We note, however, that a parton intrinsic k_T [18] could still affect the lower p_T asymmetries, for $p_T \approx 2$–3 GeV/c, and this is not addressed in the GRSV model.

The most likely x_g for PHENIX π^0 data in each p_T point is $\sim x_T/0.7$ [30], where $x_T = p_T/(\sqrt{s}/2)$. For the measured p_T range 2–9 GeV/c, the range of x_g in each bin is broad, and spans the range $x_g = 0.02$–0.3, as calculated by NLO pQCD [31].

Figure 3 shows the corresponding χ^2 versus $\Delta G_{\rm GRSV}^{x=[0.02\to0.3]}$, where we compare to an integral of ΔG over the probed x_g range. Only experimental statistical uncertainties are used to calculate χ^2, and no theoretical uncertainties are included. It is important to note, that although the range of the first moment explored represents $\sim 60\%$ of the full integral, this reflects using a specific model for the gluon polarization. For example, a gluon polarization model with a crossover from positive to negative gluon polarization within our x_g range would yield a small average asymmetry for each point. Also, other models can generate larger or smaller contributions from the gluon spin in the unmeasured region of x_g.

These data are sensitive to the first moment of the polarized gluon distribution. Using the GRSV model, we find that the gluon polarization contribution to the proton

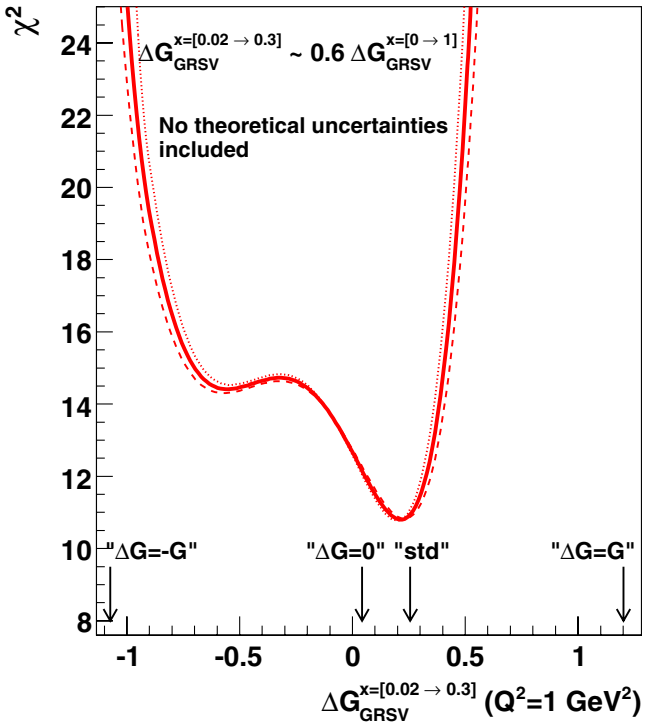

FIG. 3 (color online). The χ^2 distribution of the measured data plotted versus the value of the first moment of the polarized gluon distribution (solid line) in the x_g range from 0.02 to 0.3 corresponding to our π^0 data in p_T bins from 2 to 9 GeV/c. Dashed and dotted lines correspond to -9.4% and $+9.4\%$ variation in A_{LL} normalization related to the beam polarization uncertainty, the dominant systematic uncertainty of our data. Only statistical uncertainties were used for each curve. Arrows indicate ΔG corresponding to the different polarized gluon distributions discussed in the text.

spin (1/2) in the probed x_g range is constrained between -0.9 and $+0.5$, for $\chi^2 - \chi^2_{\rm min} = 9$, representing a "$3\sigma$" limit (a "$1\sigma$" limit would give a constraint between 0.07 and 0.3). The extremes of gluon polarization are ruled out, modulo the above remarks, with the confidence level for "$\Delta G = \pm G$" of less than 10^{-6}. Large positive gluon polarization [32] was proposed shortly after the discovery that the quark contribution to the proton spin was small [33], with the suggestion that such a large gluon polarization would mask a "bare" quark polarization. For std and "$\Delta G = 0$", the confidence levels are 20%–21% and 12%–13%, respectively, for the range of $\pm 9.4\%$ scale uncertainty of the measurement. Semi-inclusive DIS measurements [34] have also presented data on ΔG in a limited x_g range and its comparison with various ΔG scenarios.

The two minima in Fig. 3 reflect the quadratic contribution of the gluon polarization to A_{LL}, from the gluon-gluon scattering subprocess for π^0 production. The symmetry between the two minima is broken by the quark-gluon scattering subprocess, where the gluon polarization contributes linearly to A_{LL}. The quark-gluon subprocess is emphasized at higher p_T, which will become accessible

with additional running at high polarization and luminosity.

To summarize, we have presented the unpolarized cross section and double helicity asymmetries for π^0 production at midrapidity, for proton-proton collisions at $\sqrt{s} = 200$ GeV. We observe an apparent transition region in the cross section, for $p_T \approx 1$ to 2 GeV/c, with the cross section described by an exponential in p_T below $p_T \sim 1$ GeV/c, and with the cross section described by the pQCD prediction for $p_T = 2$ to 20 GeV/c, over 7 orders of magnitude in cross section. The results for A_{LL} in the pQCD region, which we take as $p_T \geq 2$ GeV/c, constrain the gluon polarization in the proton significantly. The range probed is $x_g = 0.02$ to 0.3, for the gluon momentum fraction. Using one representative model for the gluon polarization, GRSV [29], which assumes no crossover in gluon polarization versus x_g, we present a map of χ^2 versus the first moment of the polarized gluon distribution in the measured region. From this study, the present data rule out extreme values of gluon polarization suggested after the surprise of the EMC result that the quarks (and antiquarks) contribute little to the spin of the proton [33], but allow significant contribution from the gluon spin to the proton spin.

We thank the RHIC Polarimeter Group and the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We thank W. Vogelsang and M. Stratmann for providing the NLO pQCD calculations and for informative discussions. We acknowledge support from the Department of Energy and NSF (USA), MEXT, and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), MSMT (Czech Republic), IN2P3/CNRS, and CEA (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE (India), ISF (Israel), KRF and KOSEF (Korea), MES, RAS, and FAAE (Russia), VR and KAW (Sweden), U.S. CRDF for the FSU, USA-Hungarian NSF-OTKA-MTA, and USA-Israel BSF.

(Received 22 April 2007; published 21 September 2007)

Longitudinal density correlations of produced matter in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV have been measured from the inclusive charged particle distributions as a function of pseudorapidity window sizes. The extracted $\alpha\xi$ parameter, related to the susceptibility of the density fluctuations in the long-wavelength limit, exhibits a nonmonotonic behavior as a function of the number of participant nucleons, N_{part}. A local maximum is seen at $N_{\text{part}} \sim 90$, with corresponding energy density based on the Bjorken picture of $\epsilon_{\text{Bj}}\tau \sim 2.4$ GeV/(fm$^2 c$) with a transverse area size of 60 fm^2. This behavior may suggest a critical phase boundary based on the Ginzburg-Landau framework.

DOI: 10.1103/PhysRevC.76.034903 PACS number(s): 25.75.Dw

I. INTRODUCTION

Theoretical studies of quantum chromodynamics (QCD) in nonperturbative regimes indicate that QCD matter has a rich phase structure [1]. The phase diagram can be parametrized by temperature T and baryo-chemical potential μ_B. Based on the phase diagram, we can obtain perspectives on how the vacuum structure of the early universe evolved in extremely high temperature states after the Big Bang as well as what happens in extremely high baryon density states such as in the core of neutron stars. Therefore, a comprehensive and quantitative understanding of the QCD phase diagram is one

*Deceased
†PHENIX Spokesperson: jacak@skipper.physics.sunysb.edu

of the most important subjects in modern nuclear physics. At a minimum we expect the phase diagram to exhibit at least two distinct regions: the deconfined phase, where the basic degrees of freedom of QCD, quarks, and gluons emerge, and the hadron phase, where quarks and gluons are confined. There is a first-order phase boundary at $\mu_B > 0$ and $T = 0$ [2–9]. At $\mu_B = 0$ and $T > 0$ a smooth cross-over transition is expected because of finite masses of quarks [10]. Logically, we can then expect that a critical endpoint (CEP) exists at the end of the first-order phase transition line [11]. The location of the CEP would be a landmark in understanding the whole structure of the phase diagram. Although numerical calculations using lattice gauge theory, as well as model calculations, predict the existence of the CEP, none of them have reached a quantitative agreement on the location at present precision [1]. Therefore experimental investigations are indispensable to pin down the location and to establish properties of the phase point based on fundamental observables.

Strongly interacting, high-density matter has been created in nucleus-nucleus collisions at the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory (BNL) [12]. Strong suppression of hadrons at high transverse momentum (p_T) observed in central Au+Au collisions at $\sqrt{s_{NN}} =$ 200 GeV at RHIC indicate creation of high-density matter [13,14]. Strong elliptic flow indicates that the matter thermalizes rapidly and behaves like a fluid with very low viscosity [15]. Furthermore, the valence quark number scaling of elliptic flow suggests that quark-like degrees of freedom are pertinent in the evolution of the flow [16]. Those observations naturally lead us to the expectation that the initial thermalized state of matter is at $T > T_c$ in central Au+Au collisions, and possibly at $T < T_c$ in the most peripheral collisions. Therefore a system with initial $T = T_c$ may exist somewhere between peripheral and central collisions.

Since there could be different T_cs depending on order parameters in the cross-over transition [17], it is worth measuring different kinds of order parameters. It is known that density correlations in matter are robust observables for critical temperatures in general [18]. The order parameter we will focus on here is spatial density fluctuations. Following the Ginzburg-Landau (GL) framework [19] we expect a correlation between fluctuations in density at different points, which leads to a two-point correlation function of the form $\alpha e^{-r/\xi}$, where r is the one-dimensional distance, α is the strength of the correlation, and $\xi \propto |T - T_c|^{-1/2}$ is the spatial correlation length. This functional form can be derived from the GL free energy density by expanding it with a scalar order parameter that is small enough (see Appendix A). A large increase of ξ near T_c can be a good indicator of a phase transition. In addition to ξ itself, the product $\alpha\xi$ can also be a good indicator of a phase transition. As shown in Sec. II, $\alpha\xi$ behaves as $|1 - T_c/T|^{-1}$. In the GL framework, this quantity is related to the medium's susceptibility in the long-wavelength limit. (See Appendix A for the derivation.) The matter produced in the collision expands longitudinally from its earliest time, which leads to cooling after the initial thermalization. If the system's evolution takes it near a critical point as it cools, then the large correlated density fluctuations will appear as T approaches T_c from above. If the expansion after that point is rapid enough then these fluctuations can potentially survive into the final state [20].

Experimentally, spatial density fluctuations in longitudinal space z in the early stage of an $A+A$ collision at RHIC can be measured as the density fluctuation in rapidity, or pseudorapidity, space in the final state. The differential length dz between neighboring medium elements at a common proper time $\tau = \sqrt{t^2 - z^2}$ is expressed as $dz = \tau \cosh(y) dy$, where y is rapidity. If we limit the study to only a narrow region around midrapidity, then $dz \sim \tau dy$ is valid with the approximation $\cosh(y) \sim 1$. Therefore we can observe density fluctuation in the z coordinate as being mapped onto density fluctuations in rapidity space. In the region around midrapidity used in this analysis we can approximate rapidity by pseudorapidity (η) for inclusive charged particles, since the mean $\langle p_T \rangle$ ($\langle p_T \rangle = 0.57$ GeV/$c \gg m_\pi$) observed in $\sqrt{s_{NN}} = 200$ GeV collisions at RHIC is so high.

In this paper we measure charged particle density correlations in pseudorapidity space to search for the critical phase boundary in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The density correlation is extracted from inclusive charged particle multiplicity distributions measured as a function of pseudorapidity window size $\delta\eta$. Negative binomial distributions (NBDs) are fit to the measured multiplicity distributions, and the NBD parameters μ (mean) and k^{-1} (deviation from a Poissonian width) are determined. The product of the correlation strength α and the correlation length ξ is extracted from a known relation between the product of $\alpha\xi$ and the NBD k parameter as a function of $\delta\eta$. We expect a monotonic correspondence between initial temperature and measured energy density based on Bjorken picture [21], which in turn has a monotonic relation with the number of participant nucleons, $N_{\rm part}$, in a collision [22]. Thus the critical behavior of $\alpha\xi$ near T_c can be observed as a nonmonotonic increase as a function of $N_{\rm part}$.

It is worth noting that most experimentally accessible points on the phase diagram are neither phase boundaries nor the endpoint. Therefore, before searching for a special phase point such as CEP based on particular theoretical assumptions, we would rather observe and define phase boundaries by general methods. The application of the GL framework for density correlations far from T_c provides this approach. It is known that the GL framework is not applicable directly at $T = T_c$ because the fluctuations become too large to be described consistently. The correlation length ξ cannot be defined at T_c, where many length scales from small to large emerge. This is the origin of the power-law behavior, or fractal nature of fluctuations at the critical phase boundary. However, in the regions relatively far from T_c, the fluctuations are naturally expected to be small. Therefore the GL approach is suitable in the nuclear collision environment as long as the system approaches a phase boundary from a thermalized state with T well above T_c. As a future prospect, once we define a phase boundary even in the crossover region, we can further investigate the characteristic nature of the phase point, such as critical exponents based on the chiral condensate [23–25] along the phase boundary, to judge whether the point corresponds to a CEP or not.

The organization of this paper is as follows. Section II provides the exact definition of the experimental observables.

Section III describes the PHENIX detector used to make the measurements. Section IV describes the event samples used for this analysis and the method for corrections applied to the measured multiplicity fluctuations. The systematic errors on the measured fluctuations are also explained in this section. In Sec. V, fit results of the NBD parameters in each collision centrality and pseudorapidity window size are presented, and the behaviors of the $\alpha\xi$ product as a function of $N_{\rm part}$ are presented. In Sec. VI, in addition to the discussion on the observed $N_{\rm part}$ dependence of $\alpha\xi$, other possible sources of correlation between inclusive charged particles are discussed. The relation between the measured energy density and $N_{\rm part}$ is discussed to relate $N_{\rm part}$ to the initial temperature. Conclusions are given in Sec. VII. In Appendix A, the density correlation length and susceptibility are exactly defined based on the GL framework. Finally, in Appendix B all measured NBD parameters in all collision centralities are tabulated.

II. EXPERIMENTAL OBSERVABLES

In this analysis the density fluctuation will be discussed via charged particle multiplicity distributions as a function of the pseudorapidity window size for each collision centrality or $N_{\rm part}$ range.

It is known that the charged particle multiplicity distributions are empirically well described by the NBD in $A+A$, $p+p$, and e^+e^- collisions [26]. The distribution is expressed as

$$P_{k,\mu}(n) = \frac{\Gamma(n+k)}{\Gamma(n-1)\Gamma(k)}\left(\frac{\mu/k}{1+\mu/k}\right)\frac{1}{1+\mu/k}, \qquad (1)$$

Here μ is the mean of the distribution and k^{-1} corresponds to the difference between its width and that of a Poisson with that mean. Thus the NBD coincides with the Poisson distribution in the case of $k=\infty$, and with the Bose-Einstein distribution in the case of $k=1$. In this sense, the NBD k directly reflects the degree of correlation between the particles produced into the experimental window.

We can relate the k parameter for the multiplicity distribution within an η window to the correlation between phase-space densities in different η windows. Specifically, k can be mathematically related with the second-order normalized factorial moment F_2 by

$$k^{-1} = F_2 - 1, \qquad (2)$$

where F_2 corresponds to the integrated two-particle correlation function, which can be expressed as [27]

$$F_2(\delta\eta) = \frac{\langle n(n-1)\rangle}{\langle n\rangle^2} = \frac{\int\int^{\delta\eta}\rho_2(\eta_1,\eta_2)d\eta_1 d\eta_2}{\{\int^{\delta\eta}\rho_1(\eta)d\eta\}^2} = \frac{1}{(\delta\eta)^2}\int\int^{\delta\eta}\frac{C_2(\eta_1,\eta_2)}{\bar{\rho_1}^2}d\eta_1 d\eta_2 + 1, \qquad (3)$$

where n is the number of produced particles and $\delta\eta$ is the pseudorapidity window size inside which the multiplicities are measured. In Eq. (3) we introduced one- and two-particle inclusive multiplicity densities ρ_1 and ρ_2 based on the inclusive differential cross section relative to the total inelastic cross section $\sigma_{\rm inel}$ as follows [26]:

$$\frac{1}{\sigma_{\rm inel}}d\sigma = \rho_1(\eta)d\eta, \qquad \frac{1}{\sigma_{\rm inel}}d^2\sigma = \rho_2(\eta_1,\eta_2)d\eta_1 d\eta_2. \qquad (4)$$

Here $\bar{\rho_1}$ is the average density per unit length within $\delta\eta$, which is defined as

$$\bar{\rho_1} = \frac{1}{\delta\eta}\int^{\delta\eta}\rho_1(\eta)d\eta. \qquad (5)$$

With these densities, the two-particle density correlation function is defined as

$$C_2(\eta_1,\eta_2) = \rho_2(\eta_1,\eta_2) - \rho_1(\eta_1)\rho_1(\eta_2). \qquad (6)$$

Instead of measuring C_2 or F_2 directly, in this analysis we extract the NBD k parameter as a measure of particle correlations over η. This is partly for historical reasons [28] but also because, as shown in Sec. IV, we can correct the measurement of k for the detector imperfections in a very robust way by using a statistical property of NBD, whereas the same correction made at the level of F_2 would require additional information on the parent distribution.

The normalized two-particle correlation function C_2 in the experiment can be parametrized as follows, based on the one-dimensional functional form obtained in the GL framework [see Eq. (A8)]:

$$\frac{C_2(\eta_1,\eta_2)}{\bar{\rho_1}^2} = \alpha e^{-|\eta_1-\eta_2|/\xi} + \beta, \qquad (7)$$

where $\bar{\rho_1}$ is proportional to the mean multiplicity in each collision centrality bin, or range of $N_{\rm part}$, and the scale factor α is the strength of the correlations at the zero separation. The constant term β arises from any kind of experimental and physical correlations that are independent of the pseudorapidity separation, such as the residual effect of finite centrality binning.

Further, one has to take into account the fact that the damping behavior in Eq. (A8) is caused only by the spatial inhomogeneity of the system at a fixed temperature. In realistic collisions and event samples there is no single relevant temperature. For instance, finite centrality binning adds together a range of fluctuations originating from collisions with different $N_{\rm part}$. However, in principle these centrality-correlated fluctuations are independent of the thermally induced spatial fluctuations. In addition, although the self-correlation at the zero distance between two subvolumes in Eq. (A6) was excluded, the self-correlation cannot be excluded in the integrated two-particle correlation function contained in Eq. (3). We have tried various functional forms for C_2, which contained power terms and also plural correlation lengths. However, we found empirically that just adding the constant term in Eq. (7) produced the best-fit results to all data points.

Finally, the relation between the NBD k parameter and the pseudorapidity window size $\delta\eta$ can be obtained by the substitution of Eq. (7) into Eq. (3) [28,29]:

$$k^{-1}(\delta\eta) = F_2 - 1 = \frac{2\alpha\xi^2(\delta\eta/\xi - 1 + e^{-\delta\eta/\xi})}{\delta\eta^2} + \beta. \qquad (8)$$

In the limit of $\xi \ll \delta\eta$, which we believe holds in this analysis, Eq. (8) can be approximated as

$$k(\delta\eta) = \frac{1}{2\alpha\xi/\delta\eta + \beta} \quad (\xi \ll \delta\eta), \tag{9}$$

where experimentally we cannot resolve α and ξ separately, but the product $\alpha\xi$ can be directly determined. The product is related to the susceptibility in the long-wavelength limit, $\chi_{\omega=0} \propto |T - T_c|^{-1}$, for a given temperature T based on Eq. (A11). Combined with the parametrization in Eq. (7), the $\alpha\xi$ product should then follow as

$$\alpha\xi \propto \bar{\rho}_1^{-2} \frac{1}{|1 - T_c/T|}. \tag{10}$$

Since we expect that $\bar{\rho}_1$ is a monotonic function of T, in the limit of T far from T_c, $\alpha\xi$ should vary monotonically as a function of T. However, if T approaches T_c, the $\alpha\xi$ product will show a singular behavior. Therefore, any nonmonotonic increase of $\alpha\xi$ could be an indication of $T \sim T_c$ near a critical point. If the experimental bias term β is excluded in Eq. (9), the slope in k versus $\delta\eta$ thus contains crucial information on the phase transition.

It is worth mentioning that in this method, correlations on scales even smaller than the minimum $\delta\eta$ window can be meaningfully discussed based on the differences of the NBD k as a function of $\delta\eta$ window sizes, since the correlations are always integrated from the limit of the detector resolution to $\delta\eta$ window size.

III. PHENIX DETECTOR

PHENIX is one of four experiments operating at RHIC [30]. The PHENIX detector has two central spectrometer arms, denoted East and West. Each central arm covers the pseudorapidity range $|\eta| < 0.35$ and subtends an azimuthal angle range $\Delta\phi$ of $\pi/2$ around the beam axis (z direction). PHENIX includes global detectors that provide information for event triggers as well as measurement of collision points along the beam axis and collision centralities. A detailed description of the PHENIX detector can be found in Ref. [30]. The detector subsystems relevant for this analysis will be briefly explained in the following.

Charged particles are measured by a drift chamber (DC) and two multiwire chambers with pad readout (PC1 and PC3) located at 2.2, 2.5, and 5 m from the beam axis in the East arm, respectively. The collision vertex points were measured using the time difference between two Beam-Beam Counters (BBC) located at $z = +144$ cm (north side) and $z = -144$ cm (south side) from the nominal interaction point (IP) along the beam line, which cover pseudorapidity ranges of $3.0 < \eta < 3.9$ (north) and $-3.9 < \eta < -3.0$ (south), respectively. Each BBC has 64 Čerenkov counter elements with the typical time resolution of 50 ps. Combined with BBC's, two Zero Degree Calorimeters (ZDCs) were further used. The ZDCs are designed to measure energies of spectator neutrons within a cone of 2 mrad around the beam axis. The two ZDC's are located at $z = \pm 18.25$ m from the IP, respectively. The Au+Au minimum bias trigger and collision centralities were provided by combining information from both BBCs and ZDCs.

IV. DATA ANALYSIS

A. Run and event selection

We have used data taken in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV with the magnetic field off condition during RHIC Run 2 in 2002, to optimize acceptance for the low-p_T charged particles. The basic trigger required coincident hits in the two BBCs (equal or more than two hit Čerenkov elements in each side) and the two ZDCs (equal or more than one neutron in each side). The efficiency of this minimum-bias trigger is estimated as $92.2^{+2.5}_{-3.0}$% to the total Au+Au inelastic cross section by the Monte Carlo (MC) simulation based on the Glauber model [13]. Events with collision points within ± 5 cm from the nominal IP as measured by the BBC were analyzed. In total, 258,000 events taken by the minimum-bias trigger were used in this analysis. We have rigorously checked the detector stability by looking at multiplicity correlations between the relevant subdetector systems, as well as by monitoring positions of inefficient areas over the span of the analyzed dataset. We allowed 2% fluctuation on the average multiplcity of measured number of charged tracks in the entire analyzed run ranges.

B. Track selection

In this analysis, charged tracks detected in the East arm ($|\eta| < 0.35$, $\Delta\phi < \pi/2$) were used. As charged track selection criteria, we required that each straight-line track reconstructed by a DC hit pattern associated with a PC1 hit be aligned with a PC3 hit and the collision vertex point measured by the BBC. We required associations between DC tracks and PC3 hits to be within 10 cm in the distance of closest approach (DCA), which was determined to minimize the random associations. The DC has six types of wire modules; two of them are used for the track reconstruction for the azimuthal angle and the others are used for the pattern recognition. Selected tracks were reconstructed by using all wire modules of the DC.

In addition to the single track selection, we required a minimum two-track separation to minimize effects from fake tracks and associated secondary particles. When we find tracks within the minimum separation window of $\delta\eta < 0.001$ and $\delta\phi < 0.012$ rad, we count them as one track, independent of the number of reconstructed tracks in the window. These cut values were determined by looking at $\delta\eta$ and $\delta\phi$ distributions on the η-ϕ plane of any two track pairs in the real data sample. The DC track resolution of 2 mm in the z direction at a reference radius of 220 cm from the beam axis corresponds to 1.0×10^{-3} in η. PC1 and PC3, which are used for the track association, have the same solid angle, and these pixel sizes are 8.4 and 14.7 mm, respectively. These pixel sizes are greater than the requirement of two-track separation cuts; however, these resolutions are 1.7 and 3.6 mm for PC1 and PC3, respectively, in the z direction, and these values also corresponds to 1.0×10^{-3} in η. The resolution in ϕ is 1 mrad, but the maximum drift length in the DC corresponds to 0.012 rad. Therefore the two-track separation window size in η and ϕ is consistent with what is expected.

For the normal magnetic field condition at the PHENIX detector, which is used to identify the charged particles, the

threshold transverse momenta p_T correspond to 0.2, 0.4, and 0.6 GeV/c for charged pions $\pi^{\pm}$, charged kaons $K^{\pm}$, and protons p (and antiprotons $\bar{p}$), respectively [31]. Since this analysis used the data taken without magnetic field, the threshold transverse momenta p_T can be lowered to 0.1, 0.25, and 0.35 GeV/c for $\pi^{\pm}$, $K^{\pm}$, and p (and $\bar{p}$), respectively. They were estimated by the GEANT-based MC [32] simulation by requiring the equivalent single-track selection criteria. The average transverse momentum p_T for the detected inclusive charged particles used in this analysis corresponds to 0.57 GeV/c, which was also estimated by using the measured p_T spectra [31] with the MC simulation. Therefore, the difference of the rapidity and pseudorapidity is at most 3% at the edge of the PHENIX acceptance.

C. Centrality definition and the number of participant nucleons

The collision centrality was determined by looking at the correlation between a deposited charge sum in both north and south BBCs and an energy sum in both ZDCs on an event-by-event basis. As shown in Fig. 1, the centrality percentile is defined as the fraction of the number of events in a selected centrality bin on the correlation plot to the total number of minimum-bias events, corrected for the minimum-bias trigger efficiency. Each axis is normalized to its maximum dynamic range. As the standard centrality definition, we adopt a 5% centrality bin width from 0–5% (central) to 60–65% (peripheral) as indicated in the figure. The lower limit of 65% is indicated by the solid line in the figure. In the following analysis, as control samples, we also adopt a 10% bin width by merging two 5% bin width samples from 0–10% to 50–60% and from 5–15% to 55–65%. The latter is referred to as a 5% shifted 10% bin width. It is noteworthy that the change of the centrality bin width shifts the mean values in the charged particle multiplicity distributions, which becomes a strict systematic check on parameter extractions with different event ensembles, even with the same total event sample.

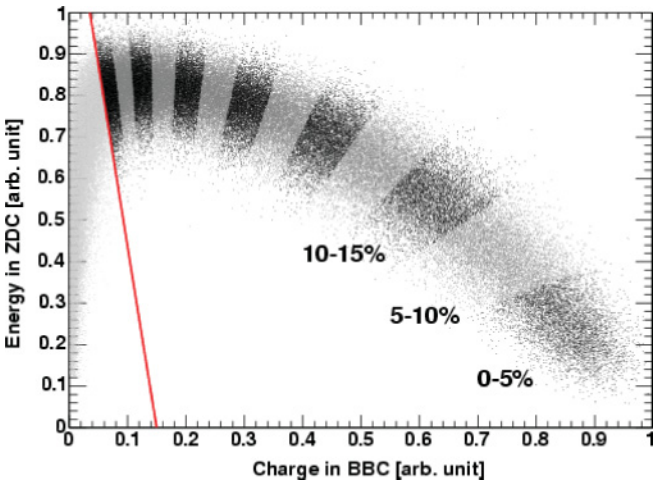

FIG. 1. (Color online) Definition of collision centrality, BBC charges versus ZDC energy. Event samples in 5% bin width are plotted from 0–5% (central) to 60–65% (peripheral). The solid line indicates the limit of the most peripheral sample used for this analysis.

Mapping the centralities to the number of participant nucleons, $N_{\rm part}$, is based on the Glauber model, which is described in detail in Ref. [22]. The quoted mean $N_{\rm part}$ and its error can be obtained from Ref. [31]. Only in the 5% shifted 10% bin width case were the mean $N_{\rm part}$ and its error evaluated by averaging two 5% centrality bins and estimated from its error propagations, respectively.

D. Measurement of multiplicity distributions of charged particles

Multiplicity distributions of charged particles were measured while changing the pseudorapidity window size $\delta\eta$ from 0.066 to 0.7 with a step size of $0.7/2^5 = 0.022$. For a given pseudorapidity window size, the window position in the pseudorapidity axis was shifted by a step of $0.7/2^8 = 0.0027$ as long as the window is fully contained within the PHENIX acceptance of $|\eta| < 0.35$. For each window position NBD fits were performed to the multiplicity distributions. Biases originating from inefficient detector areas were corrected with the procedure explained in Sec. IV E. Since even corrected NBD k parameters are not necessarily equal in the case of extremely inefficient window positions, we have truncated window positions where the reconstruction efficiency is below 50%. This truncation is mainly to exclude biases from the largest hole in the middle of the charged particle detector, as shown in Figs. 2(a) and 2(c). After the truncation, we obtained the weighted mean of corrected NBD parameters ($\langle\mu_c\rangle$, $\langle k_c\rangle$) for a given window size, which are defined as

$$\langle\mu_c\rangle \equiv \sum_{i=1}^{n} \delta\mu_{c_i}^{-2}\mu_{ci} / \sum_{i=1}^{n} \delta\mu_{c_i}^{-2},$$
$$\langle k_c\rangle \equiv \sum_{i=1}^{n} \delta k_{c_i}^{-2} k_{ci} / \sum_{i=1}^{n} \delta k_{c_i}^{-2}, \tag{11}$$

where n is the number of valid window positions after the truncation and δ indicates errors on fitting parameters by the MINUIT program [33] in each window position i. We have performed this procedure in each centrality bin with 5% and 10% centrality bin width, respectively.

The lower limit of 0.066 was determined so that small window sizes, where corrected NBD k was seen to depend heavily on window position, are all excluded. The lower limit is common for all centrality bins.

E. Correction of NBD k and μ

Any dead or inefficient areas in the detector have been identified and the bias on the NBD parameters has been corrected based on a suitable statistical property of NBD. Maps of dead areas were produced from the track projection points onto the η-ϕ plane in the data after the track selections, as shown in Fig. 2(a), where the detector acceptance is divided into $2^8 \times 2^8$ bins in the η-ϕ plane. The accumulated number of hits over the total event sample in each bin is shown by a gray scale reflecting the statistical weights. The scale is normalized to the mean number of hits in the peak position shown in Fig. 2(b). Figure 2(b) shows the number of bins among subdivided $2^8 \times 2^8$ bins as a function of the accumulated

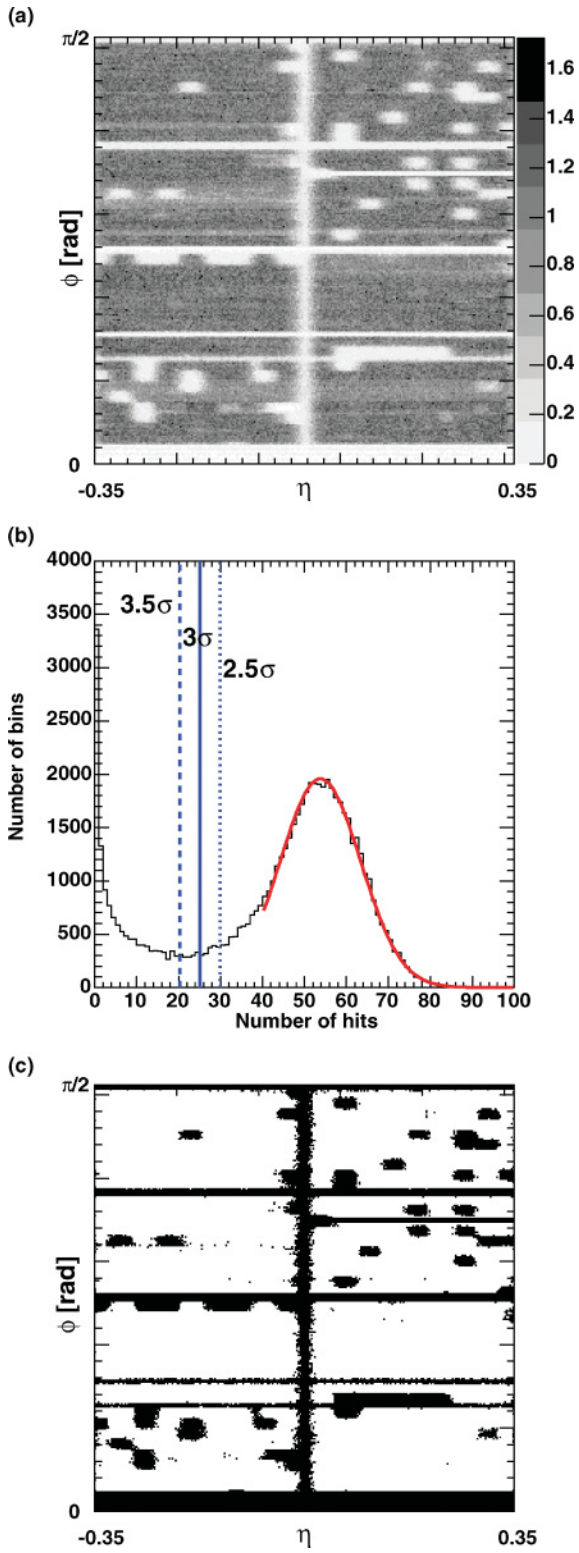

FIG. 2. (Color online) Two-dimensional dead-map definitions. (a) Track projection points onto the η-ϕ plane in the data after all track selections. The scale is normalized to the mean number of hits in the peak position in (b). (b) The number of bins among subdivided $2^8 \times 2^8$ bins as a function of the accumulated number of hits over the total event sample. (c) Definition of the central dead map by excluding the detector region below 3σ, where black parts are identified as dead areas.

number of hits over the total event sample in each $1/2^8 \times 1/2^8$ acceptance. If there were no dead or inefficient area, a binomial distribution is expected with a probability of $1/2^8 \times 1/2^8$ to the total acceptance. For the binomial part, we took a $\pm 3\sigma$ region. However, if there are any dead or inefficient areas they tend to contaminate the lower tail of the binomial distribution. We defined a central dead map by excluding detector region below 3σ, as shown in Fig. 2(c) where black indicates regions that are identified as dead areas. The fraction of good area corresponds to 78% of the total acceptance. This map was used to completely suppress particles that hit the dead areas in the real data.

As long as the baseline distribution is approximated as a NBD, which is certainly true as observed in E802 [28] and in the present analysis, one can estimate the relation between true k values of the NBD and biased k values from dead or inefficient areas based on the convolution theorem of the NBD. For two independent NBDs with (μ_1, k_1) and (μ_2, k_2), it is known that the convolution of the two NBDs is a NBD with (μ_c, k_c) that satisfies the relations

$$\begin{aligned} k_c &= k_1 + k_2, \\ \mu_c &= \mu_1/k_1(k_1 + k_2), \end{aligned} \tag{12}$$

where $\mu_1/k_1 = \mu_2/k_2$ holds [34,35]. Therefore the correction can be applied by multiplying a ratio of the total number of η-ϕ bins in a given η window size to the number of bins excluding dead area, as the geometrical acceptance corrections can be applied.

Strictly speaking, we cannot completely reproduce the original k by this correction, because NBDs in different positions are not completely independent. However, except for the large hole, which is already excluded by the truncation, small holes are scattered rather uniformly in the azimuthal direction for any position of the $\delta\eta$ windows. As the simplest overall correction to each window position, we applied the convolution theorem [34,35] by assuming a collection of independent NBD sources. As long as the correction is applied in the same manner for all the azimuthal holes, it does not greatly affect the differential measurement to the pseudorapidity space. If the correction is accurate enough, we can expect a constancy of the corrected k values that should be independent of the fraction of dead areas. Based on the degree of constancy of corrected k as a function of the fraction of dead areas in each window position for a given $\delta\eta$ window size, the incompleteness of the correction in each window size has been checked. As briefly mentioned in the last paragraph of Sec. IV D, the window sizes to be analyzed were determined so that systematic error bands on $\langle k_c \rangle$ explained in Sec. IV F can contain the most corrected k values, independently of the fraction of dead areas in each window position.

F. Statistical and systematic errors

As a convolution of statistical errors, we adopted errors on weighted mean values $(\delta\langle\mu_c\rangle, \delta\langle k_c\rangle)$ on corrected NBD parameters after the window truncation mentioned in

Sec. IV D, which are defined as

$$\delta\langle\mu_c\rangle^2 \equiv \frac{\delta\bar{\mu}_{ci}{}^2}{n_{\rm ind}},$$
$$\delta\langle k_c\rangle^2 \equiv \frac{\delta\bar{k}_{ci}{}^2}{n_{\rm ind}}, \tag{13}$$

where $\delta\bar{\mu}_{ci}$ and $\delta\bar{k}_{ci}$ are, respectively, defined as $\sum_{i=1}^{n}\delta\mu_c/n$ and $\sum_{i=1}^{n}\delta k_c/n$ with the number of valid window positions n after the truncation and $n_{\rm ind}\equiv 0.75/\delta\eta$ is the number of statistically independent window positions for a given $\delta\eta$ window size. This statistical error on $\delta\langle k_c\rangle$ is referred to as $\delta\langle k_c\rangle$ (stat).

The dominant sources of systematic errors for the correlation length measurement are the correction procedure with dead maps and the two-track separation cuts, since both introduce unphysical correlations. We have allowed 2% fluctuation on the average multiplicity of measured number of charged tracks. This fluctuation is also a result of dead channels in the tracking detectors, as discussed in Sec. IV B. To estimate this, we defined two more patterns of dead maps with the definition of $3\sigma \pm 0.5\sigma$ as indicated in Fig. 2(c). The deviation of $\langle k_c\rangle$ from the central dead-map definition is referred to as $\delta\langle k_c\rangle$ (dead), which corresponds to 3.4% typically.

The two-track separation cut serves mainly to reject fake track effects; these are dominantly observed in the ϕ direction rather than η, since the PC1 hit requirement fixes the z positions along the beam axis. Therefore, the effect of the $\delta\phi$ cut was estimated as ± 0.002 rad around the central cut value of 0.012 rad with a fixed cut value on $\delta\eta$ of 0.001. The deviation of $\langle k_c\rangle$ from the central value reslting from the fake track rejection cut is referred to as $\delta\langle k_c\rangle$ (fake). This systematic error increases at higher centrality bins and is estimated as 5.8% and 0.3% at 0–5% and 60–65% centrality bins, respectively.

The $\langle k_c\rangle$ (stat) is related to agreement between multiplicity distributions and NBDs. The $\langle k_c\rangle$ (dead) and $\langle k_c\rangle$ (fake) depends on the position of the window and the average multiplicity in a selected centrality bin, respectively. By treating these contributions as independent systematic error sources, the total systematic error $\delta\langle k_c\rangle$ (total) on $\langle k_c\rangle$ in each $\delta\eta$ in each centrality was obtained by the quadratic sum over $\delta\langle k_c\rangle$ (stat), $\delta\langle k_c\rangle$ (dead), and $\delta\langle k_c\rangle$ (fake).

V. RESULTS

In this section the results of the NBD fits are first tabulated. Then the measured NBD k as a function of the pseudorapidity window sizes in various centrality bins are shown. Lastly, the $N_{\rm part}$ dependences of extracted $\alpha\xi$ product in Eq. (9) are presented.

A. NBD fit

NBD fit results in all window sizes in all centrality bins are summarized in Tables III–XXVII in Appendix B, where $\langle\mu_c\rangle$ and $\langle\mu\rangle$ are weighted means of corrected and uncorrected μ over all window positions respectively and $\langle k_c\rangle$ and $\langle k\rangle$ are weighted means of corrected and uncorrected k over all window positions, respectively. The $\langle\mu_c\rangle$s are corrected only for the effect of the detector dead areas, as described in Sec. IV E. The mean multiplicities were confirmed to be consistent with the result of the independent analysis by a different method using only PC1 and PC3 [22], after known additional correction factors were taken into account. Statistical errors on weighted means $\delta\langle k_c\rangle$ (stat) are obtained as explained in Sec. IV F. $\langle\chi^2/NDF\rangle$ is the average of reduced χ^2 of NBD fits over all window positions. $\langle NDF\rangle$ is the average of the degree of freedom of NBD fits over all window positions, and the systematic errors $\delta\langle k_c\rangle$ (dead), $\delta\langle k_c\rangle$ (fake), and $\delta\langle k_c\rangle$ (total) are already explained in Sec. IV F.

The mean and r.m.s. values of the reduced χ^2 values in the NBD fit over all window positions and all $\delta\eta$ sizes and all centralities were obtained as 0.75 and 0.33, respectively. The mean value corresponds to typically an 80% confidence level. Therefore, it is good enough to assume NBD as a baseline multiplicity distribution to obtain the integrated correlation function via the k parameter.

As a demonstration to show how well the NBD fits work, Fig. 3 shows the charged particle multiplicity distributions

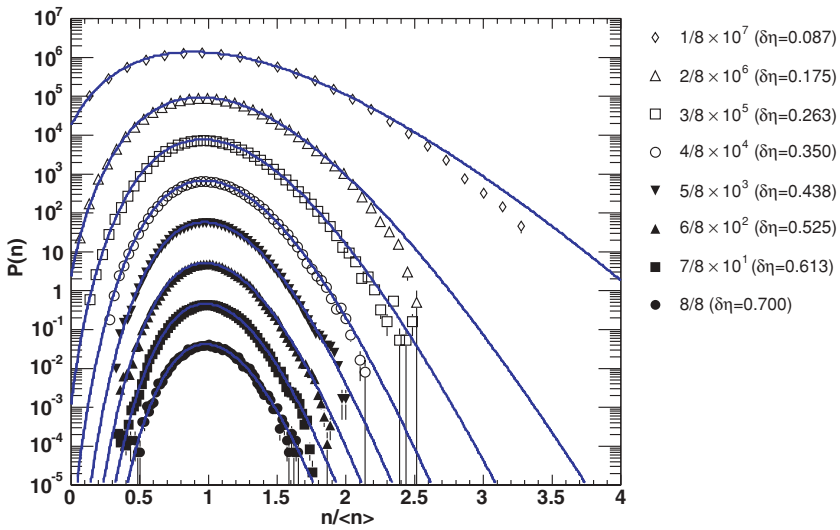

FIG. 3. (Color online) Uncorrected charged particle multiplicity distributions in each pseudorapidity window size, as indicated in the legend, at 0–10% collision centrality. The distributions are shown as a function of the number of tracks n normalized to the mean multiplicity $\langle n\rangle$ in each window. The error bars show the statistical errors. The solid curves are NBD fit results.

in each pseudorapidity window size in 1/8 fractions of the full rapidity coverage of $|\eta| < 0.35$ with 0–10% events in the collision centrality, where the uncorrected multiplicity distributions within the total error bands on $\langle k_c \rangle$ in Table III (Appendix B) are all merged. The distributions are shown as a function of the number of tracks, n, normalized to the mean multiplicity $\langle n \rangle$ in each window. The error bars show the statistical errors on the merged distributions. The solid curves are fit results with the NBD only for demonstration purposes. The fit results in Tables III–XXVII are not obtained from these convoluted distributions, whose accuracies are degraded by the convolutions with different μ values owing to different detector biases depending on the window positions.

B. k versus $\delta\eta$

Figures 4(a) and 4(b) show $\langle k_c \rangle$ as a function of pseudorapidity window size with 10% and 5% centrality bin width, respectively. Centrality classes are indicated inside the figures. The error bars show $\delta\langle k_c \rangle$ (total) defined in Sec. IV F. The solid lines in Fig. 4 indicate the fit results based on Eq. (9). The fits were performed in the $\delta\eta$ region from 0.066 to 0.7 as explained in Sec. IV D.

If we could reliably measure the NBD k parameter for arbitrarily small $\delta\eta \sim 0$ windows, then α and ξ could be treated as independent free parameters for each centrality. In the real experimental situation, there is an anticorrelation between α and ξ because of the lack of reliable data points close to $\delta\eta \sim 0$, if we attempt to fit with Eq. (8). However, at least an upper limit on the absolute scale of ξ was obtained as $\xi < 0.035$ by the free parameter fits based on Eq. (8). It is qualitatively consistent with expectation from numerical calculations [36] that the correlation lengths become smaller in the RHIC energy than for $p+p$ collisions [26] and low-energy $A+A$ collisions [28].

Since the upper limit of ξ is small enough compared to the fitting region of $\delta\eta$ ($\xi \ll \delta\eta$), Eq. (9) can be applied for the fits to the NBD k as a function of $\delta\eta$. In this case, the $\alpha\xi$ product, which is related to the susceptibility in the long-wavelength limit as defined in Eq. (A11), can be obtained by the fits without any physical assumptions. The typical χ^2/NDF in the fit based on Eq. (9) is 0.132, which corresponds to a 99%

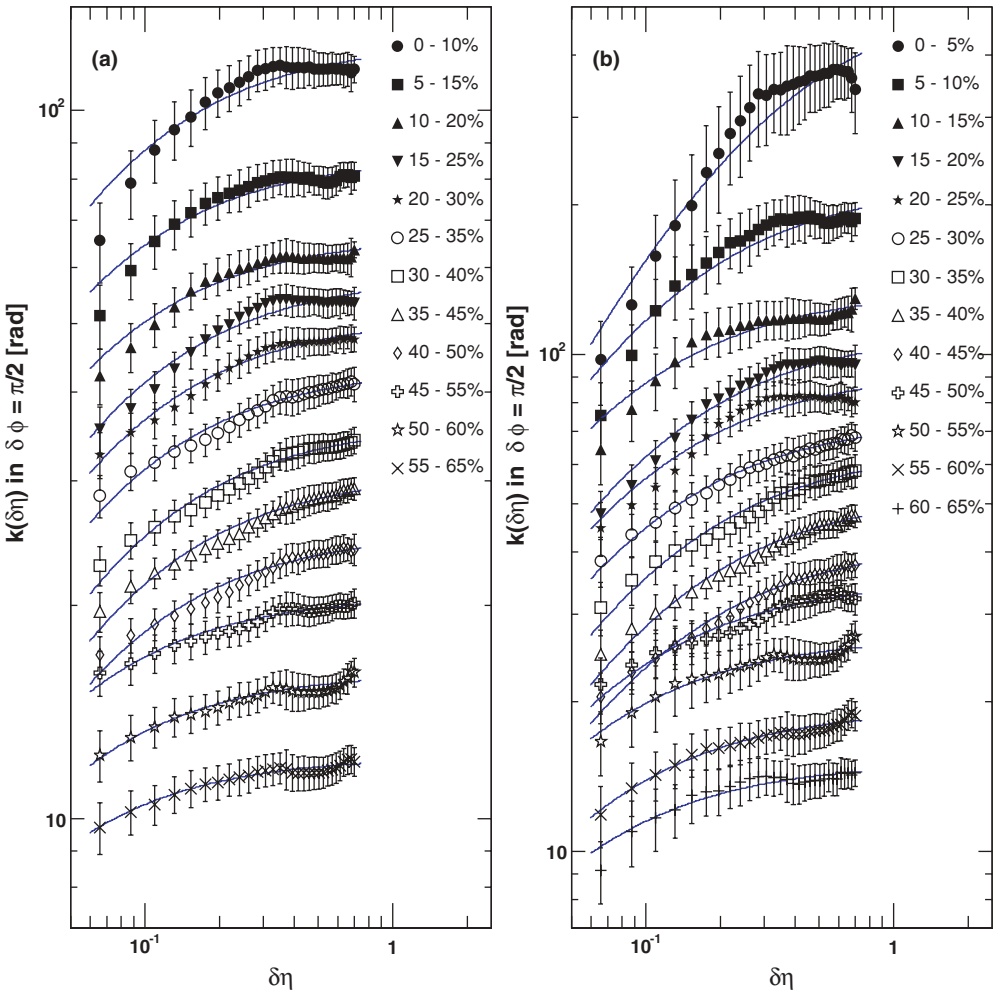

FIG. 4. (Color online) Weighted mean of corrected NBD k, $\langle k_c \rangle$, as a function of pseudorapidity window size with (a) 10% and (b) 5% centrality bin widths. Centrality classes are indicated in the figure legend. The error bars show $\delta\langle k_c \rangle$ (total), as explained in Sec. IV F. The solid lines indicate the fit curves of Eq. (9).

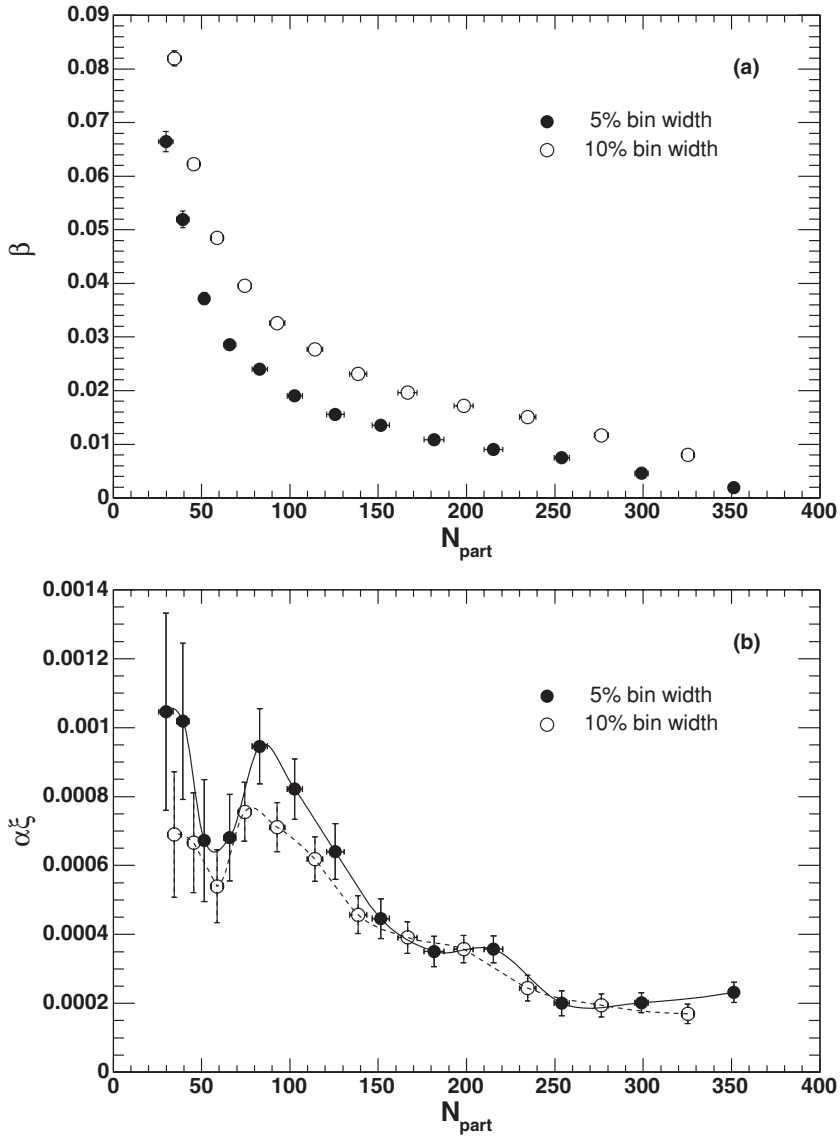

FIG. 5. Fit results based on Eq. (9): (a) β and (b) products of $\alpha\xi$ as a function of N_{part}. The horizontal error bars correspond to ambiguities in the mean value of N_{part} as explained in Sec. IV C. The vertical error bars are obtained from errors on the fitting parameter.

confidence level. Therefore, the small correlation length is confirmed as below the minimum $\delta\eta$ window sizes of 0.066.

As explained in Sec. II for Eq. (9), in the limit of $\beta = 0$, the slopes in k versus $\delta\eta$ have crucial information on the phase transition. In Fig. 4 we can identify different behaviors in slopes around the 40–50% centrality region even without fit curves.

C. $\alpha\xi$ product versus N_{part}

Figures 5(a) and 5(b) show the obtained fit parameters β and $\alpha\xi$ with Eq. (9) as a function of N_{part}, where results for both the 5% and 10% centrality bin width cases are plotted as filled and open circles, respectively. The smooth solid and dotted curves are provided to guide the eye. The horizontal error bars correspond to ambiguities on the mean value of N_{part} as explained in Sec. IV C. The vertical error bars are obtained from errors on the fitting parameter by the MINUIT program [33].

Table I summarizes the fit results where centralities and corresponding $N_{\text{part}}, \alpha\xi, \beta$, and χ^2/NDF obtained by the fit with Eq. (9) are shown for 10% and 5% centrality bin cases, respectively. The β parameter in Eq. (7) can absorb any effects independent of pseudorapidity space correlations, as discussed in Sec. II. For a wider centrality bin, the width of the multiplicity distribution becomes broader, since events with a wider range of centralities are included in the bin. This causes the systematic difference of β in the 5% and 10% centrality datasets as shown in Fig. 5(a). The systematic shift of β parameters to smaller values in the smaller centrality bin width suggests that β dominantly contains fluctuations on N_{part}. The ambiguity of N_{part} measured by PHENIX is not large compared, for example, to NA49, where a nonmonotonic behavior of the scaled variance of multiplicities was seen as a function of the number of projectile participant nucleons [37]. In NA49, only spectators from the projectile nucleus are measurable, causing an increase of scaled variance of multiplicity distributions in peripheral collisions owing to dominantly large N_{part} fluctuations in the target nucleus [38].

TABLE I. The $\alpha\xi$ and β in Eq. (9) obtained by the fits to $\langle k_c \rangle$ versus $\delta\eta$. Upper and lower columns corresponds to 10% and 5% centrality bin width cases, respectively.

Centrality (%)	$\langle N_{\rm part} \rangle$	$\alpha\xi(\propto \chi_{\omega=0})$	β	$\chi^2/NDF(NDF=27)$
0–10	325.2 ± 3.3	$0.17 \times 10^{-3} \pm 0.03 \times 10^{-3}$	$0.80 \times 10^{-2} \pm 0.02 \times 10^{-2}$	0.24

50–60	45.5 ± 3.3	$0.67 \times 10^{-3} \pm 0.14 \times 10^{-3}$	$6.22 \times 10^{-2} \pm 0.11 \times 10^{-2}$	0.11
55–65	34.6 ± 3.8	$0.69 \times 10^{-3} \pm 0.18 \times 10^{-3}$	$8.19 \times 10^{-2} \pm 0.14 \times 10^{-2}$	0.05
0–5	351.4 ± 2.9	$0.23 \times 10^{-3} \pm 0.03 \times 10^{-3}$	$0.19 \times 10^{-2} \pm 0.02 \times 10^{-2}$	0.18
5–10	299.0 ± 3.8	$0.20 \times 10^{-3} \pm 0.03 \times 10^{-3}$	$0.46 \times 10^{-2} \pm 0.02 \times 10^{-2}$	0.27
10–15	253.9 ± 4.3	$0.20 \times 10^{-3} \pm 0.04 \times 10^{-3}$	$0.75 \times 10^{-2} \pm 0.02 \times 10^{-2}$	0.17
15–20	215.3 ± 5.3	$0.36 \times 10^{-3} \pm 0.04 \times 10^{-3}$	$0.90 \times 10^{-2} \pm 0.03 \times 10^{-2}$	0.18
20–25	181.6 ± 5.6	$0.35 \times 10^{-3} \pm 0.04 \times 10^{-3}$	$1.08 \times 10^{-2} \pm 0.03 \times 10^{-2}$	0.32
25–30	151.5 ± 4.9	$0.45 \times 10^{-3} \pm 0.06 \times 10^{-3}$	$1.35 \times 10^{-2} \pm 0.04 \times 10^{-2}$	0.02
30–35	125.7 ± 4.9	$0.64 \times 10^{-3} \pm 0.08 \times 10^{-3}$	$1.55 \times 10^{-2} \pm 0.05 \times 10^{-2}$	0.09
35–40	102.7 ± 4.3	$0.82 \times 10^{-3} \pm 0.09 \times 10^{-3}$	$1.90 \times 10^{-2} \pm 0.05 \times 10^{-2}$	0.08
40–45	82.9 ± 4.3	$0.95 \times 10^{-3} \pm 0.11 \times 10^{-3}$	$2.40 \times 10^{-2} \pm 0.07 \times 10^{-2}$	0.06
45–50	65.9 ± 3.4	$0.68 \times 10^{-3} \pm 0.13 \times 10^{-3}$	$2.86 \times 10^{-2} \pm 0.08 \times 10^{-2}$	0.08
50–55	51.6 ± 3.2	$0.67 \times 10^{-3} \pm 0.18 \times 10^{-3}$	$3.72 \times 10^{-2} \pm 0.11 \times 10^{-2}$	0.11
55–60	39.4 ± 3.5	$1.02 \times 10^{-3} \pm 0.23 \times 10^{-3}$	$5.19 \times 10^{-2} \pm 0.16 \times 10^{-2}$	0.06
60–65	29.8 ± 4.1	$1.05 \times 10^{-3} \pm 0.29 \times 10^{-3}$	$6.64 \times 10^{-2} \pm 0.19 \times 10^{-2}$	0.08

This is due to the partial sampling with respect to the total number of nucleons in two colliding nuclei. Since both projectile and target nuclei on both sides can be measured by BBC and ZDC at PHENIX, such ambiguities of $N_{\rm part}$ are suppressed, even in peripheral collisions. Some $N_{\rm part}$ fluctuations remain, but the β parameter can absorb this kind of fluctuation offset. Consequently, $N_{\rm part}$ fluctuations are not harmful for the measurement of the $\alpha\xi$ products, since they are based on the differential values of fluctuations for a given centrality bin. In addition, β is expected to absorb effects from azimuthal correlations. Because the PHENIX detector does not cover the full azimuthal range, fluctuations of low-p_T particles caused by reaction plane rotations and elliptic flow should contribute to the two-particle correlation function even in the pseudorapidity direction as an offset in principle. Owing to the β parameter, the nonmonotonic behavior of the measured $\alpha\xi$ in the pseudorapidity direction cannot be biased by elliptic flow nor by initial geometrical biases, since the azimuthal correlations are constant over the narrow pseudorapidity window of $|\eta| < 0.35$ [39].

VI. DISCUSSION

A. Other correlation sources

We discuss three other sources of correlation that are not related to the density correlations we are interested in but could affect the measurement of the inclusive charged particle multiplicity fluctuations. The first is charged track pairs from particle decays in flight. The second is background charged track pairs originating from secondary particle interactions in detector materials (i.e., showers and conversion pairs). For these two sources we have estimated the effects of contaminations to the inclusive charged particle multiplicity fluctuations by GEANT-based MC [32] simulations. The third source is the known short-range correlation from the Bose-Einstein correlation of identical particles.

The detectable charged particle compositions in the no-magnetic-field condition with the selection criteria of charged tracks in Sec. IV B are estimated as 94% for charged pions, 4% for charged kaons, and 2% for protons and antiprotons in 0–70% centrality. These are obtained by MC simulations based on identified charged particle spectra measured by PHENIX [31] up to 4 GeV/c of transverse momentum p_T. The statistically dominant weak decay particles that can contribute to the inclusive charged particle multiplicity are $K^0_S \to \pi^+\pi^-$ and $\Lambda(\overline{\Lambda}) \to p(\overline{p})\pi^-(\pi^+)$. The relative invariant yields of those particles to charged pions are 15% and 5% for K^0_S and $\Lambda(\overline{\Lambda})$ [40], respectively. They were calculated by the measured production cross section in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The production cross section of K^0_S is assumed to be the same as that for charged kaons [31]. The detection efficiency of the charged track pairs from weak decay particles in the one arm acceptance of the PHENIX detector ($|\eta| < 0.35, \Delta\phi < \pi/2$) is obtained by the MC simulation. We estimated it by using the p_T spectra of charged kaons for

K^0_S as the most dominant meson, and by using the p_T spectra of charged pions with transverse mass scaling for $\Lambda(\overline{\Lambda})$ as the most dominant baryon, which contribute to the inclusive charged particle multiplicity fluctuation. As the result, the ratios of charged track pairs originating from those weak decay particles to the number of produced charged pions per event are 0.7% and 0.9% for K^0_S and $\Lambda + \overline{\Lambda}$, respectively. The effects of those correlations on k were estimated as follows. Suppose two independent NBDs in different windows have the same NBD parameters of μ and k for a given window size of $\delta\eta/2$. If there is no correlation between the two windows, NBD in the $\delta\eta$ window size becomes a convoluted distribution between the two NBDs. This is certainly true, since we know the correlation length is well below the minimum size of $\delta\eta$ windows, as already discussed. Based on the NBD convolution theorem, the convoluted NBD parameters $\mu_{\rm conv}$ and $k_{\rm conv}$ are expressed as $\mu_{\rm conv} = 2\mu$ and $k_{\rm conv} = 2k$, respectively, in the case of no correlation. For the case where the correlated pairs are embedded, we define the fraction of the number of correlated pairs with respected to μ as f. Then the mean value before the correlated pairs are embedded is expressed as $\mu(1 - f)$ in the $\delta\eta/2$ window. The effect of the embedded correlation on $k_{\rm conv}$ can be estimated by adding the number of correlated pairs to both windows simultaneously with the fraction of f. With $\mu(1 - f)$ and k, we can generate a NBD with a random number generator in each window of $\delta\eta/2$ and convolute the two NBDs. >From the NBD fit to the convoluted distribution, we can obtain $k_{\rm conv}$ including the effect of the correlated pairs. We define the ratio of the deviation of $k_{\rm conv}$ to the independent case, $\Delta k \equiv (k_{\rm conv} - 2k)/2k$ for K^0_S and $\Lambda + \overline{\Lambda}$, respectively. For all observed $(\langle\mu_c\rangle, \langle k_c\rangle)$ values in all $\delta\eta$ windows in all centralities, we have estimated Δk. The pair fraction f depends on $\delta\eta$ window size, since weak decay particles have their own correlation length owing to the kinematical constraint. The fractions f were obtained based on the two-particle correlation of decayed pairs as a function of $\delta\eta$ window size, which were evaluated from the GEANT-based MC simulation with the actual track-selection criteria. It should be noted that the integrated fractions correspond to the aforementioned fractions, 0.7% and 0.9% for K^0_S and $\Lambda + \overline{\Lambda}$, respectively. As a result, the average values of Δk over all data points were estimated as $+0.27\% \pm 0.35\%$ (standard deviation) and $+0.40\% \pm 0.35\%$ (standard deviation) for K^0_S and $\Lambda + \overline{\Lambda}$ decays, respectively. In contrast, the average value of relative errors, $\delta\langle k_c\rangle(\text{total})/\langle k_c\rangle$, in measured k is $\pm 7.34\% \pm 3.29\%$ (standard deviation). We confirmed that the estimated Δk values are all included within the range of the relative errors on measured k. Therefore, we can conclude that the effect of the statistically dominant weak decay pairs with a few percent level on the $\alpha\xi$ product cannot exceed the full error sizes of the $\alpha\xi$ products in Table I.

The amount of material before the tracking system is 1.3% of a radiation length. It produces electron-positron pairs with 1.0% photon conversion probability. Almost 100% of photons up to 4 GeV/c of p_T are produced by decays from neutral pions. The detection efficiency of electron-positron pairs that survive after the requirement of the charged track associations and two-track separations in Sec. IV B is estimated as 0.22%. It was estimated by the MC simulations with a flat p_T distribution of photons. Since the opening angle of the conversion pairs is very small, these conversion electrons are strongly suppressed by the two-track separation cuts. Consequently, electron-positron pairs of $2.2 \times 10^{-3}\%$ with respect to the produced charged pions per event contribute to the multiplicity fluctuations. The efficiency of charged track pairs, which is produced by the materials from single charged hadrons as knock-on electrons (positrons), is estimated as less than $5.8 \times 10^{-5}\%$. Since the total pair fractions are much smaller than that in weak decays by several orders of magnitude, we can conclude that the effects of those secondary particles on the $\alpha\xi$ products are negligible.

If the observed correlation were to originate only from the Bose-Einstein effect, then we would expect α to be directly related to the chaoticity parameter λ in HBT analysis, which is measured in relative momentum space q. A similar measurement in pseudorapidity space based on Eq. (7) in low-energy $A+A$ collisions [41] indicates the direct relation between λ and α. The observed two-particle correlation strength α in pseudorapidity space is weaker than λ measured in q space and essentially becomes zero for the particle pairs selected in the higher q region where the HBT effect also becomes zero. This indicates that the observed pseudorapidity correlations in the lower energy $A+A$ collisions are essentially explained purely by the HBT effect. In Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV, the measured λ shows constant behavior as a function of $N_{\rm part}$ within 12% and a monotonic $N_{\rm part}$ dependence of HBT radii has been observed [42,43]. This implies that the nonmonotonic behavior of the $\alpha\xi$ product cannot be explained solely as a result of the known HBT effect, because $\alpha \propto \lambda$ is expected to be constant for any $N_{\rm part}$, and ξ, which would be related to the HBT source radii, is expected to be monotonic, if the known HBT effect is the only source of the correlation.

B. Evaluation of the nonmonotonic behavior of $\alpha\xi$

The $\alpha\xi$ product obtained by Eq. (9) is related to susceptibility in the long-wavelength limit, $\chi_{\omega=0}$, as described in Sec. II. According to Eq. (10), if the system temperature T is far from the critical temperature T_c then $\alpha\xi$ is expected to decrease monotonically with increasing T, which is a monotonic function of $N_{\rm part}$, as will be discussed in Sec. VI C. Therefore, one can assume a monotonically decreasing function as a hypothesis of the baseline in T far from T_c. As baseline functional forms for $\alpha\xi$ versus T we consider the following two cases. The first is a power-law function, which is naturally expected from Eq. (10), and the second is a linear function, the simplest assumption. The power-law baseline and the linear baseline are parametrized as

$$\alpha\xi(N_{\rm part}) = p_1(N_{\rm part})^{p_2} \tag{14}$$

and

$$\alpha\xi(N_{\rm part}) = p_1 + p_2 N_{\rm part} \tag{15}$$

with fit parameter p_1 and p_2, respectively. As a test hypothesis, we assume a local maximum on the monotonic baselines in

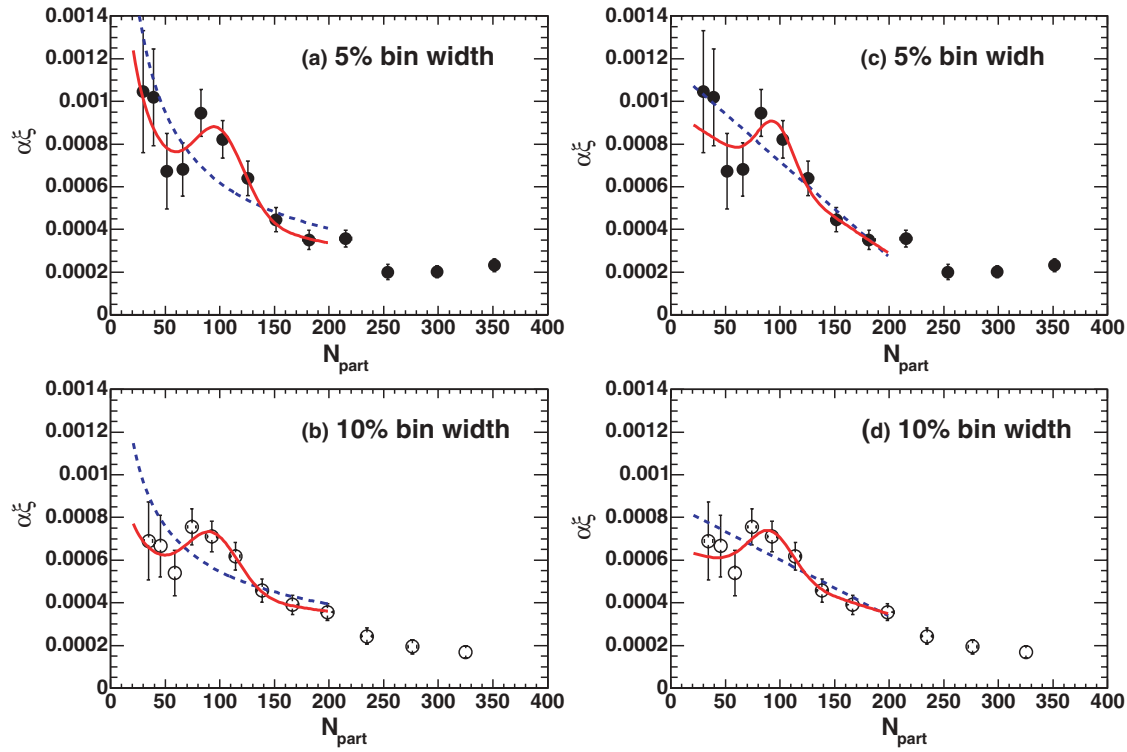

FIG. 6. (Color online) $\alpha\xi$ versus N_{part} in Table I with fit curves. The dashed and solid curves show the fit results with the baseline functions [Eqs. (14) and (15)] and with the composite functions [Eqs. (16) and (17)], respectively. (a) 5% and (b) 10% bin width cases with the power-law baselines. (c) 5% and (d) 10% bin width cases with the linear baselines.

$\alpha\xi$ versus N_{part}. Although the functional form around the local maximum is not known a priori without introducing a physical model, we can at least discuss the significance of the local maximum above the monotonic baseline by introducing a Gaussian distribution. The composite functions are defined as

$$\alpha\xi(N_{\text{part}}) = p_1(N_{\text{part}})^{p_2} + ae^{-\frac{(N_{\text{part}}-m)^2}{2w^2}} \tag{16}$$

and

$$\alpha\xi(N_{\text{part}}) = p_1 + p_2 N_{\text{part}} + ae^{-\frac{(N_{\text{part}}-m)^2}{2w^2}}, \tag{17}$$

where a, m, and w correspond to amplitude, mean, and width of the Gaussian component, respectively. Fits with the four functional forms were performed to $\alpha\xi$ versus N_{part} in the range $20 < N_{\text{part}} < 200$. Figure 6 shows $\alpha\xi$ versus N_{part} from Table I with those fit curves. The dashed and solid curves show the fit results with the baseline functions and with the composite functions. Figures 6(a) and 6(b) correspond to 5% and 10% bin width cases with the power-law baselines. Figures 6(c) and 6(d) correspond to 5% and 10% bin width cases with the linear baselines. Table II summarizes all the fit results from the MINUIT program [33], including functional forms, centrality bin widths, $\chi^2/NDF(NDF)$, the Gaussian amplitude a with its error δa, and the significance of the amplitude defined as $a/\delta a$. Although the significance of the local maximum with the linear baseline is smaller than that with the power-law baseline, this is mainly due to the larger uncertainty on a in Eq. (17) than in Eq. (16). This reflects

TABLE II. The fit parameters in Eqs. (14), (15), (16), and (17).

Functional form	Centrality bin width (%)	$\chi^2/NDF(NDF)$	$a \pm \delta a$	Significance $(a/\delta a)$
Power law in Eq. (14)	5	2.76 (7)		
Power law + Gaussian in Eq. (16)	5	0.60 (4)	$0.37 \times 10^3 \pm 0.09 \times 10^3$	3.98
Linear in Eq. (15)	5	1.23 (7)		
Linear + Gaussian in Eq. (17)	5	0.79 (4)	$0.27 \times 10^3 \pm 0.21 \times 10^3$	1.24
Power law in Eq. (14)	10	2.10 (7)		
Power law + Gaussian in Eq. (16)	10	0.38 (4)	$0.27 \times 10^3 \pm 0.08 \times 10^3$	3.21
Linear in Eq. (15)	10	1.09 (7)		
Linear + Gaussian in Eq. (17)	10	0.43 (4)	$0.22 \times 10^3 \pm 0.13 \times 10^3$	1.69

the fact that the combination of a Gaussian distribution with the linear baseline is not as good a fit as that with the power-law baseline for the given data points. The difference in the significance between 5% and 10% centrality bin width cases is not attributed to the correlations with the β parameter, since β was introduced as a parameter independent of $\delta\eta$. This can, rather, be understood as the smearing effect of a peak-like shape resulting from the difference of centrality bin widths around the mean N_{part}. In all cases in Table II, the χ^2/NDF values indicate that composite functions are favored over monotonic functions. This result supports the nonmonotonicity of $\alpha\xi$ as a function of N_{part}.

Although there is a possibility that more than one correlation length scale is dynamically present, the functional form with one correlation length can reasonably describe the region of $0.066 < \delta\eta < 0.7$ with the average χ^2/NDF of 0.132 over all centralities. We have performed a further check on the N_{part} dependence of the $\alpha\xi$ products by limiting the region of fit to $0.066 < \delta\eta < 0.306$, as shown in Fig. 7. The characteristic behavior of $\alpha\xi$ is still present at around $N_{\text{part}} \sim 90$, though

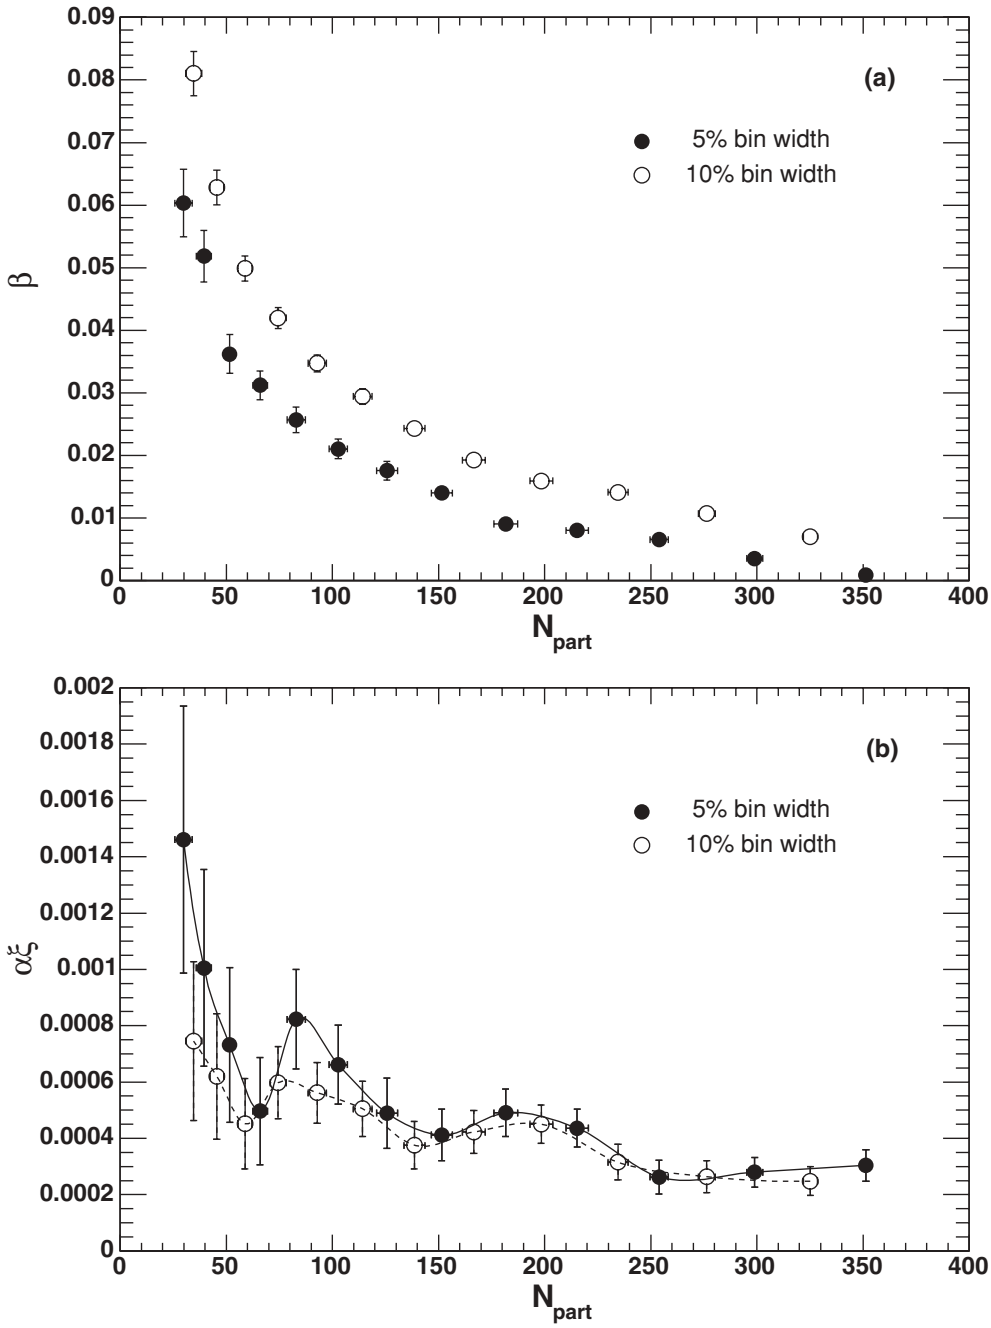

FIG. 7. Fit results based on Eq. (9) by limiting the range of $\delta\eta$ from 0.066 to 0.306: (a) β and (b) products of $\alpha\xi$ as a function of N_{part}. The horizontal error bars correspond to ambiguities in the mean value of N_{part} as explained in Sec. IV C. The vertical error bars are obtained from errors on the fitting parameter.

with smaller levels of significance than those shown in Table II. The same significance value of 1.9 was obtained for both 5% and 10% centrality bin width cases by the fit using Eq. (16) within the range $20 < N_{\rm part} < 160$. Therefore, a possible indication of a local maximum is seen at $N_{\rm part} \sim 90$.

C. Initial temperature and $N_{\rm part}$

The Bjorken energy density [21] derived from the measured $dE_T/d\eta$ in the mid-rapidity region is defined as

$$\epsilon_{\rm Bj} = \frac{1}{c\tau A_T}\frac{dE_T}{dy}, \tag{18}$$

where τ is the formation time and A_T is the nuclei transverse overlap area size. It is well known that the energy density monotonically increases with increasing $N_{\rm part}$ in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV [22].

This indicates that the change of $N_{\rm part}$ even at the fixed collision energy can yield a fine scan over the initial temperature. Therefore, the nonmonotonic behavior in the $\alpha\xi$ products could be an indication of the critical initial temperature as defined in Eq. (A11). The Bjorken energy density $\epsilon_{\rm Bj}\tau$ at the local maximum of $\alpha\xi$ seen at $N_{\rm part} \sim 90$ corresponds to $\sim$2.4 GeV/(fm^2c) with $A_T = 60$ fm^2.

VII. CONCLUSIONS

The multiplicity distributions measured in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV are found to be well described by negative binomial distributions.

The two-particle density correlations have been measured via the functional form for pseudorapidity density fluctuations derived in the Ginzburg-Landau framework, up to the second-order term in the free energy, with a scalar-order parameter defined as pseudorapidity-dependent multiplicity fluctuations around the mean value. The functional form can reasonably fit k versus $\delta\eta$ in all centralities in the $|\eta| < 0.35$ region with one correlation length assumption and the constant term β, which is independent of $\delta\eta$. We found that β is necessary to absorb residual effects of finite centrality binning.

We found that the absolute scale of the correlation length ξ depends on the magnitude of the correlation strength at zero distance, α, within the range of pseudorapidity window sizes available in this analysis. However, according to the free parameter fit results, the upper limit on $\xi < 0.035$ was obtained, and it was confirmed by the accuracy of the fits with approximated integrated correlation function in the limit of small correlation length ($\xi \ll \delta\eta$).

The $\alpha\xi$ product in the correlation function, which is monotonically related to susceptibility in the long-wavelength limit, $\chi_{\omega=0}$, was seen to exhibit a nonmonotonic behavior as a function of the number of participant nucleons, $N_{\rm part}$. A possible indication of a local maximum is seen at $N_{\rm part} \sim 90$ and the corresponding energy density based on the Bjorken picture is $\epsilon_{\rm Bj}\tau \sim 2.4$ GeV/(fm^2c) with the transverse area size of 60 fm^2.

Trivial particle correlations originating from charged track reconstructions in tracking detectors have been suppressed in this analysis a priori. The ratio of charged particles from statistically dominant weak decays and secondary particles produced in the detector materials, which contribute as correlated pairs, are respectively estimated below $\sim$1% and $\sim 10^{-3}$% with respect to the total number of charged pions in the PHENIX acceptance per event. We have estimated those effects on measured k values and the deviation resulting from the effect is well inside the total error size of observed $\delta\langle k_c\rangle$. Therefore, we conclude that their contributions are almost negligible to the observed behavior of the $\alpha\xi$ products.

The behavior may be explained by the onset of a mixture of different types of particle production mechanisms that are not necessarily related to temperature or density correlations. However, interpreted within the Ginzburg-Landau framework the local maximum of the $\alpha\xi$ product could be an indication of a critical phase boundary.

APPENDIX A: DEFINITION OF CORRELATION LENGTH AND SUSCEPTIBILITY IN THE GINZBURG-LANDAU FRAMEWORK

The Ginzburg-Landau (GL) [19] framework with the Ornstein-Zernike picture [18] for a scalar-order parameter is briefly reviewed. The relations with correlation length and susceptibility are explicitly derived in this appendix.

The first attempt to apply free energy discussions to nucleus-nucleus collisions can be found in Ref. [44]; application to the QCD phase transition is in Ref. [25]. The GL framework describes the relation between a free energy density f and an order parameter ϕ as a function of the system temperature T. By adding a spatially inhomogeneous term $A(T)(\nabla\phi)^2$ and an external field h, the general form is described as follows:

$$f(T,\phi,h) = f_0(T) + \tfrac{1}{2}A(T)(\nabla\phi)^2 + \tfrac{1}{2}a(T)\phi^2 + \tfrac{1}{4}b\phi^4 + \cdots - h\phi, \tag{A1}$$

where f_0 is the equilibrium value of the free energy, terms with odd powers are neglected owing to the symmetry of the order parameter, and the sign of b is used to classify the transition orders: $b < 0$ for the first order, $b > 0$ for the second order, and $b = 0$ at the critical point. Since the order parameter should vanish above a critical temperature T_c, it is natural for the coefficient $a(T)$ to be expressed as $a(T) = a_0|T - T_c|$, while b is usually assumed to be constant in the vicinity of T_c. In the following, we neglect higher order terms beyond second order. This approximation corresponds to a picture where a system approaches the phase boundary from afar, since ϕ is close to zero in the regions far from T_c. In this sense, the approximation is insensitive to the details of the phase transition order (i.e., higher order terms), being only sensitive to the behavior near T_c.

We apply this GL framework to density correlations in the longitudinal space coordinate z in heavy-ion collisions. The system of the produced matter dynamically evolves, so we introduce the proper time frame for each subelement. The longitudinal space element becomes $dz = \tau\cosh(y)dy$, at a fixed proper time τ, where y is rapidity, as introduced in Ref. [23]. Since we measure the density fluctuations in the mid-rapidity regions $|\eta| < 0.35$ as described in Sec. III, we use dy in place of dz by the approximation $\cosh(y) \approx 1$ to simplify the form of the correlation function derived from GL free energy.

The order parameter of this analysis corresponds to multiplicity density fluctuations of inclusive charged particles around the mean density. Fluctuations are measured as a function of a one-dimensional pseudorapidity point η, defined as

$$\phi(\eta) = \rho(\eta) - \langle\rho(\eta)\rangle, \tag{A2}$$

where the pair of brackets indicates an operator to take the average. In the rapidity region under consideration, rapidity can be represented by pseudorapidity to a good approximation, as explained in the last paragraph of Sec. IV B.

With the Fourier expansion of the density fluctuation at pseudorapidity point η, $\phi(\eta) = \sum_\omega \phi_\omega e^{i\omega\eta}$, where ω is wave number, one can express the deviation of the free energy density due to spatial fluctuations from the equilibrium value f_0 as

$$\Delta F/Y = \frac{1}{Y}\int (f - f_0)d\eta = \frac{1}{2}\sum_\omega |\phi_\omega|^2[a(T) + A(T)\omega^2], \tag{A3}$$

where Y is the total pseudorapidity range corresponding to a one-dimensional volume. Terms up to the second order are included in the approximation in the vicinity of the critical point in Eq. (A1). Given the free energy deviation, one can obtain the statistical weight w for fluctuation $\phi(\eta)$ to occur in a given temperature T as

$$W[\phi(\eta)] = Ne^{-\Delta F/T}. \tag{A4}$$

Therefore the statistical average of the square of the density fluctuation with the wave number ω is described as

$$\langle|\phi_\omega|^2\rangle = \int_{-\infty}^{+\infty} |\phi_\omega|^2 W\left(\sum_\omega \phi_\omega e^{i\omega\eta}\right) d\phi_\omega = \frac{NT}{Y}\frac{1}{a(T) + A(T)\omega^2}. \tag{A5}$$

An experimentally observable two-point density correlation function can be related to the statistical average of the square of the density fluctuation. With a density $\rho(\eta_i)$ for a given subvolume $d\eta_i$, the two-point density correlation G_2 is expressed in the case of $\langle\rho(\eta_1)\rangle = \langle\rho(\eta_2)\rangle = \langle\rho\rangle$ as

$$G_2(\eta_1,\eta_2) = \langle[\rho(\eta_1) - \langle\rho\rangle][\rho(\eta_2) - \langle\rho\rangle]\rangle, \tag{A6}$$

where case 1 coinciding with case 2 is excluded to simplify the following discussion. Multiplying both sides of Eq. (A6) by $e^{-i\omega\eta} \equiv e^{-i\omega(\eta_2-\eta_1)}$ and integrating over subvolumes $d\eta_1$ and $d\eta_2$ gives

$$Y\int G_2(\eta)e^{-i\omega\eta}d\eta = \langle|\int[\rho(\eta) - \langle\rho\rangle]e^{-i\omega\eta}d\eta|^2\rangle = \langle|\phi_\omega|^2\rangle. \tag{A7}$$

From Eqs. (A5) and (A7), G_2 can be related to the inverse Fourier transformation of the statistical average of $|\phi_\omega|^2$. Therefore in the one-dimensional case G_2 is described as

$$G_2(\eta) = \frac{NT}{2Y^2A(T)}\xi(T)e^{-|\eta|/\xi(T)}, \tag{A8}$$

where the correlation length $\xi(T)$ is introduced, which is defined as

$$\xi(T)^2 = \frac{A(T)}{a_0|T - T_c|}. \tag{A9}$$

In general, a singular behavior of $\xi(T)$ as a function of T indicates the critical temperature of the phase transition.

The wave-number-dependent susceptibility can also be defined from the expansion of the GL free energy based on

Eqs. (A1) and (A3) as follows:

$$\chi_\omega = -\left(\frac{\partial^2 f}{\partial h^2}\right) = \left(\frac{\partial h}{\partial \phi_\omega}\right)^{-1} = \left(\frac{\partial^2(\Delta F/Y)}{\partial \phi_\omega^2}\right)^{-1} = \frac{1}{a_0|T - T_c|[1 + \omega^2 \xi(T)^2]}. \quad \text{(A10)}$$

In the long-wavelength limit of $\omega = 0$, the susceptibility can be expressed as

$$\chi_{\omega=0} = \frac{1}{a_0|T - T_c|} = \frac{2Y^2}{NT}\xi(T)G_2(0). \quad \text{(A11)}$$

In this framework, the ξ and $\chi_{\omega=0}$ diverge at the same temperature.

APPENDIX B: TABLES OF NBD FIT RESULTS

NBD fit results in all window sizes in all centrality bins are shown in Fig. 4. Tables III–XIV and Tables XV–XXVII list results in 10% and 5% bin width cases, respectively. $\langle \mu_c \rangle$ and $\langle \mu \rangle$ are weighted means of corrected and uncorrected μ over all window positions, respectively. $\langle k_c \rangle$ and $\langle k \rangle$ are weighted means of corrected and uncorrected k over all window positions, respectively. Statistical errors on weighted means $\delta\langle k_c \rangle$ (stat) are obtained as explained in Sec. IV F. $\langle \chi^2/NDF \rangle$ is the average of reduced χ^2 of NBD fits over all window positions. $\langle NDF \rangle$ is the average of the degree of freedom of NBD fits over all window positions. Systematic errors $\delta\langle k_c \rangle$ (dead), $\delta\langle k_c \rangle$(fake), and $\delta\langle k_c \rangle$ (total) are explained in Sec. IV F.

TABLE III. NBD fit results in centrality 0–10%.

(Received 14 March 2007; published 31 July 2007)

Differential elliptic flow (v_2) for ϕ mesons and (anti)deuterons $(\bar{d})d$ is measured for Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The v_2 for ϕ mesons follows the trend of lighter $\pi^{\pm}$ and $K^{\pm}$ mesons, suggesting that ordinary hadrons interacting with standard hadronic cross sections are not the primary driver for elliptic flow development. The v_2 values for $(\bar{d})d$ suggest that elliptic flow is additive for composite particles. This further validation of the universal scaling of v_2 per constituent quark for baryons and mesons suggests that partonic collectivity dominates the transverse expansion dynamics.

An important goal of current ultrarelativistic heavy ion research is to map out the accessible regions of the quantum chromodynamics phase diagram. Central to this goal is the creation and study of a new phase of nuclear matter—the quark gluon plasma (QGP). Thermalization and deconfinement are important properties of this matter, believed to be produced in heavy ion collisions at the Relativistic Heavy Ion Collider (RHIC) [1–3].

Detailed elliptic flow measurements provide indispensable information about this high energy density matter [4–8]. Such measurements are characterized by the magnitude of the second-harmonic coefficient $v_2 = \langle e^{i2(\varphi_p - \Phi_{\mathrm{RP}})} \rangle$, of the Fourier expansion of the azimuthal distribution of emitted particles. Here, φ_p represents the azimuthal emission angle of a particle, Φ_{RP} is the azimuthal angle of the reaction plane, and the brackets denote statistical averaging over particles and events [9,10].

At RHIC energies, there is now significant evidence that elliptic flow, in noncentral collisions, results from hydrodynamic pressure gradients developed in a locally thermalized ''almond-shaped'' collision zone. That is, the initial transverse coordinate-space anisotropy of this zone is converted, via particle interactions, into an azimuthal momentum-space anisotropy. Indeed, when plotted as a function of the transverse kinetic energy, $\mathrm{KE}_T \equiv m_T - m$, divided by the number of valence quarks n_q of a given hadron ($n_q = 2$ for mesons and $n_q = 3$ for baryons), v_2/n_q shows universal scaling for a broad range of particle species [11–14] (m_T is the transverse mass). This has been interpreted as evidence that hydrodynamic expansion of the QGP occurs during a phase characterized by (i) a rather low viscosity to entropy ratio η/s [2,3,13,15,16] and (ii) independent quasiparticles which exhibit the quantum numbers of quarks [13,17–21]. A consensus on the detailed dynamical evolution of the QGP has not been reached [3,16].

Elliptic flow measurements for heavy, strange, and multistrange hadrons [22,23] can lend unique insight on reaction dynamics. Here, we use differential v_2 measurements for the ϕ meson and the deuteron to address the important question of how the existence of a hadronic phase affects v_2: Is elliptic flow development dominantly pre- or posthadronization?

The ϕ meson is comprised of a strange (s) and an antistrange ($\bar{s}$) quark, and its interaction with hadrons is suppressed according to the Okubo-Zweig-Izuka (OZI) rules [24]. One consequence of this is that the ϕ meson is expected to have a rather small hadronic cross section with nonstrange hadrons (~ 9 mb) [25–27]. Such a cross section leads to a relatively large mean free path λ_ϕ, when compared to the transverse size of the emitting system. Thus, if elliptic flow was established in a phase involving hadrons interacting with their standard hadronic cross sections (posthadronization), one would expect v_2 for the ϕ meson to be significantly smaller than that for other hadrons (e.g., p and π). A recent measurement [28] has ruled out the possibility of ϕ meson production via K^+K^- coalescence. If v_2 is established in the phase prior to hadronization, the ϕ meson provides an important benchmark test for universal scaling in that its mass is similar to that of the proton and the Λ baryon, but its v_2 should be additive with respect to the v_2 of its two constituent quarks (i.e., $n_q = 2$). This scenario also provides an important constraint for hydrodynamical models which predict a $v_2(p_T)$ ordering pattern based on the mass of different particle species. Therefore, a detailed comparison of the v_2 values for the ϕ meson with those for other particle species, comprised of the lighter u and d quarks or the heavier charm quark c, can provide unique insight on whether or not partonic collectivity plays a central role in reaction dynamics at RHIC [20,29,30].

The deuteron is a very shallow composite $p + n$ bound state, whose binding energy (~ 2.24 MeV) is much less than the hadronization temperature. Thus, it is likely that it would suffer from medium induced breakup in the hadronic phase, even if it was produced at hadronization. In fact, recent investigations [31,32] suggest that $(\bar{p}\,\bar{n})pn$ coalescence dominates the (anti)deuteron $(\bar{d})d$ yield in Au + Au collisions. Thus, v_2 measurements for $(\bar{d})d$ also provide an important test for the universal scaling of elliptic flow [29] in that its v_2 should be additive, first, with respect to the v_2 of its constituent hadrons and, second, with respect to the v_2 of the constituent quarks of these hadrons (i.e., $n_q = 2 \times 3$).

In the 2004 running period the PHENIX detector [33] recorded $\approx 6.5 \times 10^8$ minimum-bias events for Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The collision vertex z (along beam axis) was constrained to $|z| < 30$ cm of the nominal crossing point. The event centrality was determined via cuts in the space of beam-beam counter (BBC) charge versus zero degree calorimeter energy [34]. In the central rapidity region ($|\eta| \leq 0.35$) the drift chambers, each with an azimuthal coverage $\Delta\varphi = \pi/2$, and two layers of multiwire proportional chambers with pad readout (PC1 and PC3) were used for charged particle tracking and momentum reconstruction. The time-of-flight (TOF) and lead scintillator (PbSc) detectors were used for charged particle identification [6,7].

Time-of-flight measurements from the TOF and PbSc were used in conjunction with the measured momentum and flight-path length to generate a mass-squared (m^2) distribution [35]. A track confirmation hit within a 2.5σ matching window in PC3 or TOF/PbSc served to eliminate most albedo, conversions, and resonance decays. A momentum dependent $\pm 2\sigma$ cut about each peak in the m^2 distribution was used to identify pions ($\pi^\pm$), kaons ($K^\pm$), (anti)protons [$(\bar{p})p$], and (anti)deuterons [$(\bar{d})d$] in the range $0.2 < p_T < 2.5$ GeV/c, $0.3 < p_T < 2.5$ GeV/c, $0.5 < p_T < 4.5$ GeV/c, and $1.1 < p_T < 4.5$ GeV/c, respectively, in the TOF, and to identify $K^\pm$ in the range

$0.3 < p_T < 1.5$ GeV/c in the PbSc. This gave $\sim 59\,000 \bar{d} + d$. An invariant mass analysis of the $\phi \rightarrow K^+K^-$ decay channel yielded $\sim 340\,000 \phi$ mesons with relatively good signal to background (14%–42% for the mass window $|m_{\rm inv}| = 5$ MeV/c^2 about the ϕ meson peak) over the range $1.0 < p_T < 5.5$ GeV/c for K^+K^- pairs.

The reaction plane method [6] was used to correlate the azimuthal angles of charged tracks with the azimuth of the event plane Φ_2, determined via hits in the two BBCs covering the pseudorapidity range $3.0 < |\eta| < 3.9$. The large pseudorapidity gap $\Delta\eta > 2.75$ between the central arms and the particles used for reaction plane determination reduces the influence of possible nonflow contributions, especially those from dijets [36]. Charge averaged values of $v_2 = \langle \cos(2(\varphi_p - \Phi_2))\rangle / \langle \cos(2(\Phi_2 - \Phi_{\rm RP}))\rangle$ were evaluated for $\pi^\pm$, $K^\pm$, $(\bar{p})p$, and $(\bar{d})d$. Here, the denominator represents a resolution factor to correct for the difference between the estimated Φ_2 and the true azimuth $\Phi_{\rm RP}$ of the reaction plane [6,37]. The estimated resolution factor of the combined reaction plane from both BBCs has an average of 0.33 over centrality, with a maximum of about 0.42 in midcentral collisions [6,12]. The associated systematic error is estimated to be $\sim 5\%$ for $\pi^\pm$, $K^\pm$, and $(\bar{p})p$. A p_T dependent correction factor ($\sim 5\%$–11%) was applied to the v_2 values for $(\bar{d})d$, to account for background contributions to the (anti)deuteron peak (signal) in the m^2 distributions (dash-dotted curve in Fig. 1(a):

$$v_2^{(\bar{d})d}(p_T) = [v_2^{s+bg}(p_T) - (1 - R)v_2^{bg}(p_T)]/R, \qquad (1)$$

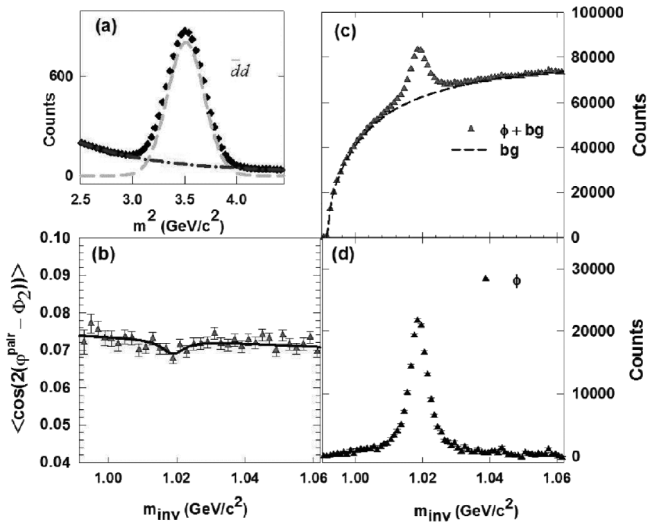

FIG. 1. (a) m^2 distribution for $\bar{d}$, d for $p_T = 1.6$–2.9 GeV/c, (b) $\langle\cos(2(\varphi^{\rm pair} - \Phi_2))\rangle$ versus $m_{\rm inv}$; the solid line is a fit to the data with Eq. (2). (c) $m_{\rm inv}$ distributions for foreground (points) and background (dashed line) K^+K^- pairs ($p_T^{\rm pair} = 1.6$–2.7 GeV/c) for 20%–60% central Au + Au collisions. (d) $m_{\rm inv}$ distribution after subtraction of the background.

where $v_2^{s+bg}(p_T)$ is the measured v_2 for $(\bar{d})d+$ background at a given p_T, R is the ratio signal/(signal + background) at that p_T, and $v_2^{bg}(p_T)$ is the elliptic flow of the background evaluated for m^2 values outside of the $(\bar{d})d$ peaks.

Extraction of the elliptic flow values for the ϕ meson (v_2^ϕ) followed the invariant mass ($m_{\rm inv}$) method [38]. For each event, $m_{\rm inv}$, $p_T^{\rm pair}$, and $\varphi^{\rm pair}$ for each K^+K^- pair were evaluated. Then, for each $p_T^{\rm pair}$ bin, $v_2^{\rm pair} = \langle\cos(2(\varphi^{\rm pair} - \Phi_2))\rangle$ was evaluated as a function of $m_{\rm inv}$ as shown in Fig. 1(b). The value $v_2^\phi(p_T)$ was then obtained from $v_2^{\rm pair}(m_{\rm inv})$ via an expression similar to Eq. (1):

$$v_2^{\rm pair}(m_{\rm inv}) = v_2^\phi R(m_{\rm inv}) + v_2^{\rm bg}(m_{\rm inv})[1 - R(m_{\rm inv})], \qquad (2)$$

where $R(m_{\rm inv}) = N_\phi(m_{\rm inv})/[N_\phi(m_{\rm inv}) + N_{\rm bg}(m_{\rm inv})]$ and $N_\phi(m_{\rm inv})$ and $N_{\rm bg}(m_{\rm inv})$ are distributions for the ϕ meson and the combinatoric background, respectively, $N_\phi(m_{\rm inv})$ is obtained from the distribution $N_{\rm pair}(m_{\rm inv})$ of K^+K^- pairs from the same event (foreground); $N_{\rm bg}(m_{\rm inv})$ is the distribution of pairs obtained from different events with similar centrality, vertex, and event plane orientation [39]. Figure 1(c) shows a representative example of the latter distributions for $1.6 \le p_T^{\rm pair} \le 2.7$ GeV/c and reaction centrality 20%–60%. A clear peak signaling the ϕ meson is apparent in the foreground distribution for $m_{\rm inv} \sim 1.02$ GeV/c^2. The background distribution was normalized to that for the foreground in the region $1.04 < m_{\rm inv} < 1.2$ GeV/c^2 and subtracted to obtain the $N_\phi(m_{\rm inv})$ distribution shown in Fig. 1(d); a relatively narrow ϕ meson peak is apparent.

Determination of the ratio $R(m_{\rm inv})$ was facilitated by fitting this distribution with a Breit-Wigner function plus a linear function, as shown by the solid curve in Fig. 1(c). To ensure robust v_2^ϕ extraction, the combinatorial background was constructed such that $v_{2(\rm mix)}^{\rm bg}(m_{\rm inv})$ gave the same value as $v_2^{\rm pair}(m_{\rm inv})$ for $m_{\rm inv}$ values not associated

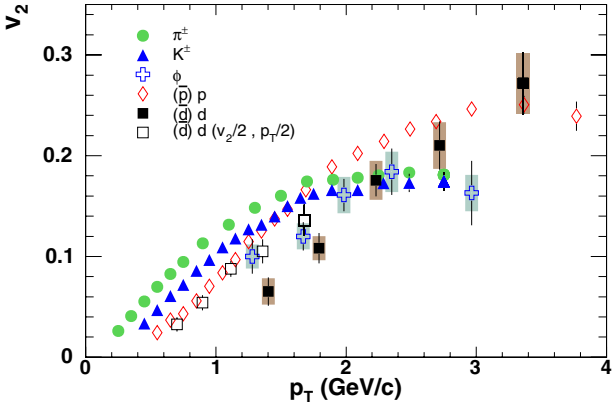

FIG. 2 (color online). Comparison of differential $v_2(p_T)$ for ϕ mesons, $(\bar{d})d$, $\pi^\pm$, $K^\pm$, and $(\bar{p})p$ (as indicated). Results are shown for 20%–60% central Au + Au collisions.

with the ϕ meson peak. Values for v_2^{ϕ} were extracted via direct fits to the $v_2^{\text{pair}}(m_{\text{inv}})$ distribution for each p_T^{pair} selection [cf. Eq. (2)]. That is, $v_2^{\text{bg}}(m_{\text{inv}})$ was parametrized as a linear or quadratic function of m_{inv} (depending on the p_T^{pair} bin) and v_2^{ϕ} was taken as a fit parameter.

The accuracy of the extraction procedure was verified by checking that the m_{inv} dependence of the sine coefficients, $v_{s,2}^{\text{pair}}(m_{\text{inv}}) = \langle \sin(2(\varphi^{\text{pair}} - \Phi_2)) \rangle$, were all zero within statistical errors. An alternative "subtraction method" [40,41], in which the raw ϕ meson yield distribution $dN/d(\varphi_\phi - \Phi_2)$ was extracted and fitted with the function $N\{1 + 2v_2^{\phi} \cos[2(\varphi_\phi - \Phi_2)]\}$, also showed good agreement, albeit with larger error bars; N is an arbitrary normalization constant.

The differential $v_2(p_T)$ obtained for $(\bar{d})d$ and the ϕ meson, for centrality 20%–60%, are compared to those for $\pi^{\pm}$, $K^{\pm}$, and $(\bar{p})p$ in Fig. 2. This centrality selection was so chosen to (i) maximize the ϕ meson signal to background ratio over the full range of p_T bins and (ii) enhance the distinction between baryon and meson v_2 in the intermediate p_T range. The shaded bands for $(\bar{d})d$ and the ϕ meson indicate systematic errors (~6%–15%), primarily associated with the determination of R and $R(m_{\text{inv}})$, v_2^{bg} and $v_2^{\text{bg}}(m_{\text{inv}})$ [cf. Eqs. (1) and (2)], and fitting.

The values for $v_2^{(\bar{d})d}$ shown in Fig. 2 are as much as a factor ≈ 2.5 lower than those for $\pi^{\pm}$ at low p_T. This mass ordering pattern reflects the detailed expansion dynamics of the created matter. As a first test of whether or not v_2 for $(\bar{d})d$ is additive with respect to its constituent hadrons, $v_2^{(\bar{d})d}/2$ versus $p_T/2$ is compared to $v_2^{(\bar{p})p}$ versus p_T. Within errors, they show good agreement as would be expected if $v_2^{(\bar{d})d}$ is additive. The large magnitude of v_2 for the ϕ meson gives an initial indication that significant flow development occurs prior to hadronization.

The left and right panels of Fig. 3 compare the unscaled and scaled results (respectively) for v_2 versus KE_T for $\pi^{\pm}$, $K^{\pm}$, $(\bar{p})p$, $(\bar{d})d$, and the ϕ meson, in 20%–60% central Au + Au collisions. The left panel clearly shows that, despite its mass which is comparable to that for the proton, $v_2(\text{KE}_T)$ for the ϕ meson follows the flow pattern of the other lighter mesons (π and K), whose cross sections are not OZI suppressed. A similar pattern is also observed for the $v_2(\text{KE}_T)$ values inferred for D mesons (comprised of charmed quarks) from nonphotonic electron measurements [13,23,42]. These observations indicate that, when elliptic flow develops, the constituents of the flowing medium are not ordinary hadrons interacting with their standard hadronic cross sections. Instead, partonic collectivity appears to dominate the transverse expansion dynamics of light, strange, and charmed quarks via a common velocity field.

Interestingly, the $v_2(\text{KE}_T)$ results shown for the $(\bar{d})d$ and the ϕ meson are essentially identical at low KE_T ($\text{KE}_T \lesssim 1$ GeV), and are in good agreement with those for other

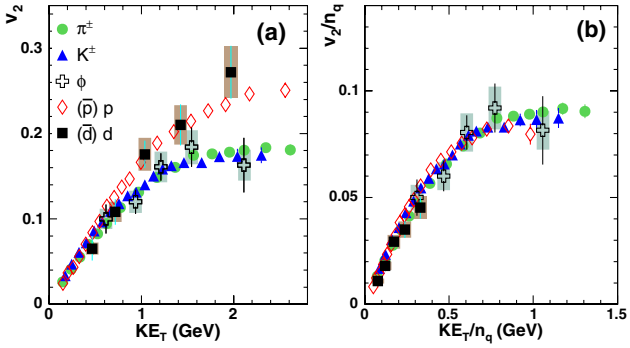

FIG. 3 (color online). (a) v_2 vs KE_T for several identified particle species obtained in midcentral (20%–60%) Au + Au collisions. (b) v_2/n_q vs KE_T/n_q for the same particle species shown in (a). The shaded bands indicate systematic error estimates for $(\bar{d})d$ and ϕ mesons (see text).

charged hadrons, including the pion with a mass ~13 times smaller than the deuteron. This strengthens the earlier finding that, for low KE_T, all particle species exhibit the same v_2 irrespective of their mass [11–13]. The expected difference between $(\bar{d})d$ and $(\bar{p})p$ for $\text{KE}_T \gtrsim 1$ GeV is not tested in Fig. 3, due to the limited KE_T range of the $(\bar{d})d$ data.

The right panel of Fig. 3 shows the results for a validation test of universal scaling for $v_2(\text{KE}_T)$ of baryons and mesons [11–13]. The value $n_q = 2 \times 3$ is used for $(\bar{d})d$ to account for its composite $(p + n)$ nature. The scaled results shown in Fig. 3(b) clearly serve as further validation for the experimentally observed universal scaling of v_2 for baryons and mesons [11–13]. This finding lends strong support to the notion that the high energy density matter, created in RHIC collisions, comprise a prehadronization state that contains the prerequisite quantum numbers of the hadrons to be formed. Thus, it appears that partonic collectivity dominates the expansion dynamics of these collisions. The special role of KE_T as a scaling variable is not fully understood.

We have presented differential v_2 measurements for the ϕ meson and deuteron. For a broad range of KE_T values, the differential $v_2(\text{KE}_T)$ for the ϕ meson follows the flow pattern for other light mesons whose cross sections are not OZI suppressed. The composites $(\bar{d})d$ follow the flow pattern for baryons with additive v_2 values. When v_2/n_q is plotted as a function of the transverse kinetic energy scaled by the number of valence quarks (i.e., KE_T/n_q), universal scaling results for all particle species measured. These observations suggest that the transverse expansion dynamics leading to elliptic flow development cannot be understood in terms of ordinary hadrons interacting with their standard hadronic cross sections, but rather in terms of a prehadronization state in which the flowing medium reflects quark degrees of freedom.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 18 November 2006; published 9 May 2007)

The PHENIX experiment at RHIC has measured the invariant cross section for ω-meson production at midrapidity in the transverse momentum range $2.5 < p_T < 9.25$ GeV/c in $p+p$ and d+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Measurements in two decay channels ($\omega \to \pi^0\pi^+\pi^-$ and $\omega \to \pi^0\gamma$) yield consistent results, and the reconstructed ω mass agrees with the accepted value within the p_T range of the measurements. The ω/π^0 ratio is found to be $0.85 \pm 0.05^{\text{stat}} \pm 0.09^{\text{sys}}$ in $p+p$ and $0.94 \pm 0.08^{\text{stat}} \pm 0.12^{\text{sys}}$ in d+Au collisions, independent of p_T. The nuclear modification factor $R_{d\text{A}}^{\omega}$ is $1.03 \pm 0.12^{\text{stat}} \pm 0.21^{\text{sys}}$ and $0.83 \pm 0.21^{\text{stat}} \pm 0.17^{\text{sys}}$ in minimum bias and central (0–20%) d+Au collisions, respectively.

Cross sections at large transverse momentum (p_T) for products of "hard" pointlike processes (e.g., inclusive hadrons, jets, direct γ's, and heavy flavor) in high-energy hadron collisions are well described in perturbative quantum chromodynamics (pQCD) [1]. As a result they are considered to be well-calibrated probes of small-distance QCD phenomena. When going from $p+p$ to p(or d)$+A$ and $A+A$ collisions, deviations from cross-section scaling with respect to the number of binary $N+N$ collisions provide information on cold nuclear matter effects such as initial state energy loss [2], shadowing [3] and hot nuclear matter effects such as in-medium energy loss [4], increasing importance of production via recombination [5], and modifications to the QCD vacuum [6].

Production of ω mesons at high-p_T is especially interesting. The ω and π^0 are vector and pseudoscalar mesons, respectively. The ω/π^0 ratio carries information about probabilities of corresponding spin states to be produced in hadronization. Furthermore, ω mesons can be used as a probe of the nuclear medium since a significant fraction of them produced in $A+A$ or $p(d)+A$ collisions will decay inside the produced medium ($c\tau = 23.8$ fm) possibly leading to changes of the mass and/or width of the ω with respect to their values in vacuum.

The PHENIX [7] experiment at RHIC has a unique capability to measure both neutral and charged products of $A+A$ and $p+p$ collisions at very high event rates. The two central arm spectrometers each cover 90° in azimuth and ± 0.35 in pseudorapidity. The electromagnetic calorimeter (EMCal), with energy resolution $\sigma/E = 8.1\%/\sqrt{E(\mathrm{GeV})} \oplus 2.1\%$, is used to reconstruct γ's and π^0's. For charged-particle reconstruction two layers of pad chambers provide 3D pattern recognition and fake track rejection, and a drift chamber gives momentum resolution $\sigma/p_\mathrm{T} = 0.7\%\sqrt{p_\mathrm{T}(\mathrm{GeV}/c)} \oplus 1.1\%$. Beam-beam counters (BBC) are used to provide minimum bias trigger and to determine the collision vertex. The minimum bias trigger cross sections measured by the BBC are 23.0 ± 2.2 mb in $p+p$ [8] and 1.99 ± 0.10 b in $d+$Au [9] collisions. In $d+$Au collisions the BBC are also used to separate events into centrality classes as explained in Ref. [10]. High p_T online triggers are implemented by adding together amplitudes in 4×4 adjacent EMCal towers and comparing them to a threshold of 1.4 GeV in $p+p$ and 2.4 GeV in $d+$Au. The trigger could be fired by one or more photons coming from ω-decay final states, including 3γ or $2\pi 2\gamma$.

The data was collected by the PHENIX experiment during RHIC Run3. After selecting good runs and cutting on the collision vertex ($|z| < 30$ cm) we analyzed approximately 4.6×10^7 and 2.1×10^7 high p_T trigger events, corresponding to a total integrated luminosity of 0.22 pb^{-1} and 1.5 nb^{-1} in the $p+p$ and $d+$Au collision systems, respectively.

Although ω mesons are relatively abundant in high-energy hadronic collisions ($\omega/\pi^0 \approx 1$ at high p_T), their measurement is challenging due to the multiparticle final states of the main decay channels and the combinatorial background associated with their reconstruction.

The procedure used to measure $\omega \to \pi^0\pi^+\pi^-$ is the same as used to measure $\eta \to \pi^0\pi^+\pi^-$ [10]. In case of ω one needs to account for a wider peak and different phase-space density of the three-body decay [11,12]. The analysis procedure for the photonic decay mode, $\omega \to \pi^0\gamma \to 3\gamma$, is very similar to earlier PHENIX measurements of other mesons with photonic decay modes, $\pi^0, \eta \to 2\gamma$ [8,13,14]. For both ω-decay modes studied the first step is to reconstruct π^0 candidates by combining photon pairs and applying a p_T-dependent cut around the mass of the π^0. The root-mean-square of the π^0 peak varies with p_T from 8 to 13 MeV/c^2. Candidates (which include combinatorial background) are combined with a third photon for $\omega \to \pi^0\gamma$ or with two unidentified charged tracks (assumed to be π mesons) for $\omega \to \pi^0\pi^+\pi^-$. Raw yields are extracted by fitting the p_T slices of the invariant mass distribution as in the insert panel in Fig. 1. The signal to background ratio (S/B) of $\pi^0\pi^+\pi^-$ decay channel is 1:7 at low p_T and grows with p_T to 1:1 in $p+p$ collisions. In $d+$Au collisions it starts at 1:20 and grows with p_T to 1:2. For the $\pi^0\gamma$ channel S/B is 1.5–2 times worse. Corrections for acceptance, trigger efficiency, and analysis cuts are described in detail in Ref. [10]. Further details about the analysis procedures can be found in Ref. [15].

We classify systematic error sources as type A (point-to-point uncorrelated, which can move each point independently), type B (point-to-point correlated, which can move points coherently, but potentially by different relative amounts), and type C (global, which move all points by the same relative amount). These errors are summarized in Table I for the different decay modes and collision systems. Major contributors include signal extraction (type A), online high-p_T trigger efficiency (type B) and the total cross-section measurement (type C). The uncertainty on the signal extraction, which is the dominant source of systematic error, is relatively large due to the fact that correlations in the triggered sample rendered background subtraction via event mixing impossible, and therefore the unknown shape of the underlying background had to be accounted for in the peak fit. This error is estimated based on variation of analysis cuts and fitting procedures [10].

Figure 1 shows the invariant cross sections for ω production in $p+p$, minimum bias $d+$Au, and central (0–20%) $d+$Au collisions at $\sqrt{s_{NN}} = 200$ GeV, as a function of p_T. The p_T range ($2.5 < p_T < 9.25$ GeV/c) is limited by statistics at high p_T and by decreasing detector acceptance and trigger efficiency at low p_T. The results for the two decay modes, which involve different kinematics, detector acceptance, and efficiency corrections, agree very well.

Figure 2 shows the results for the ratio of vector to pseudoscalar meson production (ω/π^0) in $d+$Au and $p+p$ collisions at $\sqrt{s_{NN}} = 200$ GeV. For the denominator we

TABLE I. Systematic errors for the ω production cross section for the two decay channels and the two collision systems analyzed. Error types are described in the text. Values with a range indicate variation of the systematic error over the p_T range of the measurement.

Type	$\omega \to \pi^0\pi^+\pi^-$		$\omega \to \pi^0\gamma$	
	$p+p$	$d+$Au	$p+p$	$d+$Au
A	7–20%	10–15%	25–40%	10%
B	8–10%	11–14%	5.8–9.2%	7.4–11%
C	11%	9.4%	13%	11%

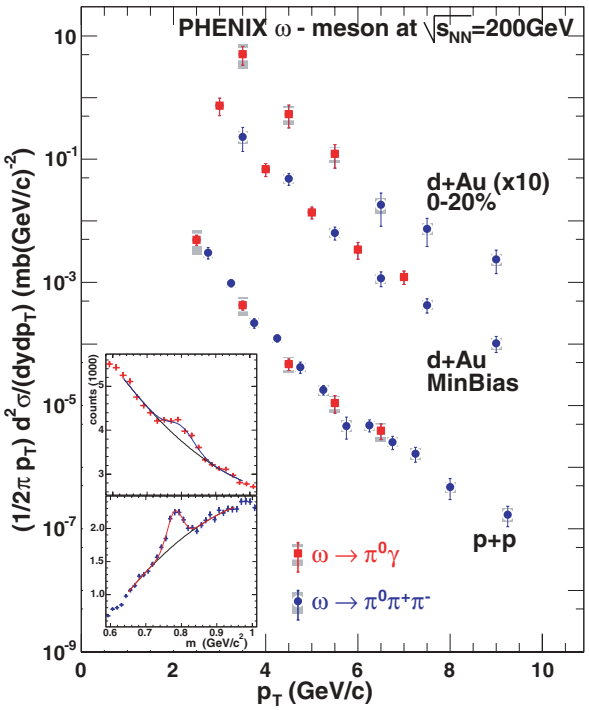

FIG. 1. (Color online) Invariant cross section of ω production in $p+p$ and $d+$Au collisions at $\sqrt{s_{NN}} = 200$ GeV measured in $\omega \to \pi^0\pi^+\pi^-$ and $\omega \to \pi^0\gamma$ decay channels. Bars and boxes represent statistical and systematic errors, respectively. Fits to invariant mass distributions of (top) $\pi^0\gamma$ and (bottom) $\pi^0\pi^+\pi^-$ are shown in the insert.

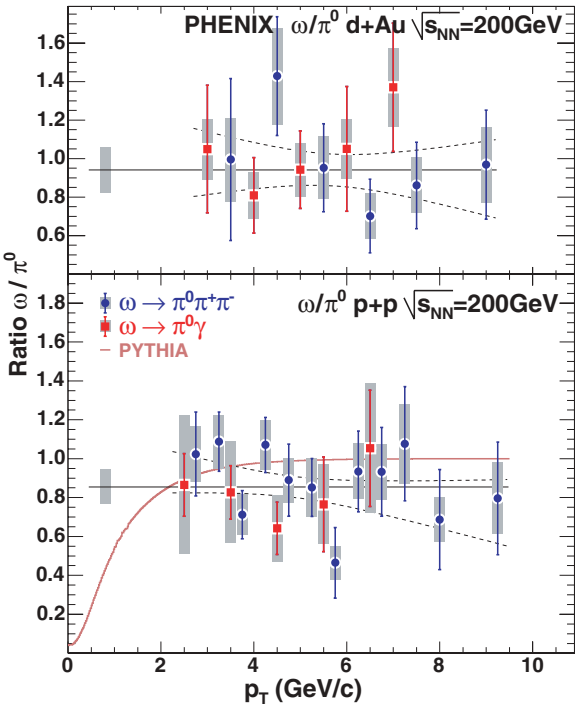

FIG. 2. (Color online) Measured ω/π^0 vs p_T in (upper panel) $d+$Au and (lower panel) $p+p$ collisions at $\sqrt{s_{NN}} = 200$ GeV. Straight lines show fits to a constant for each collision system. The boxes at the left edge of the constant fit lines show the systematic error on the data averaged over p_T. Dashed lines show values within 1σ of the best linear fits to the data. The PYTHIA prediction [17] for $p+p$ collisions at $\sqrt{s} = 200$ GeV is shown with a solid curve in the bottom panel.

use inclusive π^0 yields measured by PHENIX [8,16]. The ratios in both systems are consistent with no p_T dependence over the measured range. Fits to a constant yield $\omega/\pi^0 = 0.85 \pm 0.05^{\text{stat}} \pm 0.09^{\text{sys}}$ and $0.94 \pm 0.08^{\text{stat}} \pm 0.12^{\text{sys}}$, in $p+p$ and $d+$Au collisions, respectively. Fits assuming linear p_T dependence have slopes consistent with zero. Figure 2 also shows that for $p_T > 3$ GeV/c PYTHIA [17] predicts constant behavior for the ω/π^0 ratio.

The R-806 experiment measured ω/π^0 in $p+p$ collisions at $\sqrt{s} = 62$ GeV [18] and found this ratio to be 0.87 ± 0.17 over $3.5 < p_T < 7$ GeV/c. The E706 experiment measured ω/π^0 in π^-+Be collisions at $\sqrt{s_{\pi N}} = 31$ GeV [19] and found values consistent with the results presented in this Rapid Communication. The ω/π^0 ratios measured in hadronic interactions by three experiments at three different energies between 31 and 200 GeV, are the same within the errors.

Several LEP experiments [20–22] have measured ω production in $e^+ + e^-$ collisions at $\sqrt{s} = 91.2$ GeV and presented results as a function of $x_p = 2p_\omega/\sqrt{s}$. This is not a well-defined quantity in hadronic interactions. However, one can compare the ω/π^0 ratio at large values of p_T and x_p. Following the procedure for handling LEP data described in Ref. [10] one finds that for $x_p > 0.5$, the largest value for which statistically significant LEP data is available, the ratio has grown to approximately 0.7, close to the measurements in hadronic interactions.

Figure 3 shows the nuclear modification factor R_{dA}^{ω}, defined as the ratio between the ω meson yields in $d+$Au and $p+p$ interactions scaled by the number of binary collisions in $d+$Au, for minimum bias and central (0–20%) $d+$Au events. The precise definition of R_{dA} and the procedure to determine centrality in $d+$Au is given in sections IV.B and III.C in Ref. [10]. We find R_{dA}^{ω} to be $1.03 \pm 0.12^{\text{stat}} \pm 0.21^{\text{sys}}$ for minimum bias and $0.83 \pm 0.21^{\text{stat}} \pm 0.17^{\text{sys}}$ for central events, independent of p_T. R_{dA} values for two other neutral mesons (π^0 and η) measured by PHENIX [10,16] are also shown in Fig. 3. In all cases PHENIX observes that R_{dA} is close to one for $p_T > 2$ GeV/c and flat out to the highest p_T. Similar behavior is seen in preliminary analyses of K and ϕ mesons [15,23].

Recent publications suggest that modifications to the ω mass can be observed even in cold matter by studying not only the electron decay channel [24,25], but also hadronic channels [26]. For the hadronic decay modes presented here PHENIX lacks acceptance at low p_T where the effect is expected to be the most prominent. However, we have excellent mass resolution (20–25 MeV/c^2) for the mixed neutral-charged particle decay mode. Figure 4 shows extracted values for the ω mass as a function of p_T. In the p_T range of the measurement we observe no modification of the ω mass in either collision system we measure. For $p_T > 3$ GeV/c the mass of the ω meson in $p+p$ collisions at $\sqrt{s_{NN}} = 200$ GeV is consistent with the PDG [27] value within 7 MeV/c^2 at the 95% confidence level.

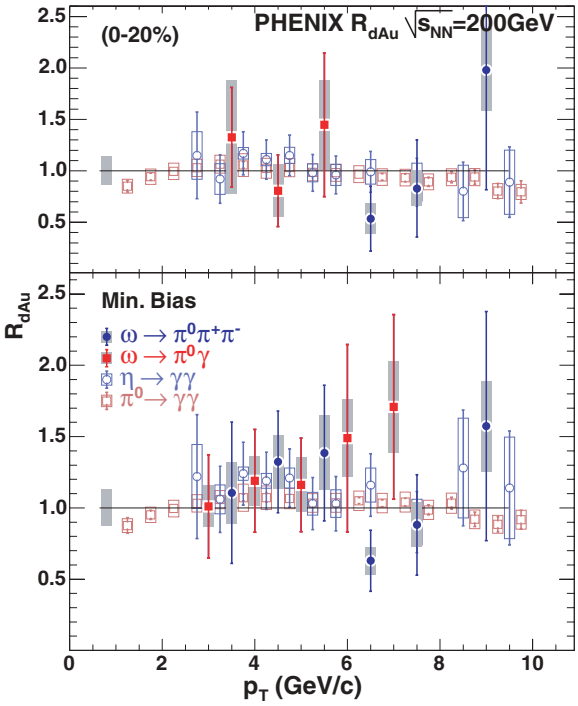

FIG. 3. (Color online) Measured R_{dA} vs p_T for neutral mesons in d+Au collisions at $\sqrt{s_{NN}} = 200$ GeV for (upper panel) 0–20% central and (lower panel) minimum bias. Values for π^0's and η's are from [10,16]. For reference a line is plotted at $R_{dA} = 1$. The scaling systematic error is shown as a box on the left.

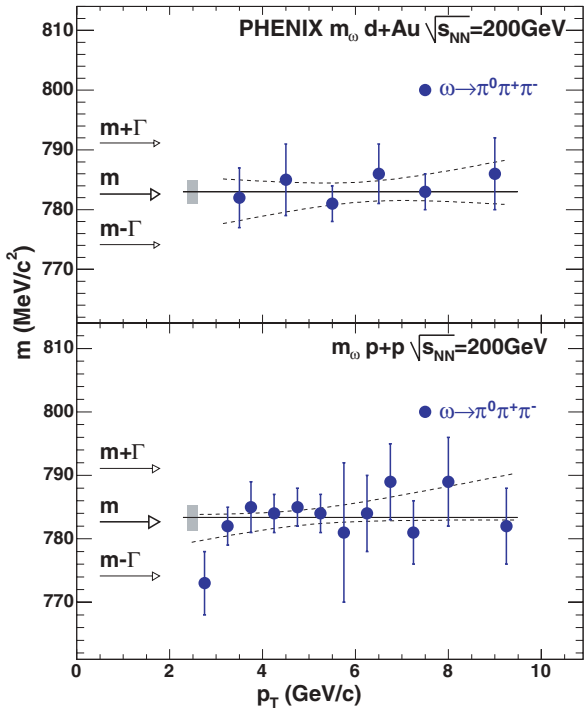

FIG. 4. (Color online) Reconstructed ω mass measured in the $\pi^0\pi^+\pi^-$ decay channel vs p_T in d+Au (upper panel) and p+p (lower panel) collisions at $\sqrt{s_{NN}} = 200$ GeV. Error bars show statistical errors. Straight lines show fits of the data to a constant. Dashed lines show values within 1σ of the best linear fit to the data. The systematic error on the fit values are shown with boxes on the left. PDG values for ω meson mass (m) and width (Γ) are shown with arrows on the left [27].

In summary we have presented the first measurement of ω production in p+p and d+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The production cross section is measured in two different decay modes with consistent results. The ω/π^0 ratio in p+p collisions is found to be $0.85 \pm 0.05^{\text{stat}} \pm 0.09^{\text{sys}}$ and $0.94 \pm 0.08^{\text{stat}} \pm 0.12^{\text{sys}}$ in d+Au over the measured p_T range. This agrees with previous measurements in hadronic collisions at lower $\sqrt{s}$. The nuclear modification factor for ω production in d+Au collisions is consistent with 1 and p_T independent for $p_T > 2$ GeV/c, consistent with other meson measurements. No modifications to the ω mass were observed in p+p or d+Au collisions. In p+p collisions the mass is consistent with the PDG [27] value within 7 MeV/c^2 at the 95% confidence level. The ω meson is also interesting as a probe of the hot nuclear medium created in A+A collisions. This measurement will serve as an excellent baseline for measurements of ω production in A+A in various decay channels.

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory for their vital contributions. We acknowledge support from the Department of Energy and NSF (United States); MEXT and JSPS (Japan); CNPq and FAPESP (Brazil); NSFC (China); IN2P3/CNRS, CEA, and ARMINES (France); BMBF, DAAD, and AvH (Germany); OTKA (Hungary); DAE and DST (India); ISF (Israel); KRF and KOSEF (Korea); RMIST, RAS, and RMAE (Russia); VR and KAW (Sweden); U.S. CRDF for the FSU, U.S.-Hungarian NSF-OTKA-MTA, and U.S.-Israel BSF.

(Received 12 November 2006; published 4 June 2007; corrected 7 June 2007)

The PHENIX experiment at the BNL Relativistic Heavy Ion Collider (RHIC) has measured J/ψ production for rapidities $-2.2 < y < 2.2$ in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The J/ψ invariant yield and nuclear modification factor R_{AA} as a function of centrality, transverse momentum, and rapidity are reported. A suppression of J/ψ relative to binary collision scaling of proton-proton reaction yields is observed. Models which describe the lower energy J/ψ data at the CERN Super Proton Synchrotron invoking only J/ψ destruction based on the local medium density predict a significantly larger suppression at RHIC and more suppression at midrapidity than at forward rapidity. Both trends are contradicted by our data.

DOI: 10.1103/PhysRevLett.98.232301 PACS numbers: 25.75.Dw

The quark-gluon plasma (QGP) is a state of deconfined quarks and gluons which is predicted by lattice quantum chromodynamics (QCD) calculations to be formed above a temperature T_c of the order of 175–192 MeV for a baryon chemical potential $\mu_b = 0$ [1,2]. Heavy quarkonia (J/ψ, ψ', χ_c, and Υ) have long been considered a promising probe to study the formation and properties of the QGP. In the deconfined state, the attraction between heavy quarks and antiquarks is predicted to be reduced due to dynamic screening effects, leading to the suppression of heavy quarkonia yield. The strength of the suppression depends on the binding energies of the quarkonia and the temperature of the surrounding system [3]. Recent lattice QCD calculations suggest that the J/ψ may not dissociate until well above T_c [4–6]. On the other hand, χ_c and ψ', which contribute to the total J/ψ yield via decay, are expected to dissolve at lower temperatures due to smaller binding energies.

A J/ψ suppression was observed at lower energies by the NA50 experiment at the CERN Super Proton Synchrotron (SPS) [7,8] that could be reproduced by various theoretical calculations [9–13]. Models that invoke the formation of a QGP predict a larger suppression at the BNL Relativistic Heavy Ion Collider (RHIC) than SPS due to the larger energy density of the medium created. On the other hand, several models also predict that the J/ψ yield will result from a balance between destruction due to thermal gluons and enhancement due to coalescence of uncorrelated $c\bar{c}$ pairs [9,14], which are produced abundantly at RHIC energy [15,16]. Cold nuclear matter (CNM) effects such as nuclear absorption, shadowing, and antishadowing are also expected to modify the J/ψ yield. PHENIX d + Au data show that CNM effects are smaller at RHIC than those observed at a lower energy [17] and can be reproduced by a nuclear absorption cross section of up to 3 mb plus nuclear shadowing [18].

We report results on J/ψ production measured by the PHENIX Collaboration at midrapidity ($|y| < 0.35$) via e^+e^- decay and at forward rapidity ($|y| \in [1.2, 2.2]$) via $\mu^+\mu^-$ decay in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. These results do not separate primordial J/ψ and J/ψ from χ_c, ψ', or B decay. The J/ψ invariant yields as a function of centrality, rapidity (y), and transverse momentum (p_T) are shown. They are combined with the yield measured in p + p collisions [19] to form the J/ψ nuclear modification factor R_{AA}.

The PHENIX apparatus is described in Ref. [20]. At midrapidity, electrons are measured with two spectrometers consisting of drift chambers (DC), pad chambers (PC), ring-imaging Cerenkov counters (RICH), and electromagnetic calorimeters (EMCal). They are identified by matching tracks reconstructed with the DC and PC to EMCal clusters and RICH hits. The energy-momentum matching requirement is $(E/p - 1) \geq -2.5$ standard deviations (σ). The position matching between the track and the EMCAL cluster is $\leq 2.5\sigma$ (4σ) in azimuth and along the beam axis, for central (peripheral) collisions. For the RICH, at least 4 (2) matching hits are required. Muons are measured with two spectrometers consisting of a front absorber to stop most hadrons produced in the collision, cathode strip chambers (MuTr), which provide momentum information, and a muon identifier (MuID), which uses alternating layers of steel absorber and Iarocci tubes. Charged particle trajectories are first reconstructed in the MuID and then in the MuTr. They must reach the last plane of the MuID and have a good geometrical match between the MuID and the MuTr to be identified as muons. The matching is $<9°$ for the slope and <15 (20) cm for the position in the first layer of the MuID at positive (negative) rapidity.

The data used for this analysis were collected during the 2004 run at RHIC using a minimum bias trigger (a coincidence of the two beam-beam counters), which covers

$92 \pm 3\%$ of the Au + Au inelastic cross section. After quality assurance and vertex cut ($|z| \leq 30$ cm), 9.9×10^8 (1.1×10^9) events were analyzed for mid (forward) rapidity, corresponding to an integrated luminosity of 157 μb^{-1} (174 μb^{-1}).

The J/ψ yield is obtained from the unlike-sign dilepton invariant mass distribution [21] after subtracting the combinatorial background using an event-mixing technique. The background is normalized to the real data by equating $2\sqrt{N^{++}N^{--}}$, with N^{++} (N^{--}) being the number of positive (negative) dilepton pairs. The accuracy of the normalization is estimated to be 2% and is accounted for in the systematic errors. At midrapidity, the J/ψ mass resolution is ~ 35 MeV/c^2. The number of J/ψ is determined by counting the remaining unlike-sign pairs in the mass range $2.9 \leq M \leq 3.3$ GeV/c^2. This number is corrected by the estimated contribution of the dielectron continuum and the loss due to the radiative tail. A total of $\sim 1000 J/\psi$ are obtained, and the signal to background (S/B) varies from 0.5 for central collisions to 15 for peripheral collisions. At forward rapidity, the J/ψ mass resolution varies from 150 to 200 MeV/c^2 and is larger than at midrapidity primarily because of the multiple scattering and energy loss straggling in the front absorber. The residual background (notably, open charm pairs and Drell-Yan processes) in the unlike-sign invariant mass distribution is evaluated using an exponential form. The J/ψ signal is estimated by counting the remaining pairs in the mass range $2.6 \leq M \leq 3.6$ GeV/c^2 and using a fit with different line shapes. The average of the resulting values is used as the number of J/ψ, and their dispersion is included in the systematic error. A total of $\sim 4500 J/\psi$ are obtained, and S/B varies from 0.2 for central collisions to 3 for peripheral collisions.

The J/ψ invariant yield in a given centrality, p_T, and y bin is

$$\frac{B_{ll}}{2\pi p_T}\frac{d^2N_{J/\psi}}{dp_T dy} = \frac{1}{2\pi p_T}\frac{N_{J/\psi}}{N_{\rm evt}\Delta y \Delta p_T A\varepsilon}, \qquad (1)$$

with B_{ll} being the branching ratio for $J/\psi \to l^+l^-$, $N_{J/\psi}$ the number of J/ψ measured in the bin, $N_{\rm evt}$ the corresponding number of events, and $A\varepsilon$ the acceptance and efficiency correction for J/ψ. $A\epsilon$ is determined by full GEANT simulation. It decreases with the collision centrality due to overlapping hits in the RICH, EMCal, and MuTr, leading to an increasing number of misreconstructed tracks, which are then rejected by the analysis cuts. This effect is evaluated by embedding simulated J/ψ in real events. For the most central collisions, the efficiency loss is 20% at midrapidity and 75% (50%) at positive (negative) rapidity.

The nuclear modification factor in a given centrality, p_T, and y bin is

$$R_{AA} = \frac{d^2N^{AA}_{J/\psi}/dp_T dy}{N_{\rm coll} d^2N^{pp}_{J/\psi}/dp_T dy}, \qquad (2)$$

TABLE I. Sources of systematic errors on the J/ψ invariant yield. When two values are given, the first (second) is for peripheral (central) collisions. Errors of type A (type B) are point-to-point uncorrelated (correlated).

Source	$\lvert y\rvert < 0.35$	$\lvert y\rvert \in [1.2, 2.2]$	Type
Signal extraction	6.5%–9%	4%–24%	A
Acceptance	6%	10%	B
Efficiency	4.5%–8%	4%–16%	B
Run by run variation	4%	5%	B
Input y, p_T distributions	2%	4%	B

with $d^2N^{AA}_{J/\psi}/dp_T dy$ being the J/ψ yield in Au + Au collisions, $N_{\rm coll}$ the mean number of binary collisions in the centrality bin, and $d^2N^{pp}_{J/\psi}/dp_T dy$ the J/ψ yield in $p + p$ inelastic collisions.

The systematic errors on the J/ψ invariant yield (Table I) are grouped into three categories: point-to-point uncorrelated (type A), for which the points can move independently one from the other; point-to-point correlated (type B), for which the points can move coherently, though not necessarily by the same amount; and global errors, for which all points move by the same relative amount. Statistical and type A errors are summed in quadrature and represented with vertical bars; type B errors are represented with boxes, and different colors or symbols are used for forward and midrapidity because they are independent; global systematic errors are quoted in the figures. For R_{AA}, additional errors are associated with uncertainties in the calculation of $N_{\rm coll}$ (10%–28%) and the J/ψ yield in $p + p$ (12% and 7% at mid and forward rapidity, respec-

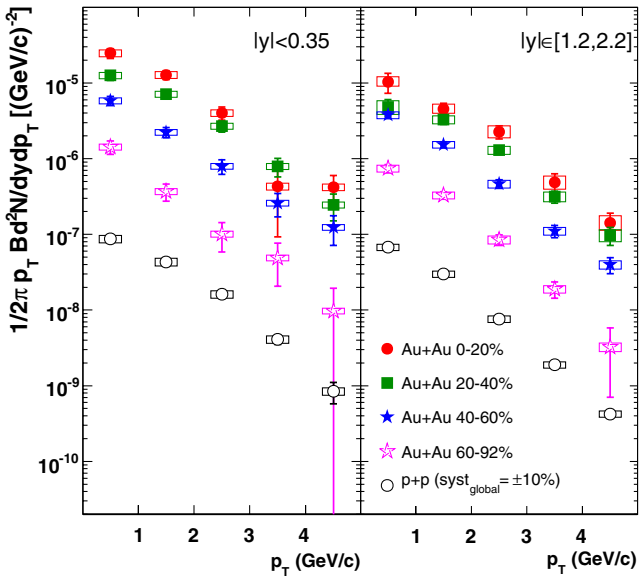

FIG. 1 (color online). J/ψ invariant yield versus p_T for different centrality bins in Au + Au collisions and in $p + p$ collisions [19]. The left (right) panel corresponds to mid (forward) rapidity. See text for description of the errors and Ref. [21] for data tables.

TABLE II. Characterization of the J/ψ, p_T, and y distributions. Column 3 (4): J/ψ $\langle p_T^2 \rangle$ calculated for $p_T \leq 5$ GeV/c at mid (forward) rapidity for different centrality bins in Au + Au collisions and in $p + p$ collisions. The first error corresponds to statistical and type A. The second error is type B.

Percent (%)	N_{part}	$\langle p_T^2 \rangle$ (GeV/c)^2 $\lvert y \rvert < 0.35$	$\langle p_T^2 \rangle$ (GeV/c)^2 $1.2 < \lvert y \rvert < 2.2$	y rms
0–20	280	$3.6 \pm 0.6 \pm 0.1$	$4.4 \pm 0.4 \pm 0.4$	1.32 ± 0.06
20–40	140	$4.6 \pm 0.5 \pm 0.1$	$4.6 \pm 0.3 \pm 0.4$	1.30 ± 0.05
40–60	60	$4.5 \pm 0.7 \pm 0.2$	$3.7 \pm 0.2 \pm 0.3$	1.40 ± 0.04
60–92	14	$3.6 \pm 0.9 \pm 0.2$	$3.3 \pm 0.3 \pm 0.2$	1.43 ± 0.04
$p + p$	2	$4.1 \pm 0.2 \pm 0.1$	$3.4 \pm 0.1 \pm 0.1$	1.41 ± 0.03

tively). On the other hand, some errors that are common to Au + Au and $p + p$ cancel.

Figure 1 shows the J/ψ yield versus p_T for different centrality bins (see Table II for the corresponding number of participants N_{part}). Data from the two muon spectrometers are combined to obtain the forward rapidity points. In each centrality bin, the J/ψ mean square transverse momentum $\langle p_T^2 \rangle$ is numerically calculated for $p_T \leq 5$ GeV/c and is shown in Table II. At midrapidity, the $\langle p_T^2 \rangle$ shows no variation versus centrality within errors. It increases slightly with N_{part} at forward rapidity.

Figure 2 shows the J/ψ yield versus y for different centrality bins. The root mean square (rms) of each distribution is shown in Table II. For the two most peripheral bins, the rms is compatible with that measured in $p + p$ collisions. For the most central bins, the rms is smaller by about 2σ.

Figures 3 and 4 show the J/ψ R_{AA} versus p_T and y, respectively, for different centrality bins. Figure 5(a) shows the p_T integrated R_{AA} versus N_{part} at mid and forward rapidity, respectively. For each rapidity, R_{AA} decreases with increasing N_{part}. For the most central collisions, R_{AA} is below 0.3 (0.2) at mid (forward) rapidity. Figure 5(b) shows the ratio of forward or midrapidity R_{AA} versus N_{part}. The ratio first decreases and then reaches a plateau of about 0.6 for $N_{\text{part}} > 100$.

In summary, a significant J/ψ suppression relative to the binary scaling of proton-proton collisions is observed for central Au + Au collisions at RHIC. Its magnitude is greater than that expected by extrapolating the CNM effects measured in d + Au collisions [17,18,22]. At midrapidity, the suppression is similar to that observed at the SPS [8], whereas at forward rapidity it is significantly larger. Models of quarkonia suppression driven by the local energy density of the medium predict a greater suppression at RHIC than SPS and less suppression at forward rapidity than at midrapidity [9,10]. Both trends are contradicted by

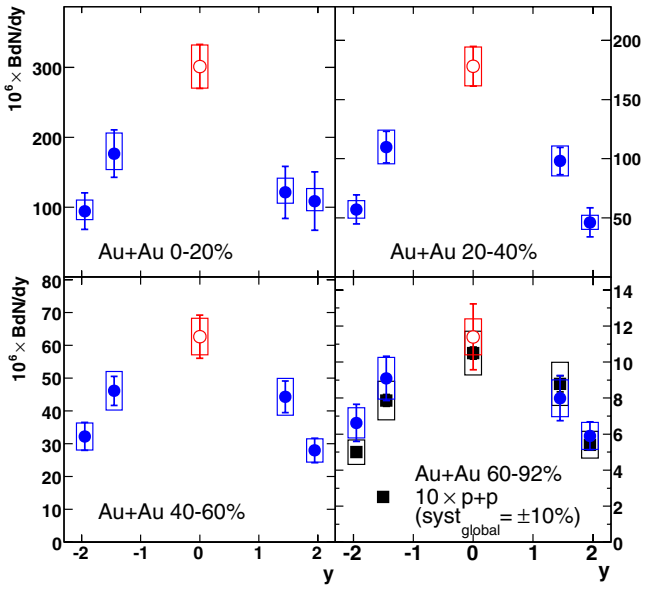

FIG. 2 (color online). J/ψ invariant yield versus y for different centrality bins in Au + Au collisions and for $p + p$ collisions. Open (solid) circles are for mid (forward) rapidity Au + Au data. Black squares are for $p + p$ data [19]. See text for description of the errors and Ref. [21] for data tables.

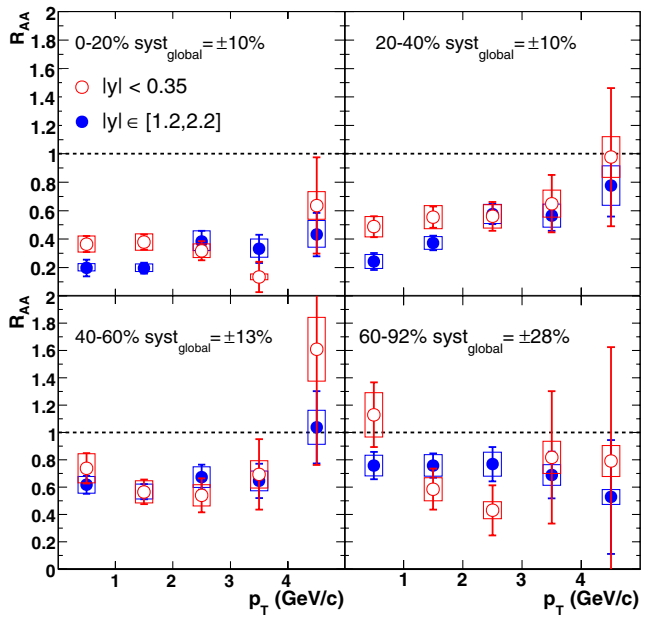

FIG. 3 (color online). J/ψ R_{AA} versus p_T for several centrality bins in Au + Au collisions. Mid (forward) rapidity data are shown with open (solid) circles. See text for description of the errors and Ref. [21] for data tables.

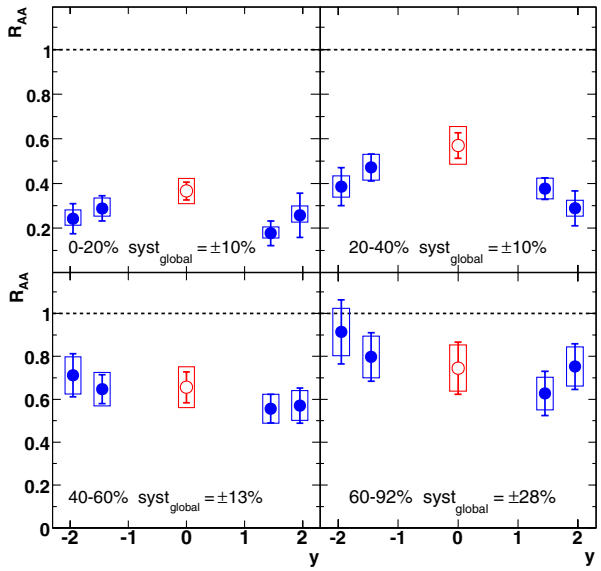

FIG. 4 (color online). J/ψ R_{AA} versus y for different centrality bins. Open (solid) circles are for mid (forward) rapidity. See text for description of the errors and Ref. [21] for data tables.

our data. Additionally, the J/ψ mean square transverse momentum, restricted to $p_T \leq 5$ GeV/c, shows little dependence on centrality. Various models of J/ψ production and suppression, which predict different transverse momentum and rapidity dependencies, can be significantly constrained by the data presented here and recent results on the open charm [16].

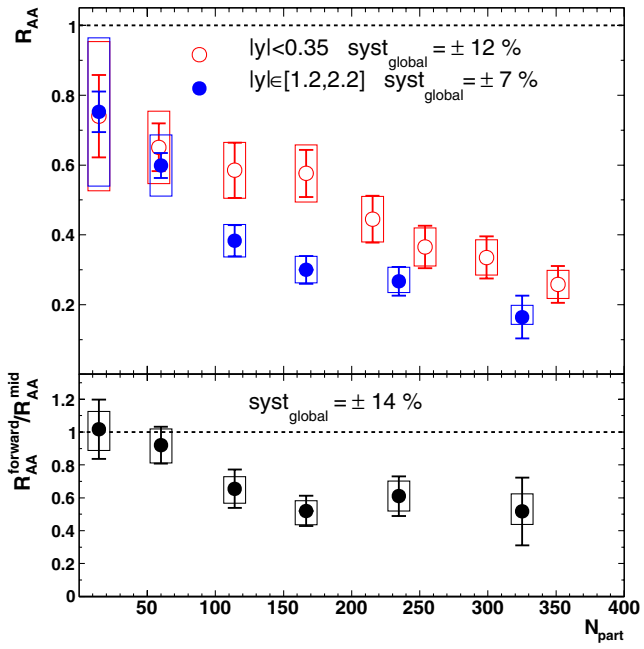

FIG. 5 (color online). (a) J/ψ R_{AA} versus $N_{\rm part}$ for Au + Au collisions. Mid (forward) rapidity data are shown with open (solid) circles. (b) Ratio of forward or midrapidity J/ψ R_{AA} versus $N_{\rm part}$. For the two most central bins, midrapidity points have been combined to form the ratio with the forward rapidity points. See text for description of the errors and Ref. [21] for data tables.

J/ψ production in $p + p$ collisions at $\sqrt{s} = 200$ GeV has been measured by the PHENIX experiment at the BNL Relativistic Heavy Ion Collider over a rapidity range of $-2.2 < y < 2.2$ and a transverse momentum range of $0 < p_T < 9$ GeV/c. The size of the present data set allows a detailed measurement of both the p_T and the rapidity distributions and is sufficient to constrain production models. The total cross section times the branching ratio is $B_{ll}\sigma_{pp}^{J/\psi} = 178 \pm 3^{\text{stat}} \pm 53^{\text{sys}} \pm 18^{\text{norm}}$ nb.

DOI: 10.1103/PhysRevLett.98.232002 PACS numbers: 13.85.Ni, 13.20.Fc, 14.40.Gx, 25.75.Dw

J/ψ mesons are produced in hadronic collisions involving hard processes that proceed primarily through diagrams involving gluons, such as gluon-gluon fusion. Once the $c\bar{c}$ pair is produced, it must evolve through a hadronization process to form a physical J/ψ meson. While this production has been extensively studied, the details of the production mechanism and hadronization remain an open question. Attempts at a consistent theoretical description of J/ψ meson production have been made, but it has proven difficult to reproduce both the observed cross sections and the polarization [1–4]. An additional complication is that nearly 30%–40% of the measured J/ψ meson yield results from feeddown of higher mass states (ψ', χ_c) [5] which reduces the observed polarization with respect to that expected from directly produced J/ψ mesons.

The color-singlet model [6], which generates a color-singlet $c\bar{c}$ pair in the same quantum state as the J/ψ meson, underpredicts the measured J/ψ cross section by approximately an order of magnitude [2]. Alternatively, the color-octet model includes color-octet $c\bar{c}$ pairs that radiate soft gluons during J/ψ meson formation [7]. However, the predicted transverse J/ψ polarization at high p_T is not seen in the data [2,4], and the color-octet matrix elements are not universal [8]. The color evaporation model, a more phenomenological approach, forms the different charmonium states in proportions determined from experimental data for any $c\bar{c}$ pair with a mass below the $D\bar{D}$ threshold and predicts no polarization. Finally, a recent perturbative QCD calculation including 3-gluon diagrams is able to successfully reproduce both the observed cross section and the polarization results [9].

A fundamental understanding of the J/ψ production process is also critical for defining the configuration of the produced $c\bar{c}$ state. This will have direct implications on the interaction of this state both with cold nuclear matter in proton or deuteron-nucleus collisions and with the high-density partonic matter observed in high-energy heavy-ion collisions. High quality experimental results over a wide kinematic range and collision energies are required to constrain models and to provide an improved understanding of J/ψ (and other heavy quarkonia) production.

In this Letter, J/ψ production in $p + p$ collisions at $\sqrt{s} = 200$ GeV measured by the PHENIX experiment at the BNL Relativistic Heavy Ion Collider (RHIC) is reported. The J/ψ cross section and transverse momentum distributions are studied in the mid ($|y| \leq 0.35$) and forward ($1.2 < |y| < 2.2$) rapidity regions. The data presented were collected during the 2005 RHIC run and exceed by more than 1 order of magnitude the previously reported number of J/ψ mesons [10,11].

At midrapidity, the PHENIX [12] drift chambers (DC), ring imaging Čerenkov detectors (RICH), and electromagnetic calorimeters (EMCal) are used to detect $J/\psi \rightarrow e^+e^-$ decays in two arms, each covering $\Delta\phi = 90°$ in azimuth. The muon detectors, consisting of cathode strip tracking chambers in a magnetic field (MuTr) and alternating layers of steel absorber and Iarocci tube planes (MuID), are used to measure $J/\psi \rightarrow \mu^+\mu^-$ at forward and backward rapidities over $\Delta\phi = 360°$.

The data were recorded using a minimum bias trigger that requires at least one hit in each of the beam-beam counters (BBCs) at forward and backward rapidities, $3.0 < |\eta| < 3.9$. Dielectron events must pass an additional trigger that consists of a logical OR between the level-1 electron and photon triggers. This trigger requires matching hits between the EMCal and RICH in a small angular area with a minimum energy deposition of 0.4 GeV in any 2×2 patch of EMCal towers. The photon trigger requires a minimum energy deposition of 1.4 GeV in any 4×4 set of overlapping EMCal towers. A trigger efficiency of 96% was achieved within the collision vertex range $|z_{\text{vtx}}| < 30$ cm for J/ψ candidates. Dimuon triggered events were selected using an online level-1 trigger that requires at least two particles penetrate the MuID. One particle must penetrate the entire MuID, while the second has a minimum penetration depth of 3 out of the 5 pairs of detector and absorber planes. Approximately 92% of the J/ψ mesons in events that satisfy the $|z_{\text{vtx}}| < 30$ cm cut fulfill this requirement. As part of the reconstruction chain, a level-2 filter is applied, consisting of a fast reconstruction of the particle trajectory in the MuTr and MuID. Events are accepted by this filter when at least two particles penetrate the entire MuID and have a reconstructed invariant mass ≥ 2.0 GeV/c^2. After applying cuts on the collision vertex position and quality assurance criteria, the sampled statistics corresponds to 2.6 pb^{-1} in the dielectron analysis, 2.7 pb^{-1} in the muon arm covering $1.2 < y < 2.2$, and 3.5 pb^{-1} in the muon arm covering $-2.2 < y < -1.2$.

At midrapidity, electron candidates are charged tracks associated with at least two hit phototubes in the RICH and one EMCal hit with a position matching of ± 4 standard

deviations (σ). The energy-momentum matching requirement is $(E/p - 1) \geq -4.0\sigma$. The number of J/ψ candidates is obtained by counting the unlike-sign dielectron pairs in a fixed mass window after subtracting the like-sign pairs. Figure 1(a) shows the invariant mass spectrum for dielectron pairs after subtracting the like-sign background. The mass window for counting the J/ψ signal is 2.7–3.5 or 2.6–3.6 GeV/c^2 depending on the number of DC hits used to reconstruct each track. The solid line in the figure is the sum of the J/ψ line shape (dashed curve) and an exponential function (dotted-dashed curve) describing the continuum component. The J/ψ line shape function accounts for detector resolution, internal radiative effects [13], and external radiative effects evaluated using a GEANT [14] simulation of the PHENIX detector. The J/ψ counts are corrected for the continuum yield, which originates primarily from open charm pairs and Drell-Yan processes inside the mass window (10% ± 5%), and the fraction of J/ψ candidates outside of the mass window (7.2% ± 1.0%). Approximately 1500 $J/\psi \rightarrow e^+e^-$ are obtained.

Muon track candidates are selected based upon their penetration depth in the MuID and the reconstructed track quality within the MuID and MuTr. The particle trajectory must contain at least 8 of 10 possible hits in the MuID, and the position matching between the MuID and MuTr must be within 15 (20) cm at positive (negative) rapidity. The J/ψ yield is obtained from the unlike-sign dimuon invariant mass distribution by subtracting the combinatorial background estimated using an event mixing technique. Three methods, shown in Fig. 1(b), are used to extract the J/ψ yield. Single Gaussian + exponential and double Gaussian + exponential functions are used to fit the J/ψ peak, while the contribution from the physical continuum and background is estimated using an exponential fit. The reported number of J/ψ mesons represents the average of the fit values. A total of 8000 $J/\psi \rightarrow \mu^+\mu^-$ are obtained.

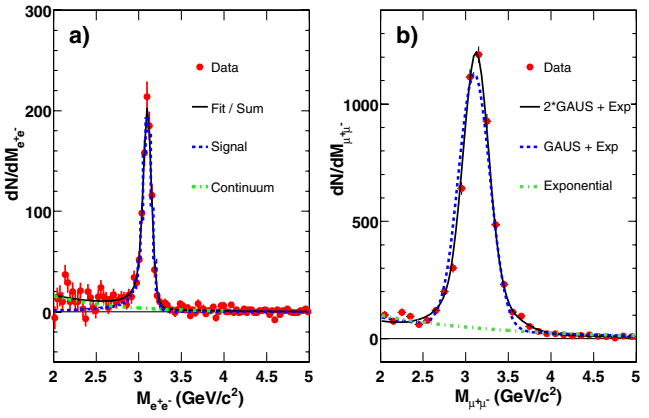

FIG. 1 (color online). Invariant mass spectra for (a) $J/\psi \rightarrow e^+e^-$ at $|y| < 0.35$ and (b) $J/\psi \rightarrow \mu^+\mu^-$ at $1.2 < |y| < 2.2$ with the functional forms used to extract the number of reconstructed J/ψ mesons.

The systematic uncertainty associated with the signal extraction is estimated from the variation between the fits.

The J/ψ cross section in a given rapidity and transverse momentum bin is calculated according to

$$\frac{B_{ll}}{2\pi p_T}\frac{d^2\sigma_{J/\psi}}{dydp_T} = \frac{1}{2\pi p_T \Delta p_T \Delta y}\frac{N_{J/\psi}}{\mathcal{L} A\epsilon_{\rm rec}\epsilon_{\rm trig}\epsilon^{\rm BBC}_{J/\psi}},$$

where B_{ll} is the J/ψ dilepton branching ratio, $N_{J/\psi}$ is the measured J/ψ yield, $\mathcal{L}$ is the integrated luminosity recorded by the minimum bias trigger, $A\epsilon_{\rm rec}$ represents the geometric acceptance and reconstruction efficiency, and $\epsilon_{\rm trig}$ is the trigger efficiency. $\epsilon^{\rm BBC}_{J/\psi}$ is the minimum bias trigger efficiency for events containing a J/ψ meson and was determined to be 0.79 ± 0.02 [10]. The cross section sampled by the BBC trigger, $\sigma^{pp}_{\rm tot} \times \epsilon^{\rm BBC}_{\rm MB} = 23.0 \pm 2.2$ mb, was used to determine the integrated luminosity.

The $A\epsilon_{\rm rec}$ and $\epsilon_{\rm trig}$ terms are determined individually for the central arm and each muon arm based upon the detection of simulated J/ψ mesons processed using the real data analysis chain. Decay events are generated and propagated through a full GEANT simulation of the detector, which includes the specific details of the detector performance including the MuTr and MuID alignment, disabled anodes, and MuID efficiency. Corrections were determined from the single electron yields for the dielectron analysis to account for the detector dead channel map, energy calibration, and run-to-run variations in the detector active area. The J/ψ trigger efficiency is incorporated via a level-1 trigger emulator tuned to describe the experimental trigger response. For the dimuon analysis, the level-2 filtering algorithms are applied to the simulated events. After reconstruction, the number of detected J/ψ mesons is compared to the number of simulated J/ψ mesons in a given rapidity and transverse momentum bin to determine the appropriate correction factors.

The systematic uncertainty associated with the measurement of the J/ψ cross section can be divided into three categories based upon the effect each source has on the measured results. All uncertainties are reported as standard deviations. Point-to-point uncorrelated uncertainties allow the data points to move independently with respect to one another. These include the signal extraction systematic, which is bin-dependent with typical values of 4% (5%) in the dimuon (dielectron) data, and the 1.5% J/ψ momentum smearing effect in the dielectron acceptance measurement. Point-to-point correlated uncertainties allow the data points to move coherently within the quoted value. Their values amount to 10% (8%) for the detector acceptance, 8% (4%) for the run-to-run variation in the detector efficiency, 4% (2.5%) for the J/ψ meson transverse momentum and vertex distributions, and 2% (2%) for the hardware efficiency of the detector. Finally, the global systematic uncertainty allows the data points to move together. The dominant source of this uncertainty originates from the estimation of the BBC triggering efficiency

for minimum bias events 9.7%, with an additional contribution from the uncertainty in the estimation of the number of sampled minimum bias events 1% and $\epsilon_{J/\psi}^{\mathrm{BBC}}$ 2.5%.

Figure 2(a) shows the transverse momentum spectra at both mid and forward rapidities, which are fit with the function $A \times [1 + (p_T/B)^2]^{-6}$ [15] to extract the value of the $\langle p_T^2 \rangle$. At midrapidity, the $\langle p_T^2 \rangle$ is $4.14 \pm 0.18 \pm^{0.30}_{0.20}$ $(\mathrm{GeV}/c)^2$, and the χ^2 per degree of freedom (χ^2/ndf) is 23/19. At forward rapidity, the $\langle p_T^2 \rangle$ is $3.59 \pm 0.06 \pm 0.16$ $(\mathrm{GeV}/c)^2$, and the χ^2/ndf is 28/17. The first error is statistical, and the second includes the systematic uncertainty from the maximum shape deviation permitted by the point-to-point correlated errors and from allowing the exponent of the fit function to be a free parameter. The statistical precision of the data is sufficient to allow the $\langle p_T^2 \rangle$ to be calculated directly from the numerical integration of the data. This calculation results in a $\langle p_T^2 \rangle$ of $4.25 \pm 0.24 \pm 0.14$ $(\mathrm{GeV}/c)^2$ at midrapidity and $3.57 \pm 0.06 \pm 0.15$ $(\mathrm{GeV}/c)^2$ at forward rapidity. Although good agreement is found with the rapidity distribution and total cross section, previously published results [11] yielded a significantly lower $\langle p_T^2 \rangle$ at forward rapidity than found here, even accounting for the quoted statistical and systematic uncertainties. The increased sample size of the present data set allows for an improved understanding of the shape of the p_T spectrum at forward rapidity due to the extended range in p_T and the finer binning at low p_T. The previous results have been revisited, and it was found that the systematic uncertainty was underestimated.

Figure 2(b) shows the ratio of the differential cross section times dilepton branching ratio at forward and midrapidity. The ratio falls with p_T and reaches a minimum of 0.5 above a p_T of 2 GeV/c. Although the present data are limited by significant systematic uncertainties, the data suggest that the forward rapidity p_T distribution is softer than at midrapidity. Such behavior could be attributed to an increase in the longitudinal momentum at forward rapidity leaving less energy available in the transverse direction.

The observed p_T distributions are substantially harder than those for lower energy $p + p$ and $p + A$ collisions as expected from the increased phase space at higher energy. Figure 3 shows the energy dependence of the average $\langle p_T^2 \rangle$ including points from the CERN Super Proton Synchrotron, Fermilab fixed target, and Tevatron measurements. A linear fit versus the log of the center of mass energy describes the general trend, although some variation is expected due to the differing rapidity ranges of the measurements and the use of $p + A$ data for some of the points.

Figure 4 shows the J/ψ differential cross section versus rapidity. The statistical precision of these results is sufficient to allow the data to be divided into 11 rapidity bins compared to the 5 bins used in the previous measurement [11]. Also shown are several models fit to the data. The dashed curve is a nonrelativistic QCD calculation [16]. The dotted-dashed curve is a pQCD calculation that includes diagrams describing a third gluon [9]. This model fails to reproduce the steeply falling cross section observed in the present data at large rapidity. An empirical double Gaussian fit (dotted-dotted curve) is able to reproduce the data best but has no theoretical foundation. The data slightly favor a flatter distribution over the rapidity range $|y| < 1.5$ than most models, but since the systematic error on the mid and forward rapidity points are independent, a narrower distribution is not excluded.

To determine the total cross section, the rapidity distribution was fit with many theoretical and phenomenological shapes including those shown in Fig. 4. A total cross section times the branching ratio of $B_{ll}\sigma_{pp}^{J/\psi} = 178 \pm 3^{\mathrm{stat}} \pm 53^{\mathrm{sys}} \pm 18^{\mathrm{norm}}$ nb is obtained from the fit that pro-

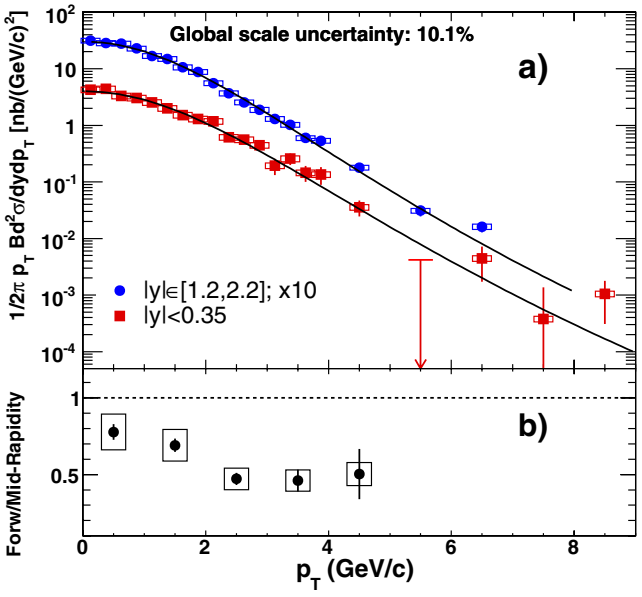

FIG. 2 (color online). (a) The forward rapidity (circles) and midrapidity (squares) J/ψ meson differential cross section times the dilepton branching ratio versus p_T and (b) the ratio of the forward and midrapidity p_T spectra.

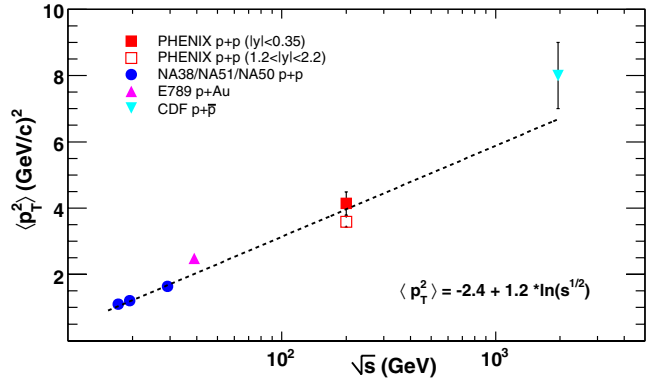

FIG. 3 (color online). PHENIX $\langle p_T^2 \rangle$ measurements compared to measurements at other energies [2,4,19] as a function of collision energy for J/ψ meson production in $p + p$ or $p + A$ collisions.

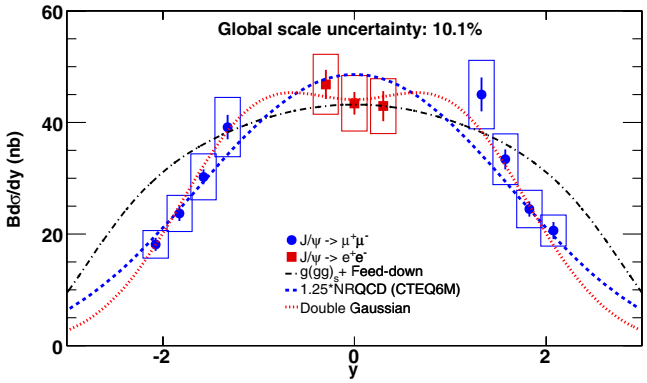

FIG. 4 (color online). The J/ψ differential cross section times the dilepton branching ratio plotted versus rapidity.

vides the best χ^2/ndf, double Gaussian. The absolute normalization error (norm) represents the uncertainty in the BBC trigger cross section. The systematic uncertainty (sys) is estimated by refitting the data with the same theoretical and phenomenological curves while simultaneously allowing the maximum variation in the shape of the distribution by shifting the mid and forward rapidity data independently by their point-to-point correlated systematic errors. Using the double Gaussian fit, the acceptance of the PHENIX data covers 92.1% of the integrated cross section. This result is consistent with our previous measurement [11].

We have presented J/ψ results for $p + p$ collisions at $\sqrt{s} = 200$ GeV that extend the reach in transverse momentum to 9 GeV/c. The measured p_T spectrum is harder than that observed at lower energies. The rapidity shape falls steeply at forward rapidity and cannot be reproduced by the pQCD calculation in Ref. [9]. Futhermore, the data slightly favor a flatter rapidity distribution than most models, but a narrower distribution is not excluded. These data not only constrain production models for heavy quarkonia but also provide a critical baseline for similar studies in deuteron-nucleus and heavy-ion collisions [11,17,18].

(Received 12 November 2006; published 4 June 2007)

We present azimuthal angle correlations of intermediate transverse momentum (1–4 GeV/c) hadrons from dijets in Cu + Cu and Au + Au collisions at $\sqrt{s_{NN}} = 62.4$ and 200 GeV. The away-side dijet induced azimuthal correlation is broadened, non-Gaussian, and peaked away from $\Delta\phi = \pi$ in central and semicentral collisions in all the systems. The broadening and peak location are found to depend upon the number of participants in the collision, but not on the collision energy or beam nuclei. These results are consistent with sound or shock wave models, but pose challenges to Cherenkov gluon radiation models.

DOI: 10.1103/PhysRevLett.98.232302 PACS numbers: 25.75.Dw

Heavy ion collisions at the Relativistic Heavy Ion Collider (RHIC) produce QCD matter at enormous energy density [1], exceeding that required for a phase transition to partonic, rather than hadronic, matter. The produced matter exhibits collective motion [2] and is opaque to scattered quarks and gluons. The opacity is observed via suppression of high momentum hadrons and intermediate energy dijets [3], and provides clear evidence of large energy loss by partons (quarks or gluons) traversing the medium. A key question is how the hot, dense medium transports the deposited energy.

As partons fragment into back-to-back jets of hadrons, angular correlations of the hadrons are used to study medium effects upon hard scattered parton pairs. Hadron pairs from the same parton appear at $\Delta\phi \sim 0$ (the near side), while those with one hadron from each parton in the hard scattered pair appear at $\Delta\phi \sim \pi$ (the away side). For brevity, we refer to these dijet induced dihadron azimuthal correlations as "dijet correlations."

Of great interest are intermediate transverse momentum (p_T) hadrons, as they can arise from intermediate energy jets or involve partons from the medium [4,5]. Their correlations can provide information about energy loss mechanisms, dissipation of the radiated energy in the medium, and collective modes induced by the deposited energy. Theoretical ideas include Mach cones from density waves induced by supersonic partons [4], comoving radiated gluons producing "wakes" in the medium [5], ultrarelativistic partons creating Cherenkov gluon radiation [6], and medium-induced gluon radiation at large emission angles [7,8]. They all imply significant modifications of dijet correlations in the away side, when the parton path through the medium is long. In particular, some of these theoretical models [4,6,7] imply a transition from the peaked distribution at $\Delta\phi \sim \pi$ characteristic of $p + p$ and $p + A$ collisions to a distribution with a peak away from $\Delta\phi \sim \pi$ in head-on Au + Au collisions.

Low p_T ($\geq$0.15 GeV/c) hadrons associated with high p_T hadrons ($\geq$4 GeV/c) have modified away-side dijet correlations and softened p_T distributions relative to those in $p + p$ collisions, suggesting that at least some of the lost energy is thermalized in the medium [9]. At intermediate p_T, a strong non-Gaussian shape modification of the dijet away-side correlation [10] indicates the possible existence of a local minimum at $\Delta\phi = \pi$. This Letter shows how the away-side jet modification depends on the size of the produced medium, and not on the collision energy or beam species. We report dijet correlations measured by the PHENIX experiment at RHIC.

The data were collected in the years 2005 (Cu + Cu at $\sqrt{s_{NN}} = 200$ and 62.4 GeV), 2004 (Au + Au at $\sqrt{s_{NN}} =$ 200 and 62.4 GeV), and 2003 (d + Au at $\sqrt{s_{NN}} =$ 200 GeV). Charged hadrons are tracked using the drift chambers and pad chambers of the PHENIX central arm spectrometers at midrapidity in the same way as described in [10]. The number of events in the Au + Au data at 200 GeV used here is 30 times higher than that in [10]. Collision centrality and number of participant nucleons

($N_{\rm part}$) are determined using the beam-beam counters (BBCs) and zero degree calorimeters [11].

Relative azimuthal distributions $Y_{\rm same}(\Delta\phi)$ between "trigger" hadrons with $2.5 < p_T < 4$ GeV/c and "associated" hadrons with $1 < p_T < 2.5$ GeV/c are formed. We correct for the nonuniform azimuthal acceptance of the PHENIX central arms by using the mixed event pairs $Y_{\rm mixed}(\Delta\phi)$ from the same data sample [10]:

$$C(\Delta\phi) \equiv \frac{Y_{\rm same}(\Delta\phi)}{Y_{\rm mixed}(\Delta\phi)} \frac{\int Y_{\rm mixed}(\Delta\phi)d\Delta\phi}{\int Y_{\rm same}(\Delta\phi)d\Delta\phi}. \quad (1)$$

Extensive Monte Carlo simulations were performed to ensure that the true pair distribution shape is recovered.

In Au + Au and Cu + Cu collisions, hadrons have an azimuthal correlation with the reaction plane orientation $\Phi_{\rm RP}$ which is proportional to $1 + 2v_2\cos[2(\phi - \Phi_{\rm RP})]$. This generates a significant correlated background to our dijet source $J(\Delta\phi)$ of azimuthal correlations:

$$C(\Delta\phi) = b_0[1 + 2\langle v_2^{\rm assoc}\rangle\langle v_2^{\rm trigg}\rangle\cos(2\Delta\phi)] + J(\Delta\phi). \quad (2)$$

The charged hadron $\langle v_2\rangle$ at midrapidity ($|\eta| < 0.35$), where "$\langle\,\rangle$" signifies an event average, was measured through a reaction plane analysis using the BBCs ($3 < |\eta| < 4$) [10,12]. The large rapidity gap between the BBCs and the central arms substantially reduces nonflow contributions to $\langle v_2\rangle$, in particular, dijet induced.

There also exists a much smaller fourth order azimuthal correlation with the reaction plane orientation. Its effect was studied with the Au + Au data at 200 GeV by including the corresponding $2\langle v_4^{\rm assoc}\rangle\langle v_4^{\rm trigg}\rangle\cos(4\Delta\phi)$ term in Eq. (2), where $\langle v_4\rangle$ has also been measured by the reaction plane analysis [12]. No significant v_4 systematic effects on the shape of the dijet correlations were found.

The background subtraction generates point-by-point ($\Delta\phi$ dependent) systematic errors from $\langle v_2^{\rm assoc}\rangle\langle v_2^{\rm trigg}\rangle$ uncertainty and an overall ($\Delta\phi$ independent) systematic error from b_0 uncertainty. The sources of $\langle v_2^{\rm assoc}\rangle\langle v_2^{\rm trigg}\rangle$ uncertainty are the $\langle v_2\rangle$ systematic error [10], dominated by the reaction plane resolution uncertainty, the $\langle v_2\rangle$ statistical error, and the systematic error from the $\langle v_2^{\rm assoc}v_2^{\rm trigg}\rangle \approx \langle v_2^{\rm assoc}\rangle\langle v_2^{\rm trigg}\rangle$ factorization approximation made in Eq. (2). The latter is estimated to be 5% of the $\langle v_2\rangle$ product for the most central events, where it is the largest.

The b_0 uncertainty is estimated by using three independent methods to calculate b_0. The first method is independent of the measured $C(\Delta\phi)$. We calculate $b_0 = \xi\kappa\langle n_{\rm trigg}\rangle\langle n_{\rm assoc}\rangle/\langle n_{\rm same}\rangle$ with hadron production rates measured from all events within each centrality class and scaled by the same-event pair rate $\langle n_{\rm same}\rangle$. The pair-cut correction κ lowers the combinatoric pair multiplicity for pair loss due to proximity cuts in tracking detectors. A residual multiplicity correlation factor, $\xi = \langle n_{\rm trigg}n_{\rm assoc}\rangle/\langle n_{\rm trigg}\rangle\langle n_{\rm assoc}\rangle$, corrects for averaging production rates over events of different multiplicity within the same centrality class, estimated from Glauber $N_{\rm part}$ and $N_{\rm coll}$ distributions [11,13]. In the second method a functional form for $J(\Delta\phi)$ is added to the background, and the sum fitted to the measured correlation with b_0 as a free parameter. Motivated by the theoretical ideas discussed above, we use a function with a near-side Gaussian, and two symmetric away-side Gaussians:

$$J(\Delta\phi) = G(\Delta\phi) + G(\Delta\phi - \pi - D) + G(\Delta\phi - \pi + D). \quad (3)$$

While the choice of this functional form is not unique, it does provide a reasonable fit to the measured correlations, as shown by the dotted line in Fig. 1. The parameter D, or peak angle, is motivated by an attempt to describe the away-side dijet correlation in terms of its symmetry around $\Delta\phi \sim \pi$. We note that it also tends to absorb any non-Gaussian character of the dijet correlation. The third method, called zero yield at minimum (ZYAM), assumes that there is a region in $\Delta\phi$ where the dijet source of particle pairs is negligible. b_0 is varied until the background component in Eq. (2) matches the measured correlation $C(\Delta\phi)$ at some value of $\Delta\phi$.

As shown in Table I for the Au + Au data at 200 GeV, there are slight b_0 variations depending on which method is used to extract its value. However, the dijet correlation shape is essentially independent of these variations.

Figure 1 summarizes the ZYAM extraction of the dijet correlations using the central (0%–5%) Au + Au data at 200 GeV: the measured correlation is shown with squares, the background term with a full line, and the background subtracted dijet correlation with circles for values and boxes for the point-by-point systematic errors. The systematic errors are correlated since they depend on the same parameter—the $\langle v_2\rangle$ uncertainty. For clarity, $J(\Delta\phi)$ is

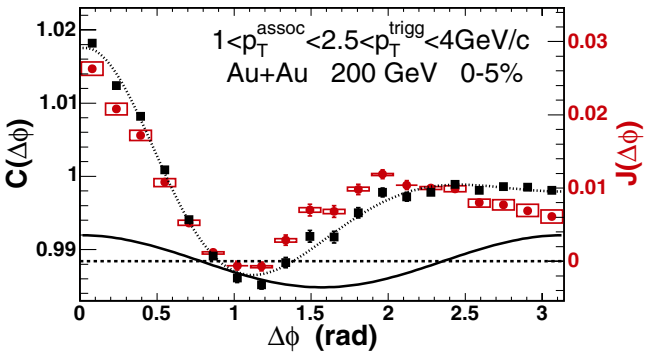

FIG. 1 (color online). The measured correlation $C(\Delta\phi)$ (squares) and the dijet correlation $J(\Delta\phi)$ (circles with boxes for point-to-point systematic errors) in central Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The full line shows the background term and the dotted line shows a $C(\Delta\phi)$ fit with Eqs. (2) and (3). The left axis shows the measured correlation amplitude and the right axis shows the dijet correlation amplitude.

TABLE I. b_0 values in Au + Au data at $\sqrt{s_{NN}} = 200$ GeV: ZYAM values (first row), variation of fit values from the ZYAM values (second row), variation of combinatorial (Comb.) values from the ZYAM values (third row).

Centrality	60%–90%	40%–60%	20%–40%	10%–20%	5%–10%	0%–5%
ZYAM b_0	0.861	0.942	0.960	0.971	0.982	0.988
Fit δb_0	−0.003	−0.003	−0.006	−0.028	−0.035	−0.022
Comb. δb_0	−0.086	−0.013	−0.004	+0.002	+0.001	+0.001

shifted up by b_0, shown with dashed line, and its amplitude is shown on the right axis. We note that, in this case, the measured correlation is flat near $\Delta\phi \sim \pi$, even before any background subtraction. Because of the cosine modulation of the background, a local minimum develops at $\Delta\phi \sim \pi$ in the dijet away-side correlation.

Figure 2 shows a central and a peripheral dijet correlation for each colliding system and energy. A remarkable away-side feature in central and semicentral collisions (<40%) is the peak location away from $\Delta\phi = \pi$, and the appearance of a local minimum at $\Delta\phi = \pi$. To quantify the significance of this minimum in the Au + Au data at 200 GeV, we have studied how much $\langle v_2^{\rm assoc}\rangle\langle v_2^{\rm trig}\rangle$ would need to change for the away side to be flat. For the four most central bins (0%–5%, 5%–10%, 10%–20%, and 20%–40%) it would have to decrease by 85%(5.1σ), 41%(4.2σ), 20%(2.3σ), and 23%(2.7σ), respectively, where σ is the total $\langle v_2^{\rm assoc}\rangle\langle v_2^{\rm trig}\rangle$ uncertainty.

We quantify the away-side shape change and deviation from a Gaussian distribution by extracting the second and fourth central moments around $\Delta\phi \sim \pi$ ($\mu_n \equiv \langle(\Delta\phi - \pi)^n\rangle$, $n = 2, 4$), in the standard form of the following statistical quantities: the root mean square $\equiv \sqrt{\mu_2}$ and the kurtosis $\equiv \mu_4/\mu_2^2$. The away side is defined here as all $\Delta\phi$ values above the dijet function $J(\Delta\phi)$ minimum, typically 1 rad. We extract these statistics on only the away-side jet peaks in $J(\Delta\phi)$; possible jet-associated flat underlying distributions, which are highly sensitive to the uncertainty in b_0 and precluded by the ZYAM assumption, are not included.

The rms and kurtosis centrality dependence is shown in Fig. 3(a). The rms increases with centrality, indicating broadening of the away-side dijet correlation, while the kurtosis decreases from the value characteristic of a Gaussian shape (three), demonstrating a flattening of its shape beyond an increase in the Gaussian width.

The peak angle D centrality dependence, extracted by fitting dijet correlations with Eq. (3), is shown in Fig. 3(b). It is consistent with zero radians in d + Au and peripheral collisions, but rapidly grows to a value around 1 rad in central collisions. Some deviation from zero radians may be due to slight non-Gaussian shapes of the dijet correlations even without medium modification. This is seen in

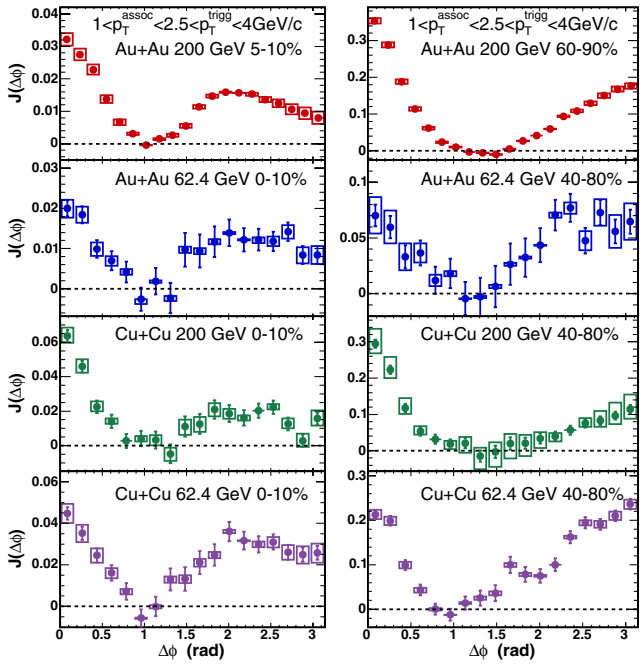

FIG. 2 (color online). Dijet correlations (circles with boxes for point-to-point systematic errors) in Au + Au and Cu + Cu collisions at $\sqrt{s_{NN}} = 62.4$ and 200 GeV. Left panels show central collisions, while right panels show peripheral collisions.

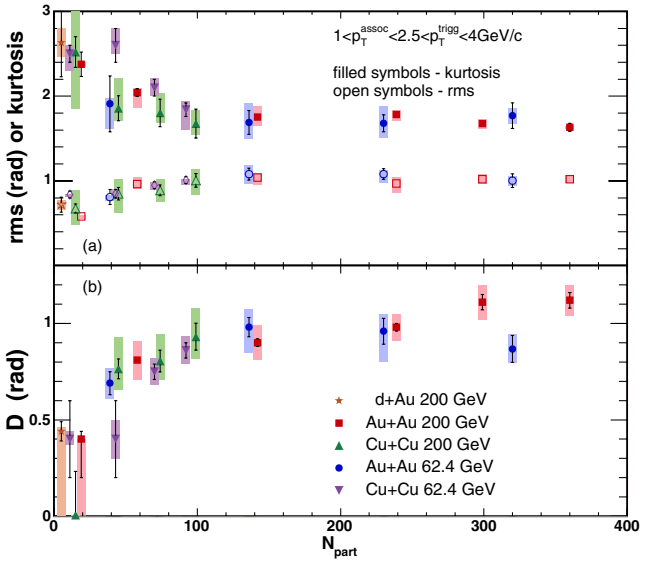

FIG. 3 (color online). Collision centrality, energy, and system size dependence of shape parameters: (a) kurtosis (filled symbols) and rms (open symbols); (b) peak angle D. Bars show statistical errors, shaded bands systematic errors.

TABLE II. Dependence of away-side shape parameters on associated hadron p_T in central (0%–20%) Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV for $3 < p_T^{\text{trigg}} < 5$ GeV/c. First error is statistical and second error is systematic.

p_T^{assoc}	D (rad)	rms (rad)	Kurtosis
1–1.5	$1.04 \pm 0.03 \pm 0.03$	$1.02 \pm 0.02 \pm 0.05$	$1.68 \pm 0.04 \pm 0.10$
1.5–2	$1.07 \pm 0.04 \pm 0.04$	$1.06 \pm 0.02 \pm 0.05$	$1.58 \pm 0.05 \pm 0.10$
2–2.5	$1.05 \pm 0.03 \pm 0.06$	$1.08 \pm 0.04 \pm 0.08$	$1.38 \pm 0.11 \pm 0.12$
2.5–3	$1.07 \pm 0.06 \pm 0.06$	$1.09 \pm 0.07 \pm 0.07$	$1.35 \pm 0.17 \pm 0.12$
3–5	$0.88 \pm 0.13 \pm 0.16$	$1.01 \pm 0.11 \pm 0.14$	$1.31 \pm 0.23 \pm 0.25$

the kurtosis values for d + Au and peripheral collisions, which have values somewhat lower than three. The systematic errors in Fig. 3 come primarily from the v_2 uncertainty for Cu + Cu and Au + Au and from the $J(\Delta\phi)$ minimum determination for d + Au.

No dependence of rms, kurtosis, or peak angle D on collision energy or species is observed, the away-side dijet shape exhibiting an N_{part} scaling also observed in the suppression of single hadron spectra [14].

Table II shows the dependence of the away-side shape parameters on the associated hadron p_T in the Au + Au data at 200 GeV for a 0%–20% centrality bin, $3 < p_T^{\text{trigg}} < 5$ GeV/c, and the following p_T^{assoc} bins: 1–1.5, 1.5–2, 2–2.5, 2.5–3, and 3–5 GeV/c. The peak angle D and the rms have no p_T dependence, while the kurtosis is consistent with a slow decrease with p_T.

Several phenomenological models for modification of the away-side jet have been proposed; all involve a strong response of the medium to the traversing jet. Bow shocks propagating as sound, or density, waves in the medium produce a peak located away from $\Delta\phi = \pi$ [4,15]. If the peak indeed arises from a sound wave, its location at 1 rad away from the nominal jet direction implies a speed of sound intermediate between that expected in a hadron gas and quark-gluon plasma [4]. A first order phase transition would cause a region with speed of sound identically zero. This region was postulated [4] to reflect sound waves and cause a second away-side peak located at about $\Delta\phi = 1.4$ rad. No clear evidence for a distinct peak is seen in our data.

If the coupling among partons in the medium is strong, then the high momentum parton may induce non-sound-wave collective plasma excitations [5]. In the strong coupling limit the anti–de Sitter/conformal field theory (AdS/CFT) correspondence was applied to calculate the wake of directional emission from a heavy quark traversing the medium, where a peak angle is found at values slightly larger than in these data [16].

The peak may also arise from Cherenkov gluon radiation [6]. Such a mechanism should disappear for high energy gluons, implying that the peak angle D should gradually approach zero with increasing momentum of associated hadrons. Table II shows that this is not supported by the data. The medium may induce gluon radiation at large angles by mechanisms other than Cherenkov radiation [7,8]. Such models can reproduce the observed peak if the density of scattering centers is large and the gluon splitting sufficiently asymmetric [7]. However, the predicted radiation is very sensitive to the treatment of geometry, expansion, and radiative energy loss framework used. Our detailed measurements constrain the options.

An important issue is whether the density wave correlations survive the underlying medium expansion [4,17]. It was shown that the interplay of the longitudinal expansion and limited experimental η acceptance preserves, and even amplifies, the signal of directed collective excitations [15]. The creation of a shock wave consistent with our data requires that 75%–90% of the parton's lost energy be transferred to the collective mode [15].

We have presented azimuthal angle correlations of intermediate transverse momentum hadrons from dijets in Cu + Cu and Au + Au collisions at $\sqrt{s_{NN}} = 62.4$ and 200 GeV. The away-side dijet correlation is seen to be broadened, non-Gaussian, and peaked away from $\Delta\phi = \pi$ in central and semicentral collisions. The away-side shape depends on the number of participants in the collision, and not on the beam nuclei or energy. The general features of the observed shape can be qualitatively accounted for by a number of phenomenological models, all having in common a strong medium response to the energy deposited by the traversing parton. The systematic data presented here provide quantitative tests that could discriminate between these models.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 11 November 2006; published 24 April 2007)

The PHENIX experiment at the BNL Relativistic Heavy Ion Collider (RHIC) has measured electrons with $0.3 < p_T < 9$ GeV/c at midrapidity ($|y| < 0.35$) from heavy-flavor (charm and bottom) decays in Au + Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV. The nuclear modification factor $R_{\rm AA}$ relative to $p + p$ collisions shows a strong suppression in central Au + Au collisions, indicating substantial energy loss of heavy quarks in the medium produced at RHIC energies. A large azimuthal anisotropy v_2 with respect to the reaction plane is observed for $0.5 < p_T < 5$ GeV/c indicating substantial heavy-flavor elliptic flow. Both $R_{\rm AA}$ and v_2 show a p_T dependence different from those of neutral pions. A comparison to transport models which simultaneously describe $R_{\rm AA}(p_T)$ and $v_2(p_T)$ suggests that the viscosity to entropy density ratio is close to the conjectured quantum lower bound, i.e., near a perfect fluid.

DOI: 10.1103/PhysRevLett.98.172301 PACS numbers: 25.75.Dw

Experimental results from the Relativistic Heavy Ion Collider (RHIC) have established that dense partonic matter is formed in Au + Au collisions at RHIC [1–4]. Strong suppression observed for π^0 and other light hadrons at high transverse momentum (p_T) [5–8] indicates partonic energy loss in the produced medium. The azimuthal anisotropy $v_2(p_T)$ [9,10] provides evidence that collective motion develops in a very early stage of the collision ($\tau \lesssim 5$ fm/c), in accordance with hydrodynamical calculations [11,12]. The comparison of v_2 with several such models suggests [13–15] that the matter formed at RHIC is a near-perfect fluid with viscosity to entropy density ratio η/s close to the conjectured quantum lower bound [16]. Energy loss and flow are related to the transport properties of the medium at temperature T, in particular, the diffusion coefficient $D \propto \eta/(sT)$.

Further insight into properties of the medium can be gained from the production and propagation of particles carrying heavy quarks (charm or bottom). A fixed-order-plus-next-to-leading-log (FONLL) perturbative QCD (pQCD) calculation [17] describes the cross sections of heavy-flavor decay electrons in $p + p$ collisions at $\sqrt{s} = 200$ GeV within theoretical uncertainties [18]. In Au + Au collisions the total yield of such electrons was found to scale with the number of nucleon-nucleon collisions as expected for pointlike processes [19]. Energy loss via gluon radiation is expected to be reduced for heavy quarks due to suppression of forward radiation, thus increasing their expected thermalization time [20–22]. Consequently, a decrease of high p_T suppression and of v_2 is expected from light to charm to bottom quarks, with the absolute values and their p_T dependence sensitive to the properties of the medium. In contrast to these expectations, a strong suppression of heavy-flavor decay electrons was discovered for $2 < p_T < 5$ GeV/c [23,24], together with nonzero electron v_2 for $p_T < 2$ GeV/c [25].

This Letter presents p_T spectra and the elliptic flow amplitude $v_2^{\rm HF}$ of electrons, $(e^+ + e^-)/2$, from heavy-flavor decays at midrapidity in Au + Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV. An increase in statistics by more than a factor of 10 and reduced systematic uncertainties compared to earlier data [19,23,25] greatly extend the p_T range both for the determination of the centrality dependence of $R_{\rm AA}$ and for the measurement of $v_2^{\rm HF}$.

The data were collected by the PHENIX detector [26] in the 2004 RHIC run. The minimum bias trigger and the collision centrality were obtained from the beam-beam counters (BBC) and zero degree calorimeters [1]. After selecting good runs, data samples of 8.1 and 7.0×10^8 minimum bias events in the vertex range $|z_{\rm vtx}| < 20$ cm are used for the spectra and v_2 analyses, respectively.

Charged particle tracks are reconstructed with the two PHENIX central arm spectrometers, each covering $\Delta\phi = \pi/2$ in azimuth and $|\eta| < 0.35$ in pseudorapidity [26]. Tracks are confirmed by matching showers in the electromagnetic calorimeter (EMC) within 2σ in position. Electron candidates have at least three associated hits in the ring imaging Čerenkov detectors (RICH) and fulfill a shower shape cut in the EMC, where they deposit an energy E, consistent with the momentum ($E/p - 1 > -2\sigma$). Below the Čerenkov threshold for pions ($p_T < 5$ GeV/c) electron misidentification is only due to random coincidences between hadron tracks and hits in the RICH. This small background (<20% at low p_T in central collisions, less toward high p_T and peripheral events) is subtracted statistically using an event mixing technique. Requiring at least five hits in the RICH and tightening the shower shape cut extends the electron measurement to 9 GeV/c in p_T, with negligible hadron background for $p_T < 8$ GeV/c and a hadron contamination of 20% for $8 < p_T < 9$ GeV/c. The raw spectra are corrected for geometrical acceptance and reconstruction efficiency de-

termined by a GEANT simulation. The centrality dependent efficiency loss $<2\%$ ($\approx 23\%$) for peripheral (central) events is evaluated by reconstructing simulated electrons embedded into real events.

The inclusive electron spectra consist of (i) ''nonphotonic'' electrons from heavy-flavor decays, (ii) ''photonic'' background from Dalitz decays and photon conversions (mainly in the beam pipe), and (iii) nonphotonic background from $K \rightarrow e\pi\nu$ (K_{e3}) and dielectron decays of vector mesons. Contribution (iii) is small ($<10\%$ for $p_T < 0.5$ GeV/c, $<2\%$ for $p_T > 2$ GeV/c) compared to (ii). The heavy-flavor signal and the ratio of nonphotonic to photonic electrons, $R_{\rm NP}$, are determined via two independent and complementary methods described in detail in [18], where the identical detector configuration was used. At low p_T ($p_T < 1.6$ GeV/c), where the heavy-flavor signal to background ratio is small ($S/B < 1$), the ''converter subtraction'' method is used, which employs a photon converter of 1.67% radiation length (X_0) installed around the beam pipe for part of the run. The converter multiplies the photonic background by a known, nearly p_T independent factor $R_\gamma \sim 2.3$. The photonic background can then be determined by comparing the inclusive electron yield with and without the converter. For higher p_T, where S/B is large, the ''cocktail subtraction'' method [23] is used. Here the background is calculated with a Monte Carlo hadron decay generator and subtracted from the data. At low p_T the dominant background source is the π^0 Dalitz decay, which is calculated for each centrality using measured pion spectra [6,27] as input. In good agreement with measured data [8], the spectral shapes of other light hadrons h (η, ρ, ω, ϕ, η') are derived from the pion spectrum assuming a universal shape in $m_T = \sqrt{p_T^2 + m_h^2}$ with a fixed constant ratio at high p_T. Photon conversions in the beam pipe, air, and helium bags (total $0.4\%X_0$) are also included, along with background from K_{e3} decays and both external and internal conversions of direct photons which are important for $p_T > 4$ GeV/c. The agreement within the systematic uncertainties in the overlap region $0.3 < p_T < 4$ GeV/c of these two methods demonstrates that the absolute value of photonic backgrounds in the PHENIX aperture is well understood.

The v_2 of inclusive electrons, $v_2^{\rm inc}$, is measured as $v_2^{\rm inc} = \langle\cos(2(\phi - \Phi_R))\rangle/\sigma_R$ [28], where Φ_R is the azimuthal orientation of the reaction plane measured with the resolution σ_R using the BBC [9]. Since σ_R is centrality dependent, v_2 is determined for narrow centrality bins (10%) and then averaged to calculate v_2 for minimum bias events. The v_2 of random hadronic background is subtracted statistically as described in [25].

The $v_2^{\rm non\text{-}\gamma}$ of nonphotonic electrons is obtained by subtracting the photonic electron v_2^γ as $v_2^{\rm non\text{-}\gamma} = [(1 + R_{\rm NP})v_2^{\rm inc} - v_2^\gamma]/R_{\rm NP}$. Here v_2^γ is calculated via a Monte Carlo generator that includes π^0, η, and direct photons. The measured $v_2(p_T)$ of $\pi^\pm$, π^0, and $K^\pm$ [9,29] is used as input, assuming $v_2^{\pi^\pm} = v_2^{\pi^0}$, $v_2^\eta = v_2^{K^\pm}$, and $v_2^{\rm direct\ \gamma} = 0$. A direct measurement of v_2^γ using the converter subtraction method confirms the calculation within statistical uncertainties. The resulting $v_2^{\rm non\text{-}\gamma}$ has a small contribution from K_{e3} background which is simulated and subtracted to obtain $v_2^{\rm HF}$ of heavy-flavor decay electrons.

Three independent categories of systematic uncertainties are considered. (a) The inclusive electron spectra include uncertainties in the geometrical acceptance (5%), the reconstruction efficiency (3%), and the embedding correction ($\leq 4\%$). (b) Uncertainties in the converter subtraction are mainly given by the uncertainty in R_γ (2.7%) and in the relative acceptance of runs with and without the converter being installed (1%). (c) Uncertainties in the cocktail subtraction rise from 8% at $p_T = 0.3$ GeV/c to 13% at 9 GeV/c, dominated by systematic errors in the pion input and, at high p_T, the direct photon spectrum. The v_2 measurement includes a systematic uncertainty of 5% due to the reaction plane uncertainty.

Figure 1 shows the invariant p_T spectra of electrons from heavy-flavor decay for minimum bias events and in five centrality classes. The curves overlayed are the fit to the corresponding data from $p + p$ collisions [18] with the spectral shape taken from a FONLL calculation [17] and scaled by the nuclear overlap integral $\langle T_{\rm AA}\rangle$ for each centrality class [6]. The inset of Fig. 1 shows the ratio of electrons from heavy-flavor decays to background. It increases rapidly with p_T, exceeding unity for $p_T > 1.8$ GeV/c, reflecting the small amount of material in the detector acceptance which makes the accurate measurement of heavy-flavor electron spectra and $v_2^{\rm HF}$ possible.

For all centralities, the Au + Au spectra agree well with the $p + p$ reference at low p_T, but a suppression with respect to $p + p$ develops toward high p_T. This is quantified by the nuclear modification factor $R_{\rm AA} = dN_{\rm Au+Au}/(\langle T_{\rm AA}\rangle d\sigma_{p+p})$, where $dN_{\rm Au+Au}$ is the differential yield in Au + Au and $d\sigma_{p+p}$ is the differential cross section in $p + p$ in a given p_T bin. For $p_T < 1.6$ GeV/c, $d\sigma_{p+p}$ is taken bin-by-bin from [18], whereas a fit to the same data (curves in Fig. 1) is used at higher p_T, taking systematic uncertainties in $d\sigma_{p+p}$ and $T_{\rm AA}$ into account.

Figure 2 shows $R_{\rm AA}$ for electrons from heavy-flavor decays for two different p_T ranges as a function of the number of participant nucleons $N_{\rm part}$. For the integration interval $p_T > 0.3$ GeV/c containing more than half of the heavy-flavor decay electrons [18], $R_{\rm AA}$ is consistent with unity for all $N_{\rm part}$ in accordance with the binary scaling of the total heavy-flavor yield [19]. For $p_T > 3$ GeV/c, the heavy-flavor electron $R_{\rm AA}$ decreases systematically with centrality, while larger than $R_{\rm AA}$ of π^0 with $p_T > 4$ GeV/c [6]. Since above 3 GeV/c electrons from charm decays originate mainly from D mesons with p_T above 4 GeV/c this comparison indicates a smaller suppression of heavy-flavor mesons than observed for light mesons in this intermediate p_T range.

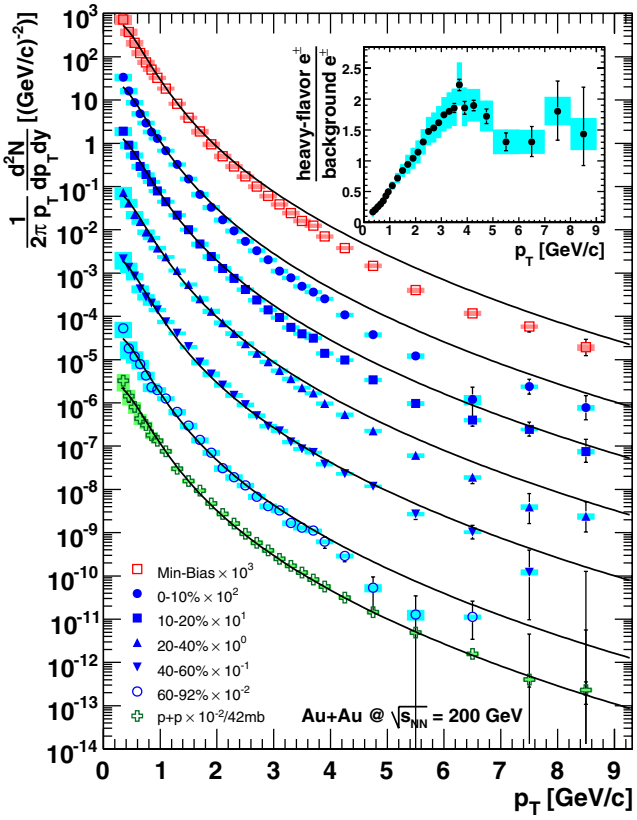

FIG. 1 (color online). Invariant yields of electrons from heavy-flavor decays for different Au + Au centrality classes and for $p + p$ collisions, scaled by powers of 10 for clarity. The solid lines are the result of a FONLL calculation normalized to the $p + p$ data [18] and scaled with $\langle T_{AA}\rangle$ for each Au + Au centrality class. The inset shows the ratio of heavy-flavor to background electrons for minimum bias Au + Au collisions. Error bars (boxes) depict statistical (systematic) uncertainties.

Figure 3 shows the measured R_{AA} and v_2^{HF} of heavy-flavor electrons in 0%–10% central and minimum bias collisions, and our corresponding π^0 data [6,29]. The data indicate strong coupling of heavy quarks to the medium. While at low p_T the suppression is smaller than that of π^0, R_{AA} of heavy-flavor decay electrons approaches the π^0 value for $p_T > 4$ GeV/c although a significant contribution from bottom decays is expected at high p_T. The large v_2^{HF} indicates that the charm relaxation time is comparable to the short time scale of flow development in the produced medium. It should be noted that much reduced uncertainties and the extended p_T range of the present data permit the comparisons of R_{AA} and v_2 of the heavy and light flavors.

More quantitative statements require theoretical guidance. Figure 3 compares the R_{AA} and v_2 of heavy-flavor electrons with models calculating both quantities simultaneously. A pQCD calculation with radiative energy loss (curves I) [30] describes the measured R_{AA} reasonably well using a large transport coefficient $\hat{q} = 14$ GeV^2/fm, which also provides a consistent description of light hadron

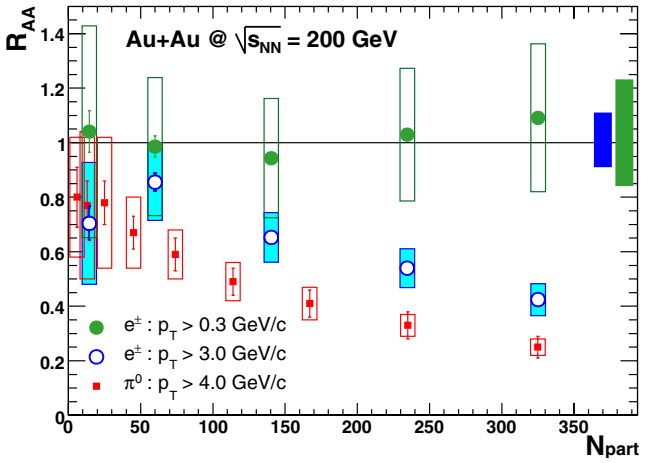

FIG. 2 (color online). R_{AA} of heavy-flavor electrons with p_T above 0.3 and 3 GeV/c and of π^0 with $p_T > 4$ GeV/c as function of centrality given by N_{part}. Error bars (boxes) depict statistical (point-by-point systematic) uncertainties. The right (left) box at $R_{AA} = 1$ shows the relative uncertainty from the $p + p$ reference common to all points for $p_T > 0.3(3)$ GeV/c.

suppression. This value of $\hat{q}$ would imply a strongly coupled medium. In this model the azimuthal anisotropy is only due to the path length dependence of energy loss, and the data clearly favor larger v_2^{HF} than predicted from this effect alone.

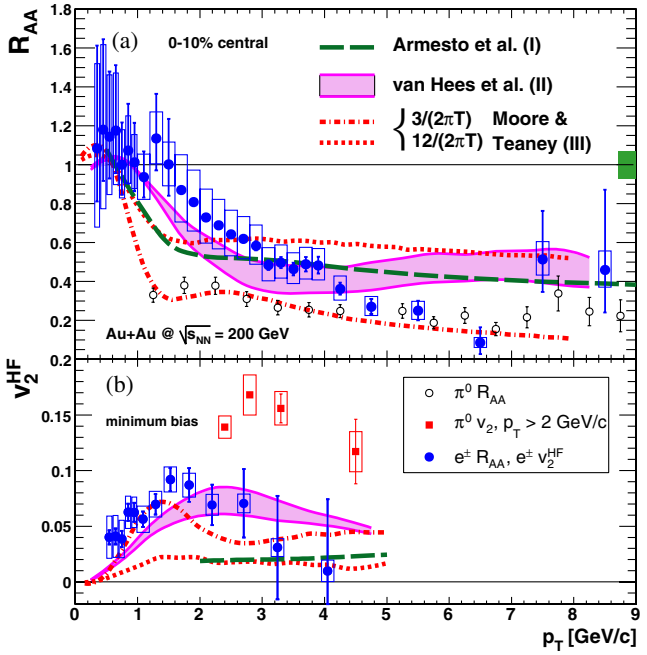

FIG. 3 (color online). (a) R_{AA} of heavy-flavor electrons in 0%–10% central collisions compared with π^0 data [6] and model calculations (curves I [30], II [31], and III [32]). The box at $R_{AA} = 1$ shows the uncertainty in T_{AA}. (b) v_2^{HF} of heavy-flavor electrons in minimum bias collisions compared with π^0 data [29] and the same models. Errors are shown as in Fig. 2.

Figure 3 also shows that the large v_2^{HF} is better reproduced in Langevin-based heavy quark transport calculations [31,32]. A calculation which includes elastic scattering mediated by resonance excitation (curves II) [31] is in good agreement with both the measured R_{AA} and v_2. This is achieved with a small heavy quark relaxation time τ which translates into a diffusion coefficient $D_{\mathrm{HQ}} \times (2\pi T) = 4$–$6$ in this model [31]. Energy loss and flow are also calculated in [32] in terms of D_{HQ} (curves III). While this model fails to simultaneously describe the measured R_{AA} and v_2 with one value for D_{HQ}, the range for D_{HQ} leading to reasonable agreement with R_{AA} or v_2 is similar to that from [31], again implying that small τ and/or $D_{\mathrm{HQ}} \times (2\pi T)$ are required to reproduce the data. Note that D_{HQ} provides an upper bound for the bulk matter's diffusion coefficient D. Using the observation [32] that $D \approx 6 \times \eta/(\epsilon + p)$ with $\epsilon + p = Ts$ at $\mu_B = 0$ provides an estimate for the viscosity to entropy ratio $\eta/s \approx (\frac{4}{3} - 2)/4\pi$, intriguingly close to the conjectured quantum lower bound $1/4\pi$ [33]. This result is consistent with estimates obtained in the light quark sector from elliptic flow [34] and fluctuation analyses [35].

The conjecture of a bound on η/s [16] was obtained using the anti–de Sitter-space/conformal-field-theory correspondence [36,37], which exploits a duality between strongly coupled gauge theories and semiclassical gravitational physics. Recently, such methods were applied to estimate $\hat{q}$ [38] and D_{HQ} in a thermalized plasma [39–41]. These authors also find a small diffusion coefficient $D_{\mathrm{HQ}} \times (2\pi T) \sim 1$.

In conclusion, we have observed large energy loss and flow of heavy quarks in Au + Au collisions at $\sqrt{s_{\mathrm{NN}}} = 200$ GeV. The data provide strong evidence for the coupling of heavy quarks to the produced medium. A short relaxation time of heavy quarks and/or a small diffusion coefficient are required by the data. A model comparison suggests a viscosity to entropy ratio of the medium close to the quantum lower bound, i.e., near a perfect fluid.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. Abstract

Correlations between p and $\bar{p}$ at transverse momenta typical of enhanced baryon production in Au + Au collisions are reported. The PHENIX experiment has measured same and opposite sign baryon pairs in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Correlated production of p and $\bar{p}$ with the trigger particle from the range $2.5 < p_T < 4.0$ GeV/c and the associated particle with $1.8 < p_T < 2.5$ GeV/c is observed to be nearly independent of the centrality of the collisions. Same sign pairs show no correlation at any centrality. The conditional yield of mesons triggered by baryons (and anti-baryons) and mesons in the same p_T range rises with increasing centrality, except for the most central collisions, where baryons show a significantly smaller number of associated mesons. These data are consistent with a picture in which hard scattered partons produce correlated p and $\bar{p}$ in the p_T region of the baryon excess.

1. Introduction

A remarkable feature of relativistic heavy ion collisions at RHIC energies is the enhanced production of baryons and anti-baryons relative to mesons at intermediate transverse momenta ($2 < p_T < 5$ GeV/c) [1,2]. In central Au + Au collisions at

✠ Deceased.

$\sqrt{s_{NN}} = 200$ GeV the baryon/meson ratio is a factor of three higher than in $p + p$ collisions, while in peripheral Au + Au collisions and in d + Au collisions [3] at the same energy only a small increase ($< 20\%$) is observed. The production of protons and anti-protons at intermediate p_T in Au + Au collisions scales with the number of binary nucleon-nucleon collisions [1], contrary to the suppression of pion production [4]. Similar behavior has been observed for strange baryons (Λ and $\bar{\Lambda}$) and mesons (K^0_S) [5].

In this same momentum range and center of mass energy in $p + p$ collisions the dominant production mechanism shifts from soft processes characterized by non-perturbative low momentum transfer scattering to hard scattering processes characterized by large momentum transfer parton–parton scattering followed by fragmentation of the scattered partons into final state hadrons. Pion production in $\sqrt{s_{NN}} = 200$ GeV $p + p$ collisions is reasonably well described by perturbative QCD (pQCD) down to $p_T \approx 2$ GeV [6]. There are large variations in the p and $\bar{p}$ yield among various fragmentation functions, which make it difficult to establish a definite pQCD expectation for the p and $\bar{p}$ spectra in $p + p$ collisions [7]. Another estimate of the transition from hard to soft physics can be obtained from the $x_T = 2p_T/\sqrt{s}$ scaling of the single particle cross sections. The cross section can be written as [8,9]:

$$E\frac{d^3\sigma}{dp^3} = \frac{1}{\sqrt{s}^{n(\sqrt{s},x_T)}} G(x_T). \tag{1}$$

At high x_T the value of n is found to be independent of both $\sqrt{s}$ and x_T. Since the power of n is related to the quantum exchanged and the number of point-like scatterers, the x_T region corresponding to the asymptotic n value is understood to be the region where particle production is dominated by hard scattering. Recent measurements of the p and $\bar{p}$ and $\pi^{\pm}$ spectra show the cross section can be described by consistent values of n for $p_T > 2$ GeV/c for both the $\pi^{\pm}$ ($n = 6.8 \pm 0.5$) and p and $\bar{p}$ ($n = 6.5 \pm 1.0$) [7] indicating, together with the agreement between the data and pQCD calculations at high p_T [6,7], that at $\sqrt{s} = 200$ GeV the transition from hard to soft particle production happens at $p_T \approx 2$ GeV/c. Since the fragmentation process is believed to be independent of center of mass energy or collision system, baryon and anti-baryon production in central Au + Au collisions appears inconsistent with hard-scattering followed by a universal fragmentation.

The theoretical models that are successful in reproducing the measured single particle spectra, baryon/meson ratios and the nuclear modification factors usually invoke some mechanism to extend the range of soft particle production for baryons to higher p_T than that for mesons. This is either done based on the particle mass (in hydrodynamics models [10,11]) or on the quark content (quark recombination models [12–14]). An alternative approach, which involves production of baryons through gluon junctions, has also been shown to reproduce the data [15]. In this Letter we study two-particle angular correlations involving p, $\bar{p}$, and mesons ($\pi^{\pm}$, $K^{\pm}$). This approach gives information about the hadron production in hard-scattering processes, which is inaccessible from single particle measurements.

Previous studies [16–18] in Au + Au collisions show that at intermediate p_T particles are correlated in azimuthal angle in a manner consistent with jet fragmentation. Namely, particles are emitted close together when they come from fragmentation of the same jet (near side correlations) or approximately back-to-back when they come from the fragmentation of the associated di-jet (away side correlations). Strong modifications of the yields, shapes and particle composition of these correlations are seen from peripheral to central Au + Au collisions. The yields are quantified by the number of associated particles per trigger (conditional yield) after the combinatorial background from the underlying event has been subtracted. The conditional yield is measured separately for the near and away side correlations. The near side conditional yield increases [16–18] with centrality and the away side shape has a peak at $\Delta\phi \approx 2$ rad and no peak at $\Delta\phi \approx \pi$ rad. Correlations between identified baryons (p, $\bar{p}$) and charged hadrons [17] rule out baryon production from $2.5 < p_T < 4.0$ GeV/c as coming dominantly from a thermal parton source with no correlations [17,19]. Moreover, the magnitude of baryon and meson triggered correlations with other charged hadrons in the same event is similar, suggesting that the baryon excess in the intermediate p_T range is associated with hard parton–parton scattering [17].

There are two main recombination models which have attempted to address the connection between hard scattering and recombination. The model of Hwa and Yang [14] has calculated that fragmenting partons from hard scattering process have a high probability to recombine with thermal quarks from the medium. The model of Fries et al. [19] finds these effects to be unimportant, but has correlations from fast partons losing energy in the medium creating a region around the parton trajectory with a slightly increased temperature and with additional momentum in the direction of the energetic parton. Partons from this region then recombine into hadrons, which are correlated with the fast parton direction and with each other.

In order to further explore the jet-like structure of the baryon excess, here we present results on the angular correlations between two identified particles. The baryon production mechanism is studied via correlations between two charge separated p and $\bar{p}$. The trigger particles are taken to be all p or $\bar{p}$ measured within the given p_T window, regardless of whether the event has any associated particles. Thus, an increasing fraction of uncorrelated trigger particles will result in a dilution of the conditional yield. However, if the main source of the baryon excess is jets that fragment outside the medium, the charge dependence of correlations between p and $\bar{p}$ should be the same from peripheral collisions, where baryon production at intermediate p_T is nearly unmodified from $p + p$ collisions, to central collisions. A centrality dependence of the charge combinations of p and $\bar{p}$ correlations would provide evidence for novel baryon production scenarios in central Au + Au collisions.

Correlations between baryon and meson triggers with associated mesons are studied as well. Meson trigger-associated mesons (meson–meson) correlations provide a baseline for jet fragmentation in Au + Au collisions. Separating the baryon–hadron correlations from [17] into baryon–meson and baryon–baryon correlations allows greater sensitivity to possible recom-

bination effects. The recombination model of Fries et al. [19] predicts a greater amplification of baryon–baryon correlations relative to baryon–meson correlations on the near side because of the larger number of possible correlations between the valence quarks.

Near side correlations from jets in $p+p$ collisions are observed to be balanced by away side correlations from the associated di-jet [20]. The away side correlations at intermediate p_T in Au + Au collisions have been shown to have a modified shape in Au + Au collisions [18]. Here we measure the away side correlations with both particles identified in order to see if the dependence on the trigger and associated particle type changes with centrality. If the baryon and meson triggers are from hard scattering with approximately the same momentum transfer, we expect the away side correlations to be independent of the trigger particle type.

The Letter is organized as follows: Section 2 describes the experimental method and setup, the results are presented in Section 3, and Section 4 is devoted to discussion.

2. Experimental procedure and setup

Two particle correlations have been widely used to study jets in heavy ion collisions [16–18,21,22] where, due to the high multiplicity and moderate jet energy the direct reconstruction of jets by standard algorithms, utilizing hadronic calorimetry and cluster algorithms, is not yet possible. In this approach particles are divided into two classes, *triggers* and *associated particles*. We classify the triggers and associated particles by their p_T, particle type and charge. The triggers have $2.5 < p_T < 4.0$ GeV/c and the associated particles have $1.8 < p_T < 2.5$ GeV/c. Thus both particles originate from a region in p_T that is consistent with hard scattering in $p+p$ collisions and shows an excess of baryons relative to mesons in Au + Au collisions. A distribution of the azimuthal angular difference $\Delta\phi$ between trigger-associated particle pairs is constructed and normalized by the number of triggers.

The data presented here are based on an analysis of 600M Au + Au events collected by the PHENIX experiment in 2004 with a minimum bias trigger. Charged particles are reconstructed in the central arms of PHENIX using a combination of drift chambers and one layer of multi-wire proportional chamber with pad readout (PC1) [23], each covering $\Delta\phi = \pi/2$ in azimuthal angle and $|\eta| < 0.35$ in pseudorapity. The pattern recognition is based on a combinatorial Hough transform in the track bend plane. The polar angle is determined from the hit position in PC1 and the collision vertex along the beam axis measured by the Beam–Beam Counters (BBC). The BBC are positioned at $|\eta| = 3$–4. Particles are identified by their mass calculated from the measured momentum and time-of-flight information. The global start time is provided by BBC, while the stop time is measured by the PHENIX high resolution time of flight detector (TOF) or the lead-scintillator electromagnetic calorimeter (EMCal), which provide a 4σ K/p separation up to $p_T \approx 4.0$ GeV/c and $p_T \approx 2.5$ GeV/c, respectively. The trigger particles are identified in the TOF, which covers a portion of the PHENIX East arm ($\Delta\phi = \pi/4$). The associated particles are identified in either the EMCal or the TOF, which together cover the entire PHENIX azimuthal acceptance. For both triggers and associated particles a 2σ spatial match is required between the track projection and the hit position in the particle identification detector. Monte Carlo studies have shown that, due to the decay kinematics in the trigger and partner p_T range used here, the contribution from $\Lambda \to p\pi^-$ and $\bar{\Lambda} \to \bar{p}\pi^+$ resonance decays, which could produce correlations mimicking the jet signal, is negligible.

We perform a correction for the non-uniform pair acceptance in $\Delta\phi$ in PHENIX. This correction is constructed by measuring the $\Delta\phi$ distribution from trigger-associated particle pairs where each particle comes from a different event. Dividing the same-event by the mixed-event distribution removes the effects of the PHENIX acceptance and leaves only the true correlations. The multiplicity of the combinatorial background of the underlying event is determined absolutely by the convolution of the measured trigger and associated particle single particle rates with an additional correction for centrality correlations [17], which raises the combinatorial background level by $\approx 0.2\%$ in the most central collisions and $\approx 25\%$ in peripheral collisions. A correction for the associated particle reconstruction efficiency and acceptance is applied by matching the observed rates for the corresponding single particle spectra measured in [2]. No correction has been made for p and $\bar{p}$ originating from weak decays of Λ and $\bar{\Lambda}$; approximately 30% of the measured p and $\bar{p}$ are from these decays [2]. The PHENIX η acceptance is narrow compared to the width of the typical jet cone in $p+p$ collisions [20], so we do not measure the entire conditional yield associated with the trigger particle in the associated particle p_T range. The results are reported for both trigger and associated particles within $|\eta| < 0.35$ without extrapolating in pseudorapidity. The centrality dependence of the conditional yields allows us to quantify changes in the jet-like correlations as a function of centrality and particle type, despite the limited acceptance.

Elliptic flow is an azimuthal correlation between particles due to the anisotropy in the initial collision geometry. This angular correlation is unrelated to jet fragmentation and thus produces a background for this measurement. The correlations due to elliptic flow are removed by modulating the azimuthally uniform combinatorial background by $1 + 2v_2^{\text{trig}} v_2^{\text{part}} \cos(\Delta\phi)$ where v_2^{trig} and v_2^{part} represent the strength of the elliptic flow signal for the trigger and associated particle, respectively. The v_2 parameter is defined by the 2nd harmonic of the azimuthal anisotropy, $v_2 = \langle \cos[2(\phi - \Psi)] \rangle$, where ϕ is the azimuthal angle of emitted particle, Ψ is the azimuthal angle of event plane in a given collision, and the bracket denotes the average over all particles and events [24]. We measure v_2 of charged baryons and mesons at mid-rapidity, $|\eta| < 0.35$, for each centrality and p_T bin through the event plane method [24]. The azimuthal angle of the event plane is determined by the BBC using the elliptic moment definition [25]. The large rapidity difference, $|\Delta\eta| \sim 3$, between the central arms and the BBCs helps to reduce the non-flow contributions to the measured v_2, especially those arising from di-jets. The systematic errors on the v_2 value are dominated by the uncertainty in the correction for the event

Table 1
The v_2 values and statistical and systematic errors for the centrality and p_T bins used in this analysis

Centrality	v_2 Values ± Statistical Error ± Systematic Error		
	Triggers	Associated particles	
	$2.5 < p_T < 4.0$ GeV/c	$1.8 < p_T < 2.0$ GeV/c	$2.0 < p_T < 2.5$ GeV/c

plane resolution [25]. The v_2 values used in this analysis are shown in Table 1. They are consistent with prior PHENIX v_2 measurements [25] in the common centrality bins. The analysis has been performed separately for associated particles in two transverse momentum ranges: $1.8 < p_T < 2.0$ GeV/c and $2.0 < p_T < 2.5$ GeV/c. This minimizes effects due to the variation of v_2 over the width of the associated particle p_T bin. In order to minimize the statistical errors, the results shown here are a sum of the two bins.

The systematic errors on the conditional yields are due to the systematic and statistical uncertainties on the v_2 values, the uncertainty in the corrections for the centrality correlations in the combinatorial background and in the centrality dependence of the efficiency corrections. The systematic error on the centrality dependence of the efficiency corrections is 6% for meson associated particles and 5% for inclusive p, $\bar{p}$ and baryon (p and $\bar{p}$ combined) associated particles independent of centrality. The size of the systematic error on the conditional yield attributed to a systematic uncertainty in the elliptic flow determination is largest in the most central collisions. The systematic error on the centrality correlations is $\approx 60\%$ of the correction in central collisions and $\approx 5\%$ of the correction in peripheral collisions. There are additional systematic errors (not shown in Section 3 plots) that come from the centrality independent normalization of the efficiency corrections and move all points with the same associated particle type together. These are 8.9% for p and $\bar{p}$ associated particles, 11.4% for baryon (p and $\bar{p}$) associated particles, and 13.6% for meson associated particles.

3. Results

Our goal is to study the jet contribution to baryon and anti-baryon production at intermediate p_T where an excess of baryons over mesons is observed. Thus we choose trigger baryons from the range $2.5 < p_T < 4.0$ GeV/c and associated particles in the range $1.8 < p_T < 2.5$ GeV/c and construct two-particle azimuthal correlation distributions. With the larger data sample obtained in 2004 we are able to extend our previous measurements [17] by studying the proton and anti-proton triggers, as well as identifying the associated particles. Several combinations of trigger-associated particle types are presented below.

We first study baryon–baryon correlation, where both trigger and associated particles are identified as either p or $\bar{p}$. The left panel of Fig. 1 shows the azimuthal angular difference, $\Delta\phi$, between charge inclusive p and $\bar{p}$ measured in six centrality classes. The solid lines show the combinatorial background level modulated by the expected correlation due to elliptic flow, $B(1 + 2v_2^{\text{trig}} v_2^{\text{assoc}} \cos(2\Delta\phi))$. The excess is attributed to jet correlations, $J(\Delta\phi)$. The azimuthal angular difference distributions are then described by:

$$\frac{1}{N_{\text{trig}}} \frac{dN}{d\Delta\phi} = B\left(1 + 2v_2^{\text{trig}} v_2^{\text{assoc}} \cos(2\Delta\phi)\right) + J(\Delta\phi). \qquad (2)$$

The region around $\Delta\phi = \pi/2$ has very limited acceptance for pairs due to the requirement that the trigger particle be measured in the TOF detector. The right panels of Fig. 1 show the $J(\Delta\phi)$ for three centralities after the combinatorial background subtraction. There is a pronounced jet peak at small relative angles (near side), however, there is no visible structure on the away side, where the yields are slightly above or at the level of the combinatorial background.

To further explore the observed structures, in Figs. 2 and 3 we perform the analysis separately for each charge combination. The correlations were measured in the same p_T range as in Fig. 1. A near side excess can be seen over the combinatorial background for opposite sign pairs (left panel of Fig. 2 and right panel of Fig. 3) while no significant excess is seen for the same sign pairs (right panel of Fig. 2 and left panel of Fig. 3).

The correlations involving mesons as associated particles provide a comparison baseline for the baryon–baryon correlations. We study both baryon and meson triggers associated with mesons. The left panel of Fig. 4 shows the baryon–meson and meson–meson correlations. The right panels of Fig. 4 show

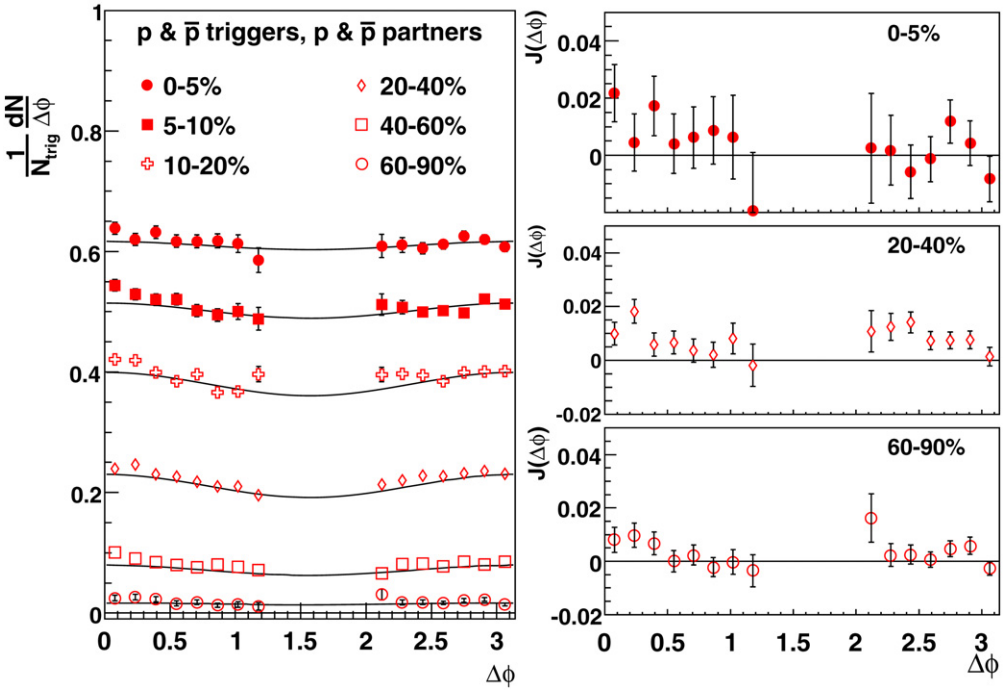

Fig. 1. Left: $\frac{1}{N_{\text{trig}}}\frac{dN}{d\Delta\phi}$ distributions for charge-inclusive baryon triggers and associated particles for six centrality bins. Triggers have $2.5 < p_T < 4.0$ GeV/c and associated particles have $1.8 < p_T < 2.5$ GeV/c. The solid lines indicate the combinatorial background modulated by elliptic flow. Right: Jet distributions, $J(\Delta\phi)$, after combinatorial background and elliptic flow subtraction for 0–5% (top), 20–40% (middle) and 60–90% (bottom) centralities. In all panels, only the statistical errors are shown.

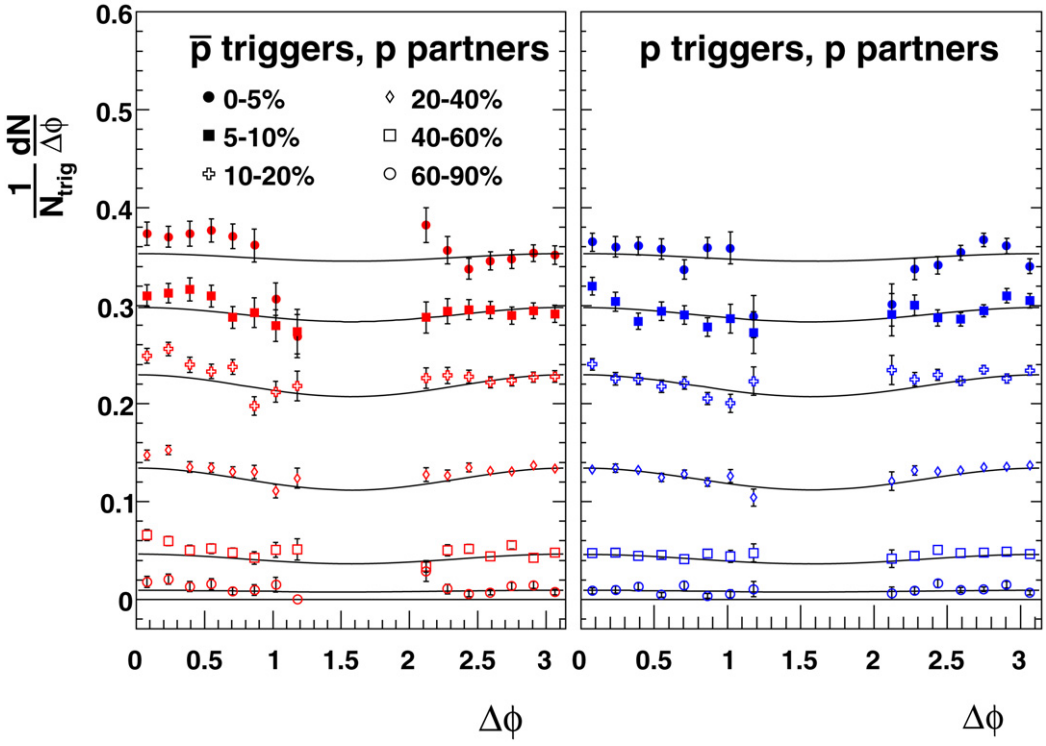

Fig. 2. $\frac{1}{N_{\text{trig}}}\frac{dN}{d\Delta\phi}$ distributions for charge selected $\bar{p}$ (left) and p (right) triggers both with associated p for six centrality bins. Triggers have $2.5 < p_T < 4.0$ GeV/c and associated particles have $1.8 < p_T < 2.5$ GeV/c. The solid lines indicate the combinatorial background modulated by elliptic flow. Only the statistical errors are shown.

$J(\Delta\phi)$ for the 0–5%, 20–40% and 60–90% centrality classes. While in the mid-central collisions the meson and baryon triggered distributions agree well, the baryon triggered distributions in the most central collisions lie systematically below the meson triggered points both before and after the combinatorial background subtraction on the near side.

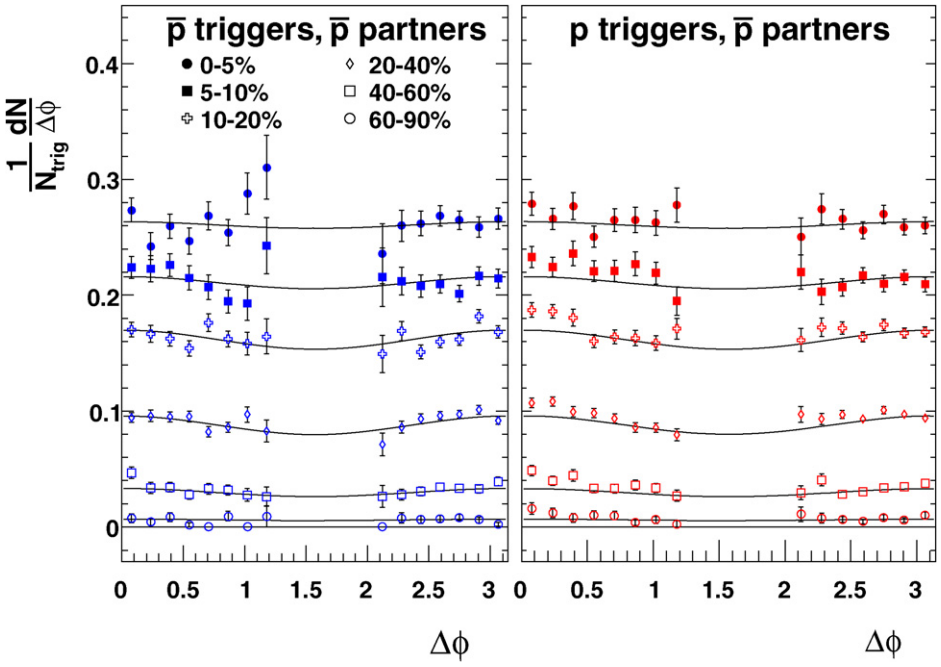

Fig. 3. $\frac{1}{N_{\text{trig}}}\frac{dN}{d\Delta\phi}$ distributions for charge selected $\bar{p}$ (left) and p (right) triggers both with associated $\bar{p}$ for six centrality bins. Triggers have $2.5 < p_T < 4.0$ GeV/c and associated particles have $1.8 < p_T < 2.5$ GeV/c. The solid lines indicate the combinatorial background modulated by elliptic flow. Only the statistical errors are shown.

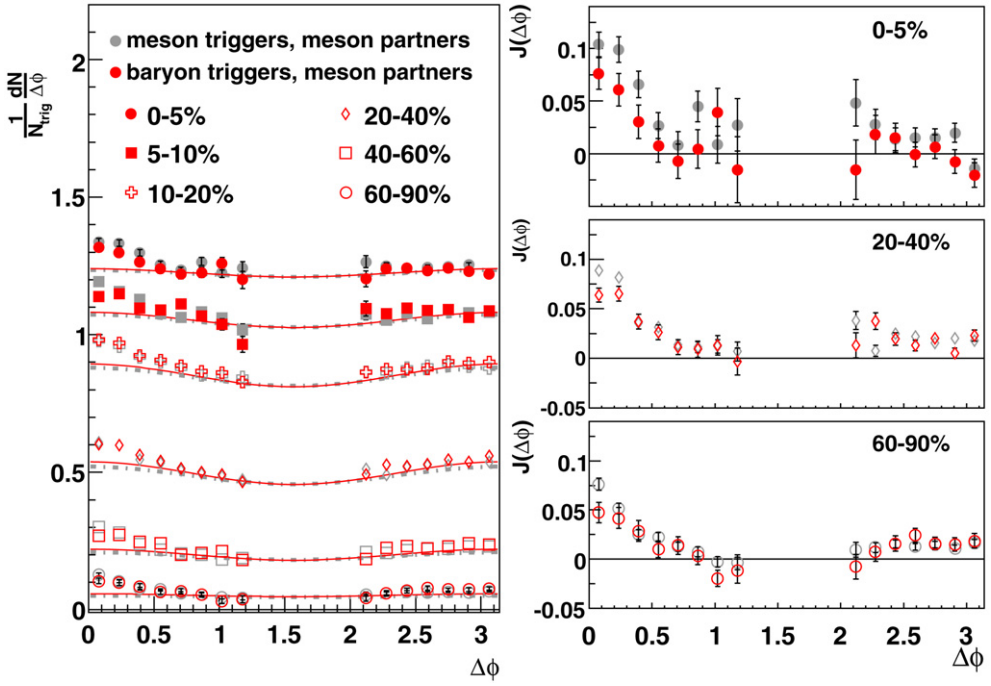

Fig. 4. Left: $\frac{1}{N_{\text{trig}}}\frac{dN}{d\Delta\phi}$ distributions for charge-inclusive baryon and meson triggers and associated mesons for six centrality bins. Triggers have $2.5 < p_T < 4.0$ GeV/c and associated particles have $1.8 < p_T < 2.5$ GeV/c. The solid (dashed) lines indicate the combinatorial background modulated by elliptic flow for baryon (meson) triggers. Right: Jet distributions, $J(\Delta\phi)$, after combinatorial background and elliptic flow subtraction for 0–5% (top), 20–40% (middle) and 60–90% (bottom) centralities. In all panels, only the statistical errors are shown.

To quantify the observed differences in the various trigger-associated particle combinations, we integrate the $J(\Delta\phi)$ distributions in the regions $0.0 < \Delta\phi < 0.94$ rad and $\pi - 0.94 < \Delta\phi < \pi$ rad to obtain the near-side and the away-side conditional yields, respectively. Figs. 5 and 6 show the conditional yield per trigger as a function of the number participating nucleons (N_{part}). The results were obtained from the data in Figs. 2 and 3 (solid points) and Fig. 1 (open points) by integrating the $J(\Delta\phi)$ in the $\Delta\phi$ ranges specified above. This integration range excludes a large part of the away side shape modifica-

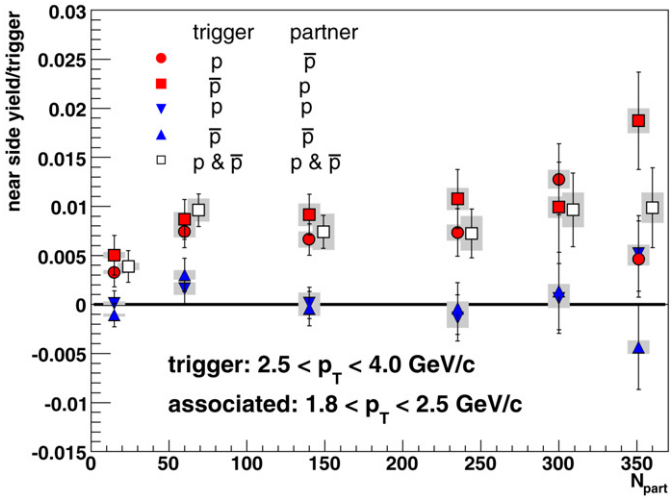

Fig. 5. Conditional yields per trigger on the near side for charge selected (solid points) and charge selected (hollow points) p and $\bar{p}$ correlations. Triggers have $2.5 < p_T < 4.0$ GeV/c and associated particles have $1.8 < p_T < 2.5$ GeV/c. The error bars are the statistical errors and the boxes show the systematic errors. There is an 11.4% additional normalization error on baryon associated particle points and 8.9% each on the p and $\bar{p}$ associated particle points.

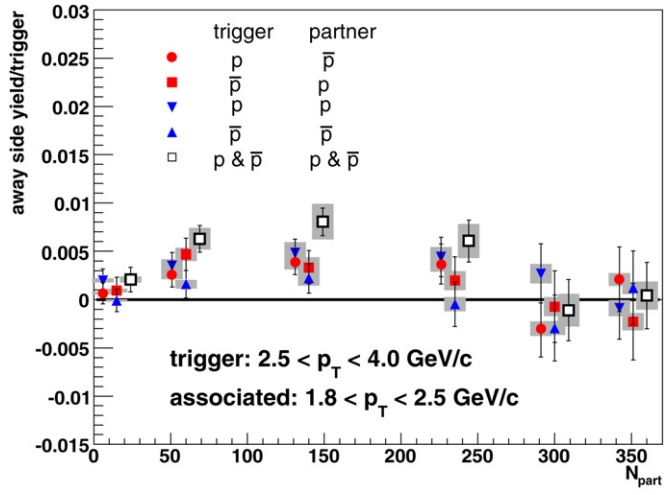

Fig. 6. Conditional yields per trigger on the away side for charge selected (solid points) and charge selected (hollow points) p and $\bar{p}$ correlations. Triggers have $2.5 < p_T < 4.0$ GeV/c and associated particles have $1.8 < p_T < 2.5$ GeV/c. The error bars are the statistical errors and the boxes show the systematic errors. The additional normalization error is the same as in Fig. 5.

tions observed in [18]. The small integration range is used in this analysis only because of the limited acceptance around $\Delta\phi = \pi/2$ due to the requirement to measure the trigger particle in the TOF. These results quantify the centrality and particle type dependence of the jet-like correlations. Fig. 5 shows that the correlations between opposite sign baryon pairs produce a significant non-zero conditional yield that is nearly independent of centrality and that there is no significant yield associated with same sign pairs. The open points in Fig. 5 are from the charge inclusive analysis and show that the conditional yield does come mainly from opposite sign pairs. For all but the most peripheral point, no centrality dependence is observed in the charge inclusive analysis. The most peripheral point sits 2.5σ

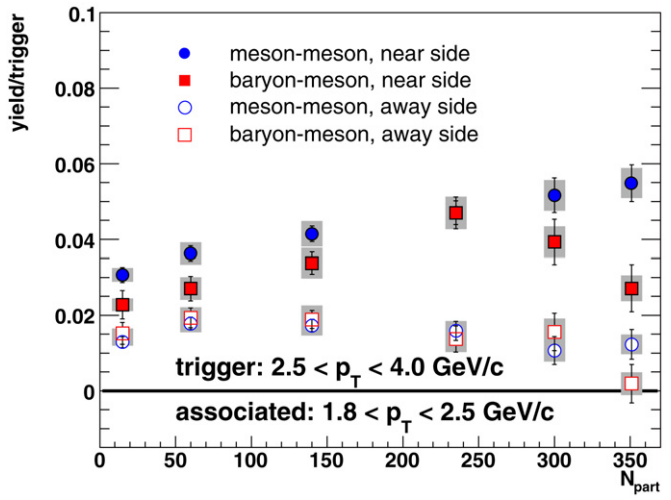

Fig. 7. Conditional yields per trigger for baryon (squares) and meson (circles) triggers with associated mesons. Triggers have $2.5 < p_T < 4.0$ GeV/c and associated particles have $1.8 < p_T < 2.5$ GeV/c. The error bars are the statistical errors and the boxes show the systematic errors. There is an additional 13.6% normalization error.

below the average conditional yield for the other centrality bins. The charge inclusive data are also consistent with a linear increase with N_{part} (χ^2/d.o.f. $= 5.5/4$).

The systematic errors on these distributions are highly correlated since the v_2 values and centrality correlation corrections are the same for all yields at a given centrality. There is an 8.6% systematic error on the relative normalizations of the associated particle p and $\bar{p}$ points, which is not shown. Fig. 6 shows the same correlations as Fig. 5 for the away side region. Here the charge inclusive yields lie above the charge selected yields for peripheral and mid-central collisions because both same and opposite charge pairs have non-zero conditional yield. The conditional yield rises from peripheral to mid-central collisions. In the most central collisions both the charge inclusive and charge selected yields are consistent with zero.

Fig. 7 shows both the near and away side conditional yield for baryon triggers and associated mesons and meson triggers with associated mesons. The meson trigger-associated mesons conditional yield on the near side rises smoothly with centrality. The baryon triggered yields are systematically lower than the meson triggered yields, but also rise linearly with N_{part} for $N_{\text{part}} < 250$. In central collisions the baryon triggered yields are lower than the linear N_{part} dependence observed in the meson–meson points for all N_{part} and the baryon–meson points for $N_{\text{part}} < 250$. The statistical errors on baryon–meson conditional yields exclude a linear increase with N_{part} on the 2.6σ level. The systematic errors on the v_2 values and the centrality correlation correction are correlated with centrality. The most central baryon triggered point is consistent with the most peripheral baryon triggered point. The most central meson–meson conditional yield is $70\% \pm 20\%$ greater than in peripheral collisions. On the away side, no significant dependence on trigger type is observed.

4. Discussion

The observed x_T scaling and pQCD calculations suggest hard scattering is the dominant mechanism for particle production for $p_T > 2$ GeV/c at $\sqrt{s} = 200$ GeV in $p + p$ collisions [7]. Neutral pion production in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV follows x_T scaling [26] and is well described by perturbative theories, which include radiative energy loss by hard partons traversing the medium [27–29] at p_T as low as 2 GeV/c. Models describing the excess of baryons relative to mesons [1] typically do so by some mechanism that extends the p_T range of soft physics. Here, we have used two particle azimuthal correlations to study the particle type dependence of jet-like correlations in Au + Au collisions in the region of the baryon excess. Since jets in $e^+ + e^-$ collisions fragment dominantly into mesons [30], we take meson–meson correlations as a baseline for jet fragmentation in Au + Au collisions. The increase in meson–meson near side conditional yield with centrality seen in Fig. 7 has also been observed in meson–hadron correlations [17] and hadron–hadron correlations [16, 18] and is not yet quantitatively understood. Here we are interested primarily in jet correlations of baryons so meson–meson correlations provide a useful reference. The yield of associated mesons per trigger baryon is systematically lower than the yield of associated mesons per trigger meson, but baryon–meson correlations on the near side increase as meson–meson correlations for all centralities except for the most central.

On the away side there is no significant dependence on the trigger type for associated mesons, as is expected if baryon and meson triggers come from jets of approximately the same energy and if the di-jets fragment independently of the trigger jet. The yield of associated baryons per baryon trigger on the near side is observed to be nearly constant with centrality, except for the most peripheral point, which is significantly lower than the others. The data are also consistent with a linear increase in the conditional yield as a function of $N_{\rm part}$. The small yield of associated baryons per baryon trigger does not imply that baryon number is not conserved within the near side jet since the p_T range of the measured associated particles is narrow, and the PHENIX η acceptance does not contain all of the associated particles.

The data presented here are qualitatively consistent with baryons at $2.5 < p_T < 4.0$ GeV/c arising predominately from hard scattering processes. First, the yield of mesons associated with baryon triggers has the same centrality dependence as associated mesons per meson trigger for $N_{\rm part} < 250$ despite a change in the $\bar{p}/\pi^-$ ratio by a factor of three from peripheral collisions. Since the yields are normalized by the number of observed trigger particles, an increasing fraction of uncorrelated baryon triggers would lead to a dilution of the yield. Second, the away side yield into 0.94 rad is independent of the trigger type, consistent with the away side jet fragmenting independently of the trigger jet. Lastly, the charge dependence of p and $\bar{p}$ correlations show that small angle p–$\bar{p}$ and $\bar{p}$–p pairs are correlated beyond the expected correlations from elliptic flow, and that small angle p–p and $\bar{p}$–$\bar{p}$ pairs are not. This is true in peripheral collisions where the $\bar{p}/\pi^-$ ratio is close to the value from $p + p$ collisions [3] and also in central collisions where the ratio is more than a factor of three larger. The weak centrality dependence of opposite sign pair conditional yields shows the number of correlated pairs increase with centrality at approximately the same rate as the number of triggers. However, quantitative understanding of the baryon production mechanism and the fragmentation process will rely on model calculations that are able to explain the single particle yields, elliptic flow, and correlation results.

The results for near side conditional yields presented here disagree with the recombination model calculation in [31], which predicts a very weak centrality dependence for meson–meson and baryon–meson conditional yields and nearly the same magnitude for baryon–meson and baryon–baryon near side conditional yields. In contrast, the data show the conditional yield of associated mesons with baryon triggers to be a factor of two to five times larger than the conditional yield of baryons associated with baryon triggers, depending on centrality.

The results presented here also appear to exclude baryon production via higher twist mechanisms [32], which would produce isolated p and $\bar{p}$. No correlation calculations are available from the gluon junction model [15], so a comparison beyond the successfully described single particle data could not be done at this point.

We have systematically explored the particle type dependence of jet fragmentation at intermediate p_T in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The new data disagree with calculations from the recombination model presented in [19, 31]. Given the success of recombination models in reproducing elliptic flow and hadron spectra data it would be interesting to see if other recombination calculations are able to describe the data presented here. We find that near side correlations between meson triggers and associated mesons increase with centrality. Near side correlations between baryon triggers and associated mesons show the same centrality dependence except for the most central collisions where there is a significant decrease. The first measurements of baryon pairs on the near side are found to be largely due to opposite charge p–$\bar{p}$ pairs. Under the assumption that the above centrality dependencies of particle pairs and single particles are not coincidental, one can explain the observed baryon excess at intermediate p_T in Au + Au collisions via jet induced production of baryon–antibaryon pairs.

(Received 7 November 2006; published 25 September 2007)

Measurements of neutral pion (π^0) production at midrapidity in $\sqrt{s_{NN}} = 200$ GeV Au+Au collisions as a function of transverse momentum, p_T, collision centrality, and angle with respect to reaction plane are presented. The data represent the final π^0 results from the PHENIX experiment for the first RHIC Au+Au run at design center-of-mass energy. They include additional data obtained using the PHENIX Level-2 trigger with more than a factor of 3 increase in statistics over previously published results for $p_T > 6$ GeV/c. We evaluate the suppression in the yield of high-p_T π^0's relative to pointlike scaling expectations using the nuclear modification factor $R_{\rm AA}$. We present the p_T dependence of $R_{\rm AA}$ for nine bins in collision centrality. We separately integrate $R_{\rm AA}$ over larger p_T bins to show more precisely the centrality dependence of the high-p_T suppression. We then evaluate the dependence of the high-p_T suppression on the emission angle $\Delta\phi$ of the pions with respect to event reaction plane for seven bins in collision centrality. We show that the yields of high-p_T π^0's vary strongly with $\Delta\phi$, consistent with prior measurements [1,2]. We show that this variation persists in the most peripheral bin accessible in this analysis. For the peripheral bins we observe no suppression for neutral pions produced aligned with the reaction plane, whereas the yield of π^0's produced perpendicular to the reaction plane is suppressed by a factor of $\sim$2. We analyze the combined centrality and $\Delta\phi$ dependence of the π^0 suppression in different p_T bins using different possible descriptions of parton energy loss dependence on jet path-length averages to determine whether a single geometric picture can explain the observed suppression pattern.

I. INTRODUCTION

High transverse momentum particles resulting from hard scatterings between incident partons have become one of the most effective tools for probing the properties of the medium created in ultra-relativistic heavy ion collisions at RHIC. Data from the four RHIC experiments have unequivocally established the phenomenon of high transverse momentum hadron suppression in Au+Au compared to (appropriately scaled) $p+p$ collisions [3–9], whereas the lack of similar suppression in d+Au collisions [9–12] provides strong evidence that the suppression is not due to modification of parton distributions in the incident nuclei. This suppression has been observed for a large variety of hadron species, at highest p_T for π^0 and most recently η [13], supporting further the notion that energy loss occurs at the parton level. Conversely, direct photon measurements by the PHENIX collaboration show that the yield of hard photons in Au+Au collisions is consistent with $p+p$ expectations scaled by the number of incoherent nucleon-nucleon collisions [14] and, thus, provide final confirmation that hard scattering processes occur at rates expected from pointlike processes. This observation makes definitive the conclusion that the suppression of high-p_T hadron production in Au+Au collisions is a final-state effect. Measurements of azimuthal angle correlations between hadron pairs resulting from fragmentation of hard-scattered partons into jets have provided additional confirmation of final-state medium effects on these partons [15].

Predictions of high-p_T suppression were made before the start of RHIC operation [16,17] and confirmation of these predictions may be considered one of the key successes of the RHIC program so far. The suppression of high-p_T single hadrons was predicted to result from the energy loss of hard-scattered quarks and gluons in the hot and dense quantum chromodynamics (QCD) medium created in ultrarelativistic heavy-ion collisions (see Refs. [18,19] and references therein). In the canonical models, medium-induced gluon bremsstrahlung is expected to dominate the energy loss process [16], and calculations of the high-p_T suppression factor incorporating this effect have been able to successfully describe the experimental measurements [20–22]; however, recent measurements of heavy quark suppression pose some questions to this canonical view. Nonetheless, from comparisons of the energy loss calculations with the experimental data, estimates of the initial net color charge density that is usually expressed in terms of a gluon rapidity density, dN_g/dy, have been obtained yielding $dN_g/dy \approx 1000$ and, assuming thermalization, estimates of the initial energy density have produced values in excess of $10\,\mathrm{GeV/fm}^3$ [23,24].

However, in spite of this success, there are still a number of outstanding issues with the interpretation of the Au+Au high-p_T single-hadron suppression. Because the properties of the medium created in heavy-ion collisions are not *a priori* known, the energy-loss calculations necessarily use the observed suppression to infer initial parton densities, usually through an intermediate parameter that appears in the energy loss calculations. Although the initial parton density obtained by such "tomographic" studies has to be consistent with the final (measured) total particle multiplicity, it is fair to acknowledge that the p_T dependence of the suppression (rather than its absolute magnitude) is a more discriminating observable to test the various energy loss models. For π^0 spectra, the suppression in central Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV is found to be approximately constant with p_T over the range, $3 < p_T < 10$ GeV/c. Although the different energy loss calculations can reproduce this p_T-independent suppression, the detailed explanation of the constancy is different in each model. The effects invoked to explain the p_T dependence of the observed Au+Au high-p_T suppression include finite-energy effects, absorption of energy from the medium, evolution from incoherent (Bethe-Heitler) to coherent (Landau-Pomeranchuk-Migdal or LPM) radiation with increasing parton energy [25], the p_T-dependent mixture of quark and gluon contributions to the hard-scattered parton spectrum, the increasingly larger exponent of the underlying (power-law) parton p_T spectra [22], and shadowing/EMC effect [26]. Although most calculations of the high-p_T suppression in Au+Au collisions account for shadowing/EMC modifications of the nuclear parton distributions and for the relative mixture of quarks and gluons in the hard-scattered parton spectra, finite-energy corrections, absorption of energy from the medium, and the description of the energy loss process itself differs from calculation to calculation. Clearly the central Au+Au single-particle spectra are not sufficient, by themselves, to validate or exclude any of the different energy loss models; we must use more "differential" probes of medium-induced energy loss to better understand the phenomenon.

A robust prediction of non-Abelian parton energy loss calculations is that the average energy loss as a function of the in-medium path length L shows a quadratic dependence $\propto L^2$ [27]. Such a behavior predicted for a *static* QCD medium turns into an effective $\propto L$ dependence in an expanding quark-gluon plasma (QGP) [28]. In principle, the centrality dependence of the high-p_T suppression [5,6,8] provides an effective test of energy-loss calculations because the length of the path of the partons in the medium will change between peripheral and central collisions. However, the energy loss calculations also have to account for changes in the initial properties of the medium with centrality and the extra flexibility in the description of the initial conditions means that the measured centrality dependence of the high-p_T suppression also does not stringently constrain energy loss models [29]. However, the path length of the parton in the medium can also be controlled by selecting high-p_T hadrons in different bins of azimuthal angle difference from the event-by-event determined reaction plane. Indeed, shortly after experimental observations of azimuthal anisotropy were reported [1,15], arguments were made that the high-p_T anisotropy in noncentral collisions was due to the spatial asymmetry of the medium and the resulting $\Delta\phi$ dependence of parton path lengths [30,31]. However, recent analyses have argued that the large azimuthal anisotropies at high p_T cannot be accounted for by energy loss alone—at least when realistic nuclear geometry is used to

*Deceased.
†PHENIX Spokesperson: zajc@nevis.columbia.edu

describe the spatial asymmetry of the initial state [29,32,33]. Some of these analyses were based on a picture of the energy loss process in which quarks or gluons that have emitted radiation effectively disappear from the steeply falling high-p_T spectrum because they are overwhelmed by partons of lower energy that escape from the medium losing little or no energy. In this picture, the medium effectively attenuates the high-p_T quarks and gluons and the high-p_T spectrum is dominated by partons originating near the surface—i.e., partons originating in the "corona" [29,32,33]. Then, the azimuthal anisotropy could be largely determined by the shape of the surface [32]. However, it has been separately argued that fluctuations in the number of emitted gluons may be large and such fluctuations may weaken the corona effect [28].

In this article we present measurements of π^0 production in $\sqrt{s_{NN}} = 200$ GeV Au+Au collisions from the PHENIX experiment at RHIC. These data, obtained during Run-2 operation of RHIC in 2002, include additional data obtained with the PHENIX Level-2 trigger, which improved the total statistics by a factor of $\sim$3 compared to the prior analysis in Ref. [6]. The analyses presented here have also benefited from advanced electromagnetic calorimeter calibrations and from improved understanding of the systematic errors in the π^0 measurement in course of the direct photon analysis presented in Ref. [14], where the π^0 decay photons provide the main source of background. With the improved statistics, the p_T reach of the data is extended to higher p_T, allowing us to test whether the suppression starts to diminish above 10 GeV/c in p_T. In addition, we extend the measurement of the centrality dependence of the suppression up to 8 GeV/c.

We present measurements of the dependence of the π^0 yield as a function of the angle $\Delta\phi$ of the π^0 with respect to the event reaction plane. By measuring the high-p_T hadron suppression as a function of $\Delta\phi$, for a given centrality bin, we can keep the properties of the medium fixed and vary only the average geometry of the jet propagation in the medium. By comparing different centrality bins we can, in principle, test how the initial properties of the medium affect the induced energy loss. Traditionally, measurements of the $\Delta\phi$ dependence of hadron yields have been analyzed in terms of the azimuthal asymmetry parameter, v_2, and we note that the data presented here were used to obtain measurements of π^0 v_2 for comparison to inclusive photon v_2 [34]. However, in this publication we focus not on v_2, but explicitly on the suppression as a function of $\Delta\phi$, expressed in terms of the $\Delta\phi$-dependent nuclear modification factor $R_{\rm AA}(\Delta\phi)$. Although the data presented this way contain, in principle, the same information as the combination of $\Delta\phi$-averaged $R_{\rm AA}$ and v_2, $R_{\rm AA}(\Delta\phi)$ provides a useful alternative way to evaluate the dependence of high-p_T suppression on geometry because it effectively combines $R_{\rm AA}(p_T)$ and v_2 into a single set of data. We analyze the combined $\Delta\phi$ and centrality dependence of the high-p_T suppression in the context of different path-length and density dependencies of the parton energy loss process to evaluate whether any geometric picture can simultaneously describe the centrality and $\Delta\phi$ dependence of the observed high p_T deficit.

II. EXPERIMENTAL DETAILS

The data presented in this article were obtained during Run-2 operation of the PHENIX experiment [35] at the Relativistic Heavy Ion Collider facility at Brookhaven National Laboratory [36]. The primary detectors used to obtain the presented results were the PHENIX central arm spectrometers, particularly the electromagnetic calorimeters [37], and the two beam-beam counters (BBC's) [38]. In addition, the PHENIX zero-degree calorimeters [39] were used for triggering and centrality determination.

Two-photon decays of neutral pions were measured in the PHENIX electromagnetic calorimeter, located at a radial distance of $\sim$5.1 m from the beam-line, which has a pseudo-rapidity acceptance of $-0.35 < \eta < 0.35$ and covers π radians in azimuth. The electromagnetic calorimeter is divided into eight sectors, with each sector covering the full pseudo-rapidity range and $\pi/8$ in azimuth. The calorimeter consists of two distinct parts using different technologies. A lead-scintillator sandwich calorimeter (PbSc) with 5 cm $\times$ 5 cm towers covers 3/4 (6 sectors) of the central arm acceptance. A lead-glass Čerenkov calorimeter (PbGl) with 4 cm $\times$ 4 cm towers covers the remaining 1/4 (2 sectors) of the central arm acceptance. The corresponding $\Delta\eta \times \Delta\phi$ acceptance of a single tower at $\eta = 0$ is 0.011^2 and 0.0075^2 for the PbSc and PbGl calorimeters, respectively.

The event reaction plane in Au+Au collisions was measured in the two BBC's. Each BBC consists of 64 hexagonal, quartz Čerenkov radiators closely packed around the beam pipe, in an approximately azimuthally symmetric configuration. The beam-beam counters, located 144 cm in each direction from the nominal center of the interaction diamond, are used to count charged particles produced in the pseudorapidity range $3.0 < |\eta| < 3.9$. The distribution of particles over the individual channels of the BBC's allows measurement of the azimuthal distribution, $dN_{\rm ch}/d\phi$, of charged particles within this pseudorapidity acceptance. The BBC's also provide measurement of the collision vertex position along the interaction diamond with a resolution of 0.6 cm [38].

The data presented here were obtained using the PHENIX minimum-bias Level-1 trigger, based on the BBC's and the PHENIX zero-degree calorimeters, that selects $92.2^{+2.5}_{-3.0}\%$ of the total Au+Au hadronic interaction cross section of 6.9 b [6]. For a subset of the data, events selected by the Level-1 trigger were subjected to software Level-2 trigger filtering after full assembly of events in the PHENIX event builder [40]. A software algorithm performed a crude reconstruction of electromagnetic clusters by summing the pedestal-subtracted and gain-calibrated energies of "tiles" made of adjacent 4 $\times$ 4 calorimeter towers groups. The tiles are allowed to overlap such that every possible such tile that can be constructed in each calorimeter is tested. One of the Level-2 triggers (LVL2A) selected events in which at least one cluster (tile) had energy >3.5 GeV. Another Level-2 trigger (LVL2B) selected events in the 50–92% centrality range (50% most peripheral events) with at least one cluster having energy >1.5 GeV.

The measurements presented in this article were obtained from 31.4 M minimum bias triggers and approximately

1.7 M Level-2 trigger selected events. Of the Level-2 triggered events, 743 K events were selected by the higher energy LVL2A trigger and the remainder were selected by the peripheral, lower-energy LVL2B trigger. Taking into account their rejection factors, the two triggers sampled the equivalent of 44.4×10^6 LVL2A and 28.7×10^6 LVL2B minimum-bias triggers. The difference is due to different online trigger pre-scale factors. Thus, the combined event sample contains approximately a factor of 2.5–3 (considering both triggers over all centralities) more π^0's above 6 GeV/c than previously published Run-2 π^0 measurements [6].

III. DATA ANALYSIS

A. Event selection and centrality

In the offline analysis, the timing difference measured between the two PHENIX BBC's is used to determine the position of the collision vertex along the beam axis and to select events with vertex position within 30 cm of the nominal center of the detector for subsequent analysis. The energies measured in the zero-degree calorimeters and the charged-particle multiplicity measured in the BBC's are used to determine the collision centrality [41]. For the π^0 spectrum measurements presented here the total measured centrality range (0–92.2%) is subdivided into nine bins: 0–10, 10–20, 20–30, 30–40, 40–50, 60–70, 70–80, 80–92.2%. For the reaction plane-dependent analysis, the most central and two most peripheral bins are excluded, the peripheral due to their large uncertainty in the reaction plane resolution, and the 0–10% bin simply because of its smaller intrinsic eccentricity. Additionally, we present also combined 0–20%, 20–60%, and 60–92% data sets for comparison with other PHENIX analyses of high p_T hadron production that use such centralities.

B. Reaction plane measurement

PHENIX has previously published measurements of elliptic flow using an event-by-event measured reaction plane [34,42,43], and the same technique is used for the analysis presented here. Each BBC detector consists of 128 quartz radiators placed in hexagonal, roughly concentric rings whose light is individually collected by photomultiplier tubes (PMT's). The calibrated charge from each radiator is converted into an estimate for the number of charged particles within the acceptance of each detector, N_i, using the measured single-particle peak centroid.

For the reaction plane measurement the measured N_i values are corrected such that the weight of the inner rings that have the fewest radiators covering the full azimuthal angle range is reduced. Then, in terms of the corrected N_i values, N_i^{adj}, the angle of the reaction plane Ψ is obtained from the formula

$$\tan(2\Psi) = \frac{\sum_i N_i^{\mathrm{adj}} \sin(2\phi_i) - \left\langle \sum_i N_i^{\mathrm{adj}} \sin(2\phi_i) \right\rangle}{\sum_i N_i^{\mathrm{adj}} \cos(2\phi_i) - \left\langle \sum_i N_i^{\mathrm{adj}} \cos(2\phi_i) \right\rangle}, \quad (1)$$

where ϕ_i represents the azimuthal angle of the center of a given radiator i. The subtraction of the average centroid position in Eq. (1) removes the bias in the reaction plane measurement resulting from nonzero angle of the colliding beams, nonuniformities in detector acceptance, and other similar effects. The average is taken over many events localized in time with the event in question. A final correction is applied to remove nonuniformities at the 20% level in the Ψ distribution.

TABLE I. Relative systematic uncertainty of the reaction plane resolution for the centrality bins shown in Fig. 1.

Centrality	Syst. error
0–10%	20.3%
10–20%	5.1%
20–30%	3.9%
30–40%	3.8%
40–50%	4.1%
50–60%	4.6%
60–70%	22.5%

Because the above-described procedure can also be applied individually to each BBC, we have a redundant measurement of the reaction plane in the north and in the south, and we exploit this to determine the resolution of the full reaction plane measurement using standard procedures [44]. The resolution of the reaction plane is directly measured from the quantity $\langle \cos 2(\Psi_1 - \Psi_2) \rangle$ where Ψ_1 and Ψ_2 are the reaction plane angles measured in each of the two beam-beam counters individually and the average is taken over events. Figure 1 and Table I show the variation of the resolution, usually determined as $\langle \cos 2(\Psi_{\mathrm{meas}} - \Psi_{\mathrm{true}}) \rangle = \sqrt{(2\langle \cos 2(\Psi_1 - \Psi_2) \rangle}$. The needed correction factors can be derived from this using Eq. (11) in Sec. III F, where the reaction plane corrections are described in more detail.

The systematic errors associated with the measurement of the reaction plane come dominantly from how well the resolution is known. The uncertainty on this quantity is also shown with Fig. 1 for all but the most peripheral centralities. This error is determined by observing comparison of the

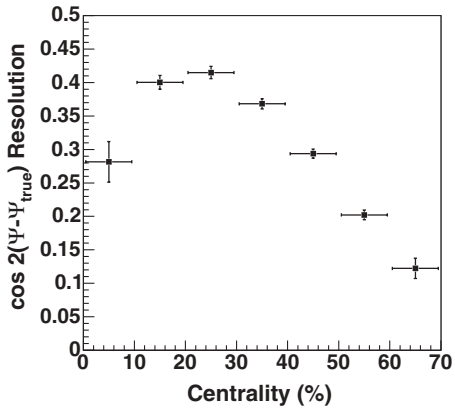

FIG. 1. Resolution of the reaction plane determined in the BBC versus centrality. As usual, the resolution is defined as the unitless quantity $\langle \cos 2(\Psi_{\mathrm{meas}} - \Psi_{\mathrm{true}}) \rangle$, equal to the inverse of the v_2 correction factor.

similarly calculated quantity $\langle \sin 2(\Psi_1 - \Psi_2)\rangle$ which should by definition be equal to zero. The value of $\langle \sin 2(\Psi_1 - \Psi_2)\rangle$ is found to be consistent with 0 for all centralities. The mean size of its fluctuations around 0 are compared to the size of the $\langle \cos 2(\Psi_1 - \Psi_2)\rangle$ to derive the systematic errors in the table. Because the value of $\langle \cos 2(\Psi_1 - \Psi_2)\rangle$ decreases dramatically in the lower multiplicity peripheral events, the relative size of the error increases. The size of this relative error is also cross checked by comparing it to the relative error on elliptic flow (v_2) measurements which is directly comparable since, as discussed in Sec. III F, the resolution correction for v_2 is a plain multiplicative factor. For the cross check, the v_2 error is derived by taking the difference of v_2 made with reaction planes from the BBC North and BBC South separately.

Because of the large rapidity gap between the PHENIX BBC's and the PHENIX Central Arm ($\Delta\eta > 2.7 - 4.0$), the measurements made in the BBC's are assumed to have no correlations (except collision geometry) with processes detected in the central arm that would affect the results presented in Sec. III F. Specifically, PYTHIA studies [45] indicate that any large rapidity-gap production correlated with jets (and thus the hard π^0's we study) detected in the central arm have a negligible effect on reaction plane determination even for the most peripheral events considered in this article. Further, we average both the North and South BBC, which are separated by $\Delta\eta > 6.0$, making potential effects of this nature especially unlikely.

C. Neutral pion detection

The detection of neutral pions is one of the major sources of information on identified particle production at high p_T at RHIC, and PHENIX has already published the results of a number of π^0 measurements in different colliding systems [3,6,10,46,47]. Here we will describe the technique for obtaining π^0 yields as a function of p_T and centrality, which is now well established within PHENIX.

Neutral pions are detected via their $\pi^0 \to \gamma + \gamma$ decay channel. Due to the relatively short mean lifetime of neutral pions of about 10^{-16} s, typical of electromagnetic decays, the pions decay close to the interaction point ($c\tau \approx 25$ nm). This makes the decay vertex well known and the pions can be reconstructed via an invariant mass analysis of photon pairs measured by the EMCal.

In the EMCal, hits or clusters are reconstructed by finding contiguous calorimeter towers with pulse heights above the ADC pedestal value. In order to obtain a cleaner sample of electromagnetic hits shower shape cuts are applied to select candidate photons and time-of-flight cuts are applied to reject slow hadrons. For the PbSc we require measured cluster times to be $t_{\rm clust} < L/c \pm 1.2$ ns, where L is the straight-line path from the collision vertex to the reconstructed cluster centroid. For the PbGl we require reconstructed clusters to have times, $t_{\rm clust} < L/c \pm 2$ ns; the difference is due to the intrinsic timing resolutions of the two calorimeter technologies.

The energy of each EMCal cluster is corrected for angular dependence and nonlinearity based on test beam results and simulation. The linearity corrections for both detector types are different with the PbGl showing a stronger dependence on the energy. The correction factors for a photon with a detected energy of 1 GeV (10 GeV) are 1 (0.95) for the PbSc and 1.05 (0.975) for the PbGl, respectively. The PbGl calorimeter also shows a stronger variation of the measured photon energy with the angle of incidence on the detector surface, at 20° the measured energy is reduced by 5% compared to perpendicular incidence (0°), whereas in the PbSc the effect is only of the order of 2%.

In a typical Au+Au central event the EMCal detects $\gtrsim$300 clusters corresponding to an occupancy of $\sim$10% and therefore a non-negligible probability of cluster overlaps. To minimize the effects of cluster overlaps in high multiplicity events, the energy of each cluster in the PbSc calorimeter is determined not only from the sum of all contiguous towers with deposited energy above a given threshold (15 MeV was our default value) but also, alternatively, "extrapolating" the measured "core energy" of the four to five central towers assuming a standard electromagnetic shower profile in an event with zero background. For this latter case, the *ecore* energy was computed from the experimentally measured center of gravity, central shower energy, and impact angle in the calorimeter using a parameterized shower profile function obtained from electromagnetic showers measured in the beam tests. Such an *ecore* energy represented an estimate of the true energy of a photon impinging on the PbSc unbiased by background contributions from other particles produced in the same event and depositing energy in the neighborhood of a given cluster. The use of *ecore* instead of the total cluster energy for photon reconstruction, helped to reduce considerably the effects of cluster overlaps in central Au+Au collisions.

For a photon pair originating from a π^0 decay the invariant mass

$$m_{\gamma\gamma} = \sqrt{\left(P_{\gamma_1} + P_{\gamma_2}\right)^2} = \sqrt{2E_1 \cdot E_2 \cdot (1 - \cos\theta_{12})} \qquad (2)$$

is identical to the π^0 rest mass. However, due to the finite energy and position resolution in the detection of the photon pair, the actual reconstructed value is smeared around a mean value, which can deviate from the nominal value. The reconstructed peak position is also influenced by the high multiplicity in a heavy-ion collision, where overlapping clusters can shift the measured energy of each photon.

With the invariant mass analysis, π^0's cannot be identified uniquely because all possible photon-photon combinations have to be considered. This leads to a large combinatorial background, which increases quadratically with the multiplicity. The π^0 yield is instead determined on a statistical basis, with the background contribution established via a *mixed event* technique as described below.

One possibility to reduce the combinatorial background is to make use of the phase-space distribution of the photons in a π^0 decay. For the $\pi^0 \to \gamma + \gamma$ decay, the two photons have minimum opening angle

$$\tan\theta_{12}/2 = \frac{m}{p}, \qquad (3)$$

where m is the π^0 mass and p its momentum, with $p \simeq p_T$ in the PHENIX central spectrometer. The angular distribution of

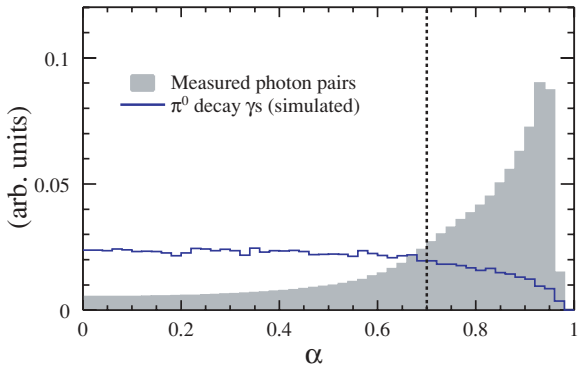

FIG. 2. (Color online) Asymmetry of photon pairs with $3\,\mathrm{GeV}/c \leqslant p_T < 5\,\mathrm{GeV}/c$ within the acceptance of one PbGl sector, for simulated single π^0s and measured within minimum bias events. An asymmetry cut used during the analysis is also shown. (Due to the limited acceptance of the detector, the distribution of the energy asymmetry shows a slight decrease toward $\alpha = 1$.)

the γ pair in the π^0 rest frame, $d\sigma/d\cos\theta^*$, is constant, which leads to a flat distribution in the measured energy asymmetry of the two photons from π^0 decay:

$$\alpha = \frac{|E_1 - E_2|}{E_1 + E_2} = \beta|\cos\theta^*|, \tag{4}$$

where $\beta = p/E \sim 1$ is the velocity of the π^0. However, high p_T combinatorial pairs are strongly peaked near $\alpha = 1$ because of the steeply falling spectrum of single photon candidates. This is illustrated in Fig. 2, where the asymmetry distribution for photons from π^0s in a simulation is compared to the measured asymmetry for photon candidate pairs in real Au+Au collisions. In two independent analyses, asymmetry cuts of $\alpha < 0.7$ and $\alpha < 0.8$ were employed, other values were used as a cross-check and to verify the energy scale (see below).

Pairs of candidate photon clusters within the PbGl and the PbSc calorimeter that satisfy the asymmetry cut are considered candidate π^0's. Figure 3 shows example invariant mass distributions for π^0 candidates with $3.0 < p_T < 3.5$ GeV/c in Au+Au collisions for two different bins of collision centrality. The background under the clear π^0 mass peak in these figures is due to combinatorial mixing of photons from two different decaying π^0's or from pairs containing one or two nonphoton clusters that nonetheless pass the above-described cuts.

Such a combinatorial background can be determined by a so-called *mixed event* technique. It is a widely used method to determine the combinatorial background of combined particle properties, e.g., the invariant mass of a photon pair. The basic idea is to compare the result obtained by combining particles within one event to the result for particle combinations from different events, which are *a priori* not correlated.

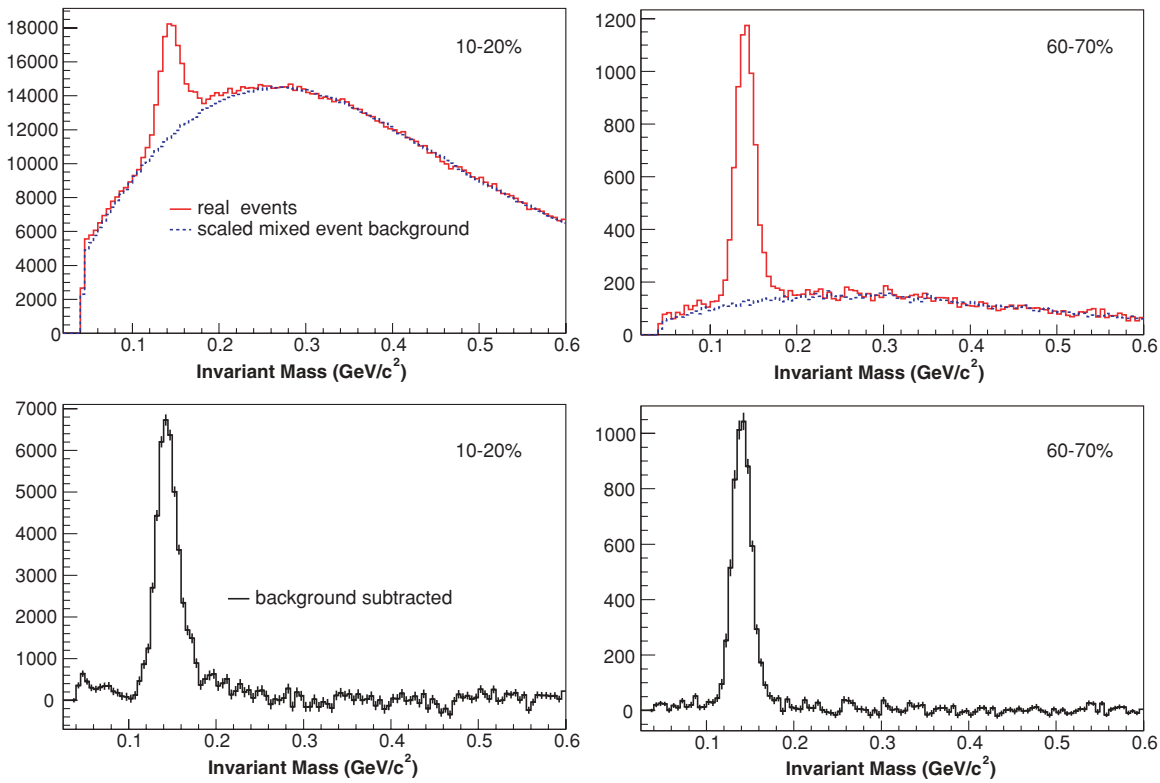

FIG. 3. (Color online) Invariant mass distributions of pairs of electromagnetic clusters passing photon selection cuts for pair transverse momenta satisfying $3.0 < p_T < 3.5$ GeV/c. (Top panels) $m_{\gamma\gamma}$ distributions in Au+Au events compared to a normalized mixed-event sample representing the combinatoric background. (Bottom panels) The $m_{\gamma\gamma}$ distributions after subtraction of the combinatoric background. (Left) 10–20% centrality bin; (right) 60–70% centrality bin.

In the case of the π^0 invariant mass, the mixed event distribution is determined by combining one photon candidate from the current event with all photon candidates from previous events stored in a buffer. The number of previous events used for the pair combinations determines the statistical error of the background, which can be made small by increasing the buffer size. In this analysis, the buffer is varied from ~3 to 10 previous events depending on centrality due to the centrality-dependent multiplicity.

To describe the combinatorial background correctly it is essential that the events used for mixing have similar properties as the real event. Different event classes for collision vertex, centrality, and reaction plane are employed. Also events are chosen for mixing so that they are not biased toward a certain reaction. This is because triggered samples, even from the high-p_T photon trigger, contain biases, e.g., in momenta and centrality distributions, which do not accurately represent the dominant uncorrelated background. For this reason only minimum bias events are used for mixing with both the trigger and minimum bias data sets.

For the photons used in the event mixing the same criteria are applied as for the pair combinations from one event, such as PID cuts, cuts on bad modules, and the asymmetry cut. Other properties valid *a priori* for the real photon pairs, e.g., a minimum distance that allows to distinguish them, have to be considered in addition. In the analysis a minimum distance cut of a least 8 cm is required for each photon pair combination, within one event and for mixed events, respectively.

For a given p_T bin the mixed-event background is normalized to the same-event invariant mass distribution outside the range of the π^0 peak by scaling the mixed-event background with a function $f(m_{\text{inv}})$. This scaling function is determined by fitting the ratio of the same-event and mixed-event invariant mass distribution for p_T bins up to 3 GeV/c with a linear function. This is needed because at low p_T correlations in the real-event background due to overlapping clusters cannot be reproduced by the mixed-event technique. For the p_T bins above 3 GeV/c, a constant is used. To cross-check the result, the linear and the constant scaling function are also determined over the complete invariant mass region, including the π^0 peak, which is taken into account by an additional Gaussian in the fit function (e.g., a linear plus a Gaussian function).

The determination of the scaling function for large pair-p_T is limited by statistics in the real event sample and does not lead to stable results. Instead a constant scaling factor is used if the ratio of the invariant mass distribution shows bins with zero entries in the fit region. The scaling factor is determined by integrating the real and the mixed invariant mass distributions in the range with the peak region excluded.

The scaled mixed-event background is subtracted from the same-event distribution to produce a statistical measure of the true π^0 yield. The result of such a subtraction procedure is shown in the bottom plots of Fig. 3. The raw π^0 yield is obtained in each p_T bin by integrating the subtracted invariant mass distribution in a range around the peak mean (m_{π^0}) of ± 3 times the Gaussian width (σ_{π^0}) of the π^0 peak. Values of the mean and σ_{π^0}, can be seen in Fig. 4. Varying the size

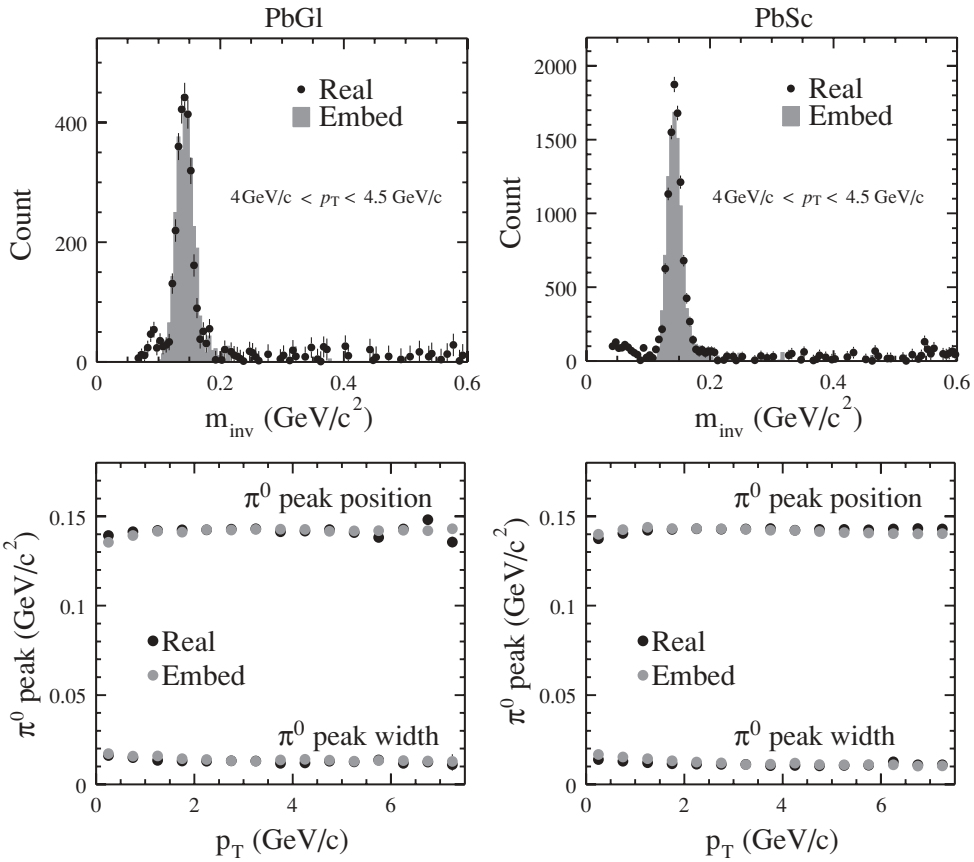

FIG. 4. Comparison of the π^0 peak position in real events (MB) measured with the PbGl and the PbSc with the results obtained for embedded π^0s. The p_T dependence of the peak position and width is due to calorimeter energy resolution as discussed in the text.

of the integration window results in slightly different results, which contributes to the overall systematic uncertainty of the measurement, discussed in Sec. III D4.

Residual differences between the mixed background and the foreground are still apparent in some p_T bins, especially below $\sim$2 GeV/c. Cluster merging, cluster splitting (fluctuations in the two-dimensional $\phi - z$ energy profile cause multiple local maxima that are incorrectly separated into distinct clusters), antineutron annihilation, and even second-order residual physics correlations such as three and multibody decays, flow, HBT, etc., can all cause such differences. These remaining differences are compensated by the shape of the scaling function. In addition, as a systematic check, the shape of the remaining background after subtraction is also fit with various low order polynomial functions and potential contributions to the peak yield are considered in the determination of the total systematic error from the peak extraction procedure.

The values of the peak width and mean are extracted in one initial analysis of the invariant mass distribution in which a p_T-dependent parameterization is determined for different centralities. The use of predefined values for the position and spread of the π^0 peak has the advantage that even in p_T regions where no fit to the subtracted invariant mass distribution is possible, the integration region is well defined just by extrapolation from low p_T.

D. π^0 spectrum measurement

For the reaction-plane independent π^0 spectrum measurement in a given centrality class *cent*, the aforementioned analysis is applied in $\Delta p_T = 0.5$ GeV/c bins for $p_T >$ 1 GeV/c. We cease attempting to extract π^0 yields at high p_T when the number of pairs within the selected (background-subtracted) π^0 mass window falls below 4 counts. We then correct the resulting raw π^0 spectrum for the geometric acceptance $a_{\Delta y}(p_T)$, the overall detection efficiency $\varepsilon_{\rm cent}(p_T)$, which accounts for the cluster cut efficiency, the π^0 mass cut efficiency, for losses due to cluster overlaps in high multiplicity events, for cuts on bad modules and for the calorimeter energy and position resolution. In addition a correction for conversion losses ($c_{\rm conv}$) in the material of the PHENIX central arms and for the branching ratio of the two photon decay ($c_{\gamma\gamma}$) is applied:

$$\frac{1}{2\pi p_T}\frac{d^2N^{\pi^0}_{\rm cent}}{dp_T\,dy} \equiv \frac{1}{2\pi p_T N^{\rm event}_{\rm cent}} \times \frac{1}{a_{\Delta y}(p_T)\varepsilon_{\rm cent}(p_T)c_{\rm conv}c_{\gamma\gamma}} \times \frac{N^{\pi^0}_{\rm cent}(\Delta p_T)}{\Delta p_T \Delta y}. \quad (5)$$

1. Acceptance and detector efficiency

The geometric acceptance of the EMCal for the $\pi^0 \to \gamma\gamma$ decay is evaluated using a Monte Carlo (MC) program that generates π^0s in a rapidity interval Δy with the same vertex distribution and rapidity distribution as observed in real events and contains the complete geometry information of the EMCal. The π^0 decay is calculated via JETSET routines that are part of the PYTHIA event generator [48]. For each π^0 it is verified that both decay photons hit the detector. The resulting p_T distribution of accepted π^0s is divided by the transverse-momentum distribution of the generated π^0s and provides the geometrical acceptance of the PbSc and PbGl, respectively.

The detection efficiency is determined using GEANT to simulate the complete response of the calorimeter to single π^0 decays. The data from each simulated π^0 is then embedded into real Au+Au events by adding the EMCal tower information of the simulated π^0 to the tower information of the real event and recalculating the EMCal clusters. The efficiency for detecting the embedded π^0 is then again determined by comparing the input p_T spectrum to the reconstructed p_T spectrum of the embedded π^0's. Using this technique we determine "efficiency" corrections that account for the energy resolution and position resolution of the calorimeter, as well as for the losses due to overlapping clusters in a real event environment. In addition, the embedding allows for a precise determination of the effect of edge cuts and bad modules. Though these effects can be in principle considered as acceptance corrections, they depend not only on the geometry but also on the energy deposition of an electromagnetic shower in the different calorimeter towers.

In the embedding procedure the effects of photon conversions are also included, as the GEANT simulation considers the material budget in front of the EMCal and the information for decay-photon conversions is retained. The final conversion correction, which is factorized from the rest of the efficiency for book-keeping purposes, is evaluated by comparing the π^0 yield with and without including conversions in the simulation. The final conversion correction, constant with p_T depends on the photon PID cuts and material in front of each individual sector and ranges from 6 to 8% in PbGl and 9 to 10% in PbSc. Comparing this to the sheer probability of a π^0 having at least one photon which converts, 21% PbGl and 14% PbSc, we see that a large portion of these π^0 are still reconstructable.

For the embedding, the input π^0 spectrum is weighted to match a fit function (see below, at the end of Sec. III D3) which is fit to the measured π^0 spectrum so that the correct folding of the π^0 spectrum with the resolution is obtained. This procedure is iterated, with the fit of the p_T dependence of the input weights adjusted as the estimate of the efficiency correction improves, until the procedure converges within the nearly p_T-independent statistical error of the embedded sample, approximately 3%.

Figure 4 compares the invariant-mass peak after background subtraction in the real data and the invariant mass peak of the embedded π^0 for the two different detector types in minimum bias events. The measured π^0 peak position is shifted from the nominal value of approximately 134.98 MeV due to the finite energy resolution of the detector in combination with the steeply falling spectrum and due to the additional effect of overlapping clusters. As illustrated the effects are well reproduced by the embedded π^0's.

2. Trigger efficiency

The efficiency of the Level-2 trigger is separately evaluated by processing recorded minimum-bias events with the Level-2

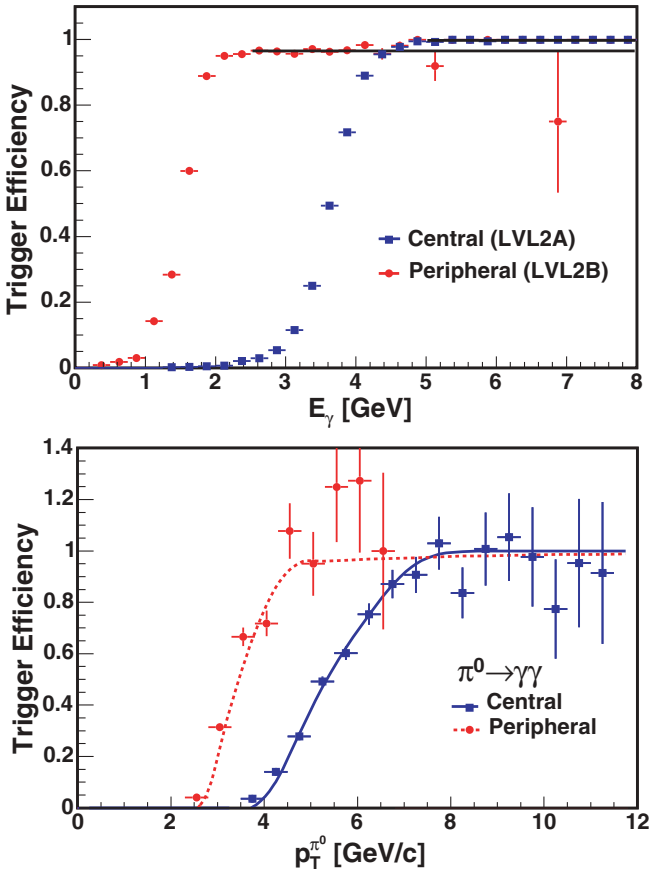

FIG. 5. (Color online) (Upper) Measured efficiency of single clusters of LVL2A (blue) and LVL2B (red) triggers as discussed in the text. The black lines are constant value fits to the plateau efficiency, greater than 99.7 (95%) for LVL2A (LVL2B). (Lower) Efficiency for neutral pion detection of the triggers as a function of π^0 p_T, calculated (solid curves) based on the efficiencies in (upper) and, as a cross-check (data points), compared to ratio of per equivalent minimum-bias event yields in the full trigger sample with the same in the true minimum bias sample. Because the latter is the ratio of two separate data samples, independent statistical fluctuations, as well as ∼8% systematic effects in the yield extraction (discussed Sec. III D4) in either sample can cause this measured ratio to be greater than 100%.

trigger and evaluating the efficiency for the trigger to select events containing a high p_T cluster. This analysis shows complete (100%) efficiency for the LVL2A trigger at momenta well above the trigger threshold of 3.5 GeV/c (95% above 1.5 GeV/c for LVL2B) for obtaining clusters that also pass all offline cluster cuts. This is demonstrated in Fig. 5 (upper). The "plateau" values are determined from fitting the region above the turn-on also shown.

The related trigger efficiency of reconstructed π^0's is calculated from a fast MC simulation based on these measured single cluster efficiencies. The calculation is performed both by using a integrated Gaussian fit to the single cluster efficiency and by directly using the finely binned histogram and constant plateau fit. Both methods give consistent results. The result for the latter method is shown in Fig. 5 (lower), solid curves. The calculation is cross-checked, as demonstrated by the data

TABLE II. Corrections in the PbGl and PbSc to the raw π^0 yield in central collisions (0–10%) and with TOF and shower shape cut applied. The main part of the efficiency loss in PbGl is due to the effect of bad module and edge cuts which is approximately 40% at high p_T for the PbGl and 20% for the PbSc, respectively.

p_T	PbGl		PbSc	
	3.25 GeV/c	8.5 GeV/c	3.25 GeV/c	8.5 GeV/c
$a_{\Delta y}$	0.068	0.080	0.216	0.246
ε	0.351	0.358	0.455	0.515
c_{conv}	0.93	0.93	0.90	0.90
$c_{\gamma\gamma}$	0.98798			

points in Fig. 5 (lower), which show the ratio of the yield from the two Level-2 trigger samples per *equivalent* number of minimum bias events to the same from the true minimum bias sample itself. We combine the yields obtained in the minimum bias event sample and the LVL2A (LVL2B) trigger sample above a cutoff of 6.5 GeV/c (3.5 GeV/c) where the trigger reaches efficiencies greater than 0.4 such that the correction factor is not allowed to be large. A conservative error of 3% is assigned to the efficiency calculations, resulting in a total error of ∼3–5%, based on the three studies: (1) comparisons of the data shown in Fig. 5, (2) comparisons of the two calculational methods, and (3) a study of the yields in the subsample of minimum bias events that also fired the triggers, similar to (1).

3. Other corrections

The calculated corrections are applied to the raw π^0 yield as given by Eq. (5). Table II shows the corrections in central collisions for two different bins in transverse momentum and for the PbGl and PbSc, respectively. As discussed above the effect of the cut on bad modules is included in the efficiency correction, due to its dependence on the depth of the electromagnetic shower.

Following the usual PHENIX procedure of modifying the quoted yield values for each finite sized p_T bin such that the measurement corresponds to p_T value at the bin center instead of the average p_T of the bin [49] (thereby facilitating taking ratios of spectra from different collision systems), a final correction is applied to the *yield* of each data point. Using a continuous function that is fit to the data points, values for the invariant yields at the centers of the chosen p_T bins are scaled by the ratio of the fit value at the fit's average p_T to the fit value at the bin center. This is an iterative procedure similar to the final efficiency correction described in Sec. III D1 above, with a smaller convergence criteria of <0.1% of the previous correction. The fit function is empirically determined and several functional forms were found to give similar performance (e.g., see Fig. 6 below) and negligible differences in the resulting corrections. All the functional forms either explicitly contain or implicitly converge quickly to, a pure power law form (const/p_T^n) above $p_T \sim 4$ GeV/c.

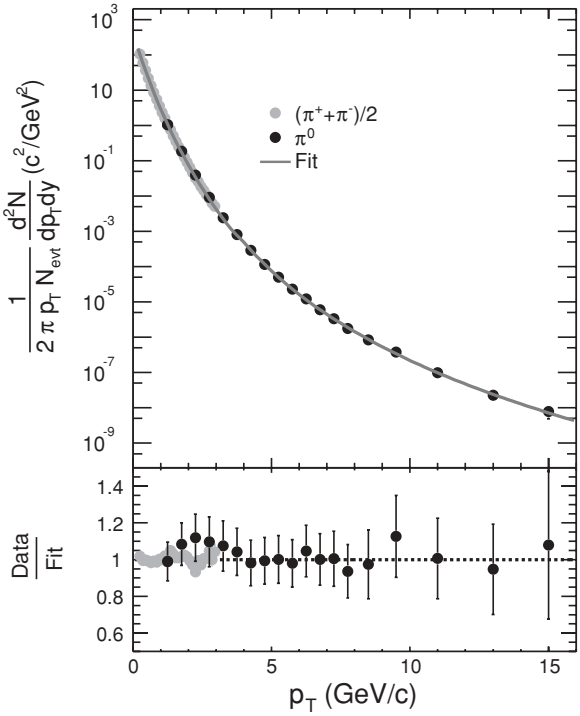

FIG. 6. Comparison of the combined π^0 result to the measurement of charged pions within the PHENIX experiment in minimum bias events. The fit (see previous Sec. III D3) considers the averaged result of the π^+ and π^- measurement [7] below $p_T = 3\,\mathrm{GeV}/c$ and the π^0 data above.

The spectral shape is discussed further under Secs. IV A and IV B.

4. Systematic errors

Each correction of the raw yield following Eq. (5) is afflicted with its own uncertainty, but already the determination of the π^0 raw yield itself is sensitive to the method of extraction. In particular it is sensitive to the choice of the fit function for the background scaling and the extraction window. In principle, both should be taken into account by the detector efficiency, but in the efficiency calculation no background subtraction is necessary. For this reason the systematic error of the peak extraction method is determined in two steps: first via the comparison of the raw yield obtained with two different fits for the background scaling, and second through the comparison of the fully corrected spectra for different sizes of the extraction window, for the real data as well as for the efficiency calculation.

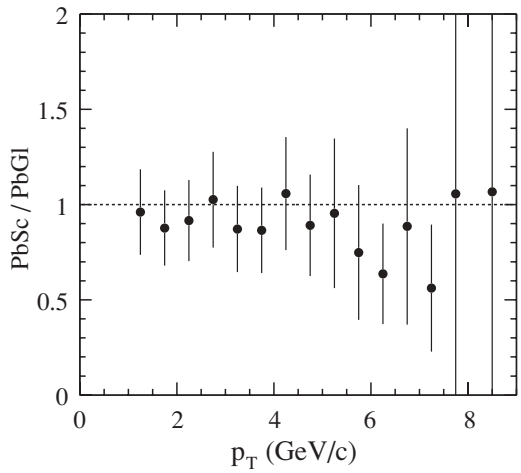

FIG. 7. Comparison of fully corrected spectra for the PbGl and the PbSc for peripheral events. Similar consistency is observed for all centralities. The error bars represent the statistical and systematic uncertainties.

The systematic error introduced by the efficiency calculation is estimated by comparing the fully corrected spectra for different PID criteria as well as for different additional smearing. The smearing (or energy resolution in the simulation) is changed in a way that a clear disagreement between the measured π^0 peak width and the peak width from the embedding is observed.

Apart from the uncertainty of the efficiency, the main contribution to the systematic error is the determination of the absolute energy scale. Based on the comparison of the π^0 peak positions in the data to the expectation from simulation the energy scale can only be determined or confirmed with limited accuracy, $\Delta(E)/E = 1.6\%$ in the PbSc and, because of the smaller acceptance, $\Delta(E)/E = 2\%$ in the PbGl.

The additional contributions to the systematic error that have not been discussed in detail involve the uncertainty of the conversion correction (2.9%) and of the acceptance calculation (2.5%) both due to small uncertainties in detector material and alignment. Table III provides a final overview of the various contributions to the total error of the π^0 measurement in the PbSc and the PbGl, respectively.

The most important cross-check of the final result is the comparison of the result for the two different detector types PbGl and PbSc, which is shown for peripheral events in Fig. 7. A good agreement within the errors is seen and similar consistency is found in all centralities. Because they represent essentially independent measurements, the two

TABLE III. Summary of the dominant sources of systematic errors on the π^0 yields extracted independently with the PbGl and PbSc electromagnetic calorimeters in central events for different p_T. For comparison the statistical uncertainty is also shown.

p_T (GeV/c)	PbGl		PbSc	
	3.25	8.5	3.25	8.5

Statistical	10.6%	50%	8.1%	26.6%

results are averaged and the total error of the combined result is reduced using a standard weighted least-squares method also described in Ref. [50]. An additional cross-check of the final result based on isospin symmetry is provided by the measurement of charged pions in the central arm [7], this is shown for minimum-bias collisions in Fig. 6. The neutral pion measurement smoothly extends the result for charged pions to larger transverse momenta.

E. $R_{AA}(p_T)$ measurement

Using the invariant yields obtained from the above-described analysis and the separately measured invariant cross section for π^0 production in $p+p$ collisions [46], we calculate the nuclear modification factor, R_{AA}, according to

$$R_{AA}(p_T) = \frac{\left(1/N_{AA}^{evt}\right) d^2N_{AA}^{\pi^0}/dp_T\,dy}{\langle T_{AA}\rangle \times d^2\sigma_{pp}^{\pi^0}/dp_T\,dy}, \tag{6}$$

where $\langle T_{AA}\rangle$ is the average Glauber nuclear overlap function for the centrality bin under consideration

$$\langle T_{AA}\rangle \equiv \frac{\int T_{AA}(\mathbf{b})\,d\mathbf{b}}{\int \left(1 - e^{-\sigma_{pp}^{inel} T_{AA}(\mathbf{b})}\right) d\mathbf{b}}, \tag{7}$$

from which the corresponding average number of nucleon-nucleon collisions, $\langle N_{coll}\rangle = \sigma_{pp}^{inel}\langle T_{AA}\rangle$, can be easily obtained [51].

F. $R_{AA}(\Delta\phi)$ measurement

The measurement of the raw π^0 yield with respect to the event reaction plane, $\Delta\phi = \phi(\pi^0) - \Psi$, proceeds as described in Sec. III D for the p_T spectrum except that we measure the yields as a simultaneous function of both p_T and $\Delta\phi$. Because the beam-beam counters have 2π acceptance, PHENIX can measure the π^0 yields with uniform acceptance over $0 < \Delta\phi < 2\pi$ even though the electromagnetic calorimeters have only 1π nominal azimuthal acceptance. Because the measurement of Ψ is ambiguous with respect to a 180° rotation of the reaction plane, and because we expect the π^0 yields to be symmetric with respect to reflection around $\Delta\phi = 0$, we measure the π^0 yields in six bins of $|\Delta\phi|$ over the range $0 < |\Delta\phi| < \pi/2$. For each p_T bin we evaluate the ratio,

$$R(\Delta\phi_i, p_T) = \frac{\Delta N(\Delta\phi_i, p_T)}{\sum_{i=1}^{6} \Delta N(\Delta\phi_i, p_T)}, \tag{8}$$

where $N(\Delta\phi_i, p_T)$ is the measured number of π^0's in a given $(\Delta\phi, p_T)$ bin, $\Delta\phi_i$ representing one orientation of $\Delta\phi$. Because the PHENIX central arm acceptance is effectively constant as a function of $\Delta\phi$ and we do not expect any azimuthal dependence of our π^0 efficiency corrections, $R(\Delta\phi_i, p_T)$ can be written as:

$$R(\Delta\phi_i, p_T) = R_{AA}(\Delta\phi_i, p_T)/R_{AA}(p_T). \tag{9}$$

Using the measured $R_{AA}(p_T)$ values we can directly convert the $R(\Delta\phi, p_T)$ to $R_{AA}(\Delta\phi, p_T)$ without having to apply acceptance and efficiency corrections to the reaction-plane dependent yields. These corrections are already included in the $R_{AA}(p_T)$ values as described above.

However, before applying this procedure we must first correct the $R(\Delta\phi, p_T)$ values for the finite resolution of the reaction plane measurement. One goal of our measurement is to determine $R_{AA}(\Delta\phi, p_T)$ without assuming any particular functional dependence on $\Delta\phi$. For purposes of correcting for reaction plane resolution, we take advantage of the fact that the observed π^0 yields and hence the nuclear modification vary with $\Delta\phi$ to first order as

$$R^{raw}(\Delta\phi, p_T) \approx R_0\left[1 + 2v_2^{raw}\cos(2\Delta\phi)\right], \tag{10}$$

ignoring the much smaller higher-order harmonics such as v_4 terms. The superscript "raw" denotes the values not corrected for the reaction plane resolution. This resolution reduces v_2 by the factor $\sqrt{2\langle\cos 2(\Psi_1 - \Psi_2)\rangle}$ [44], which is given by the independent measurement of Ψ in the two BBC's shown previously in Fig 1. For each p_T bin in a given centrality class we fit the $R(\Delta\phi, p_T)$ values to the functional form in Eq. (10) and then correct each measured $R(\Delta\phi, p_T)$ value according to

$$R^{corr}(\Delta\phi, p_T) = R^{raw}(\Delta\phi, p_T)\left[\frac{1 + v_2^{corr}\cos(2\Delta\phi)}{1 + v_2^{raw}\cos(2\Delta\phi)}\right], \tag{11}$$

with $v_2^{corr} = v_2^{raw}/\sqrt{2\langle\cos 2(\Psi_1 - \Psi_2)\rangle}$. We estimate the systematic error in the reaction plane resolution correction by propagating the centrality dependent uncertainties in $\sqrt{2\langle\cos 2(\Psi_1 - \Psi_2)\rangle} = \langle\cos 2(\Psi_{meas} - \Psi_{true})\rangle$ from Table I. Of course, the above-described correction only strictly applies if $R_{AA}(\Delta\phi)$ is well described by the functional form in Eq. (10). Although we do observe some departure from this harmonic form in the data, the differences are typically below 5% so our correction will not introduce a large error.

IV. RESULTS

A. π^0 transverse-momentum spectra and nuclear modification factors

The π^0 invariant yields obtained using the procedure described in Sec. III D are presented in Fig. 8 as a function of p_T for the nine chosen centrality bins. With the increased statistics included in this analysis, we have extended the p_T range of the previous PHENIX measurement by at least 2 GeV/c for all centrality bins. The p_T range of the central bin has been extended from 10 to 14 GeV/c. Where the spectra overlap, the results shown here are consistent with the previously published results within systematic errors. The errors shown on the points in Fig. 8 include statistical errors and point-to-point varying systematic errors. The appendix tabulates the π^0 spectra plotted in Fig. 8 (centralities: 0–10, 10–20, ... , 70–80, 80–92%) plus the combined spectra for centralities 0–20, 20–60, and 60–92%, which are used for

comparison to other neutral meson measurements [13]. The spectra in Fig. 8 depart from the exponential-like shape above 3 GeV/c, which is consistent with the expectation that high-p_T hadron production is dominated by hard-scattering processes that produce a power-law p_T spectrum [52] for hadrons resulting from quark and gluon fragmentation.

In previous publications, we have established the suppression of high-p_T π^0 production in Au+Au collisions [3,6]. This suppression cannot be easily seen given the large range of invariant yield covered by Fig. 8.

To evaluate the suppression of high-p_T π^0's, we show in Fig. 9 the p_T dependence of the π^0 nuclear modification factor, $R_{\rm AA}(p_T)$, for the nine individual bins of collision centrality and for the full minimum-bias centrality range 0–92.2%. We make use of the PHENIX Run3 $p+p$ baseline π^0 data. [47]. The error bars on the data in Fig. 9 include contributions from statistical errors in the Au+Au and $p+p$ measurements and from the systematic errors that do not cancel between the measurements. The separate band shown in each panel indicates p_T-independent errors on the $R_{\rm AA}$ measurement resulting from uncertainties in estimating $T_{\rm AA}(x, y)$ and systematic errors on the normalization of the Au+Au and $p+p$ measurements that do not cancel. As in previously published articles (e.g., Refs. [4,5,7]), a factor of ∼5 high p_T π^0 suppression in the most central Au+Au collisions, $R_{\rm AA} \approx 0.2$, is observed, with the suppression approximately p_T independent for $p_T > 5$ GeV/c. The suppression at high p_T decreases in more peripheral collisions such that the two most peripheral bins have $R_{\rm AA}$ values consistent with unity for $p_T > 3$ GeV/c.

B. Suppression via spectrum shift

The suppression of high-p_T particles as shown above was determined by comparison of the semi-inclusive measured yields as a function of centrality in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV to the $\langle T_{\rm AA}\rangle$ scaled p_T spectrum from $p+p$ collisions [53]. A direct comparison of the 0–10% centrality Au+Au spectrum to the scaled $p+p$ spectrum is shown in Fig. 10 as a log-log plot to emphasize the pure power law

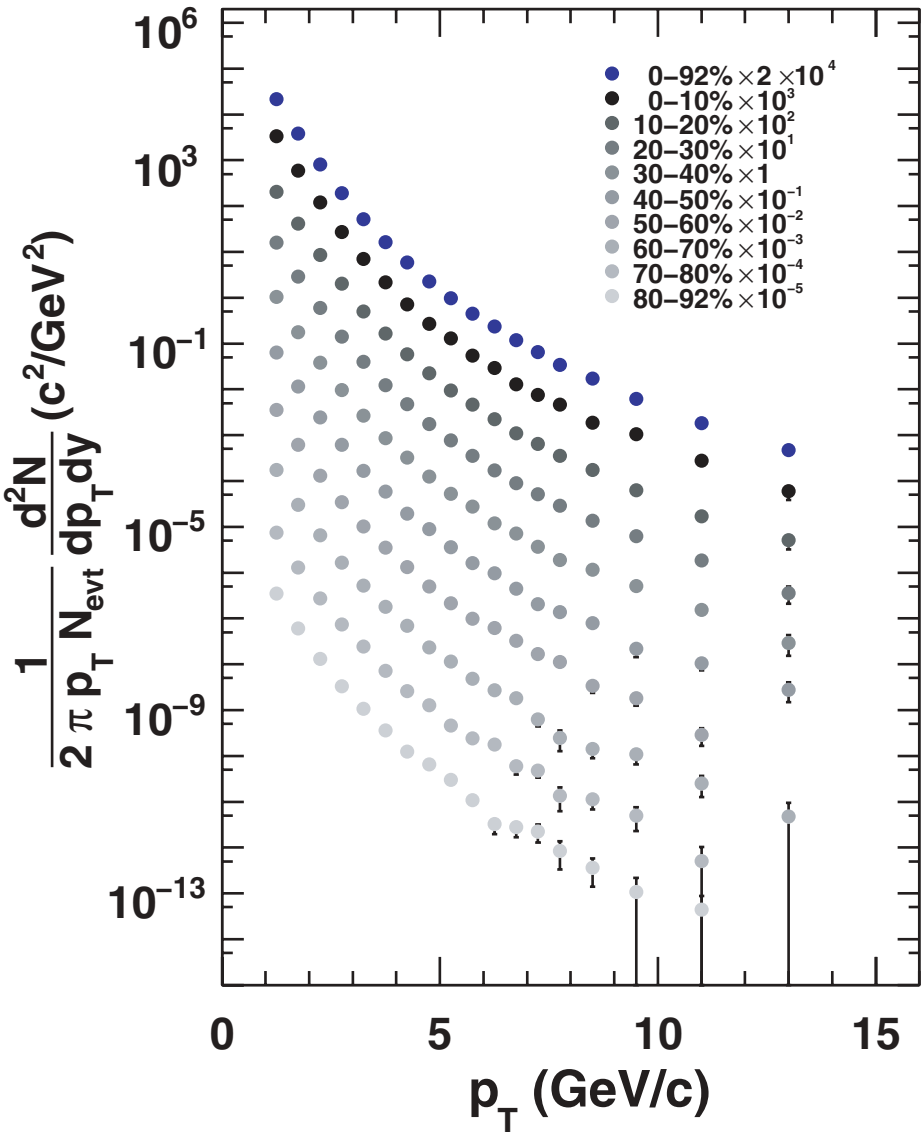

FIG. 8. (Color online) Neutral pion invariant yields as a function of p_T measured in minimum bias and nine centrality classes in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Spectra for different centralities are scaled for clarity. Errors are total errors, full systematic, and statistical added in quadrature.

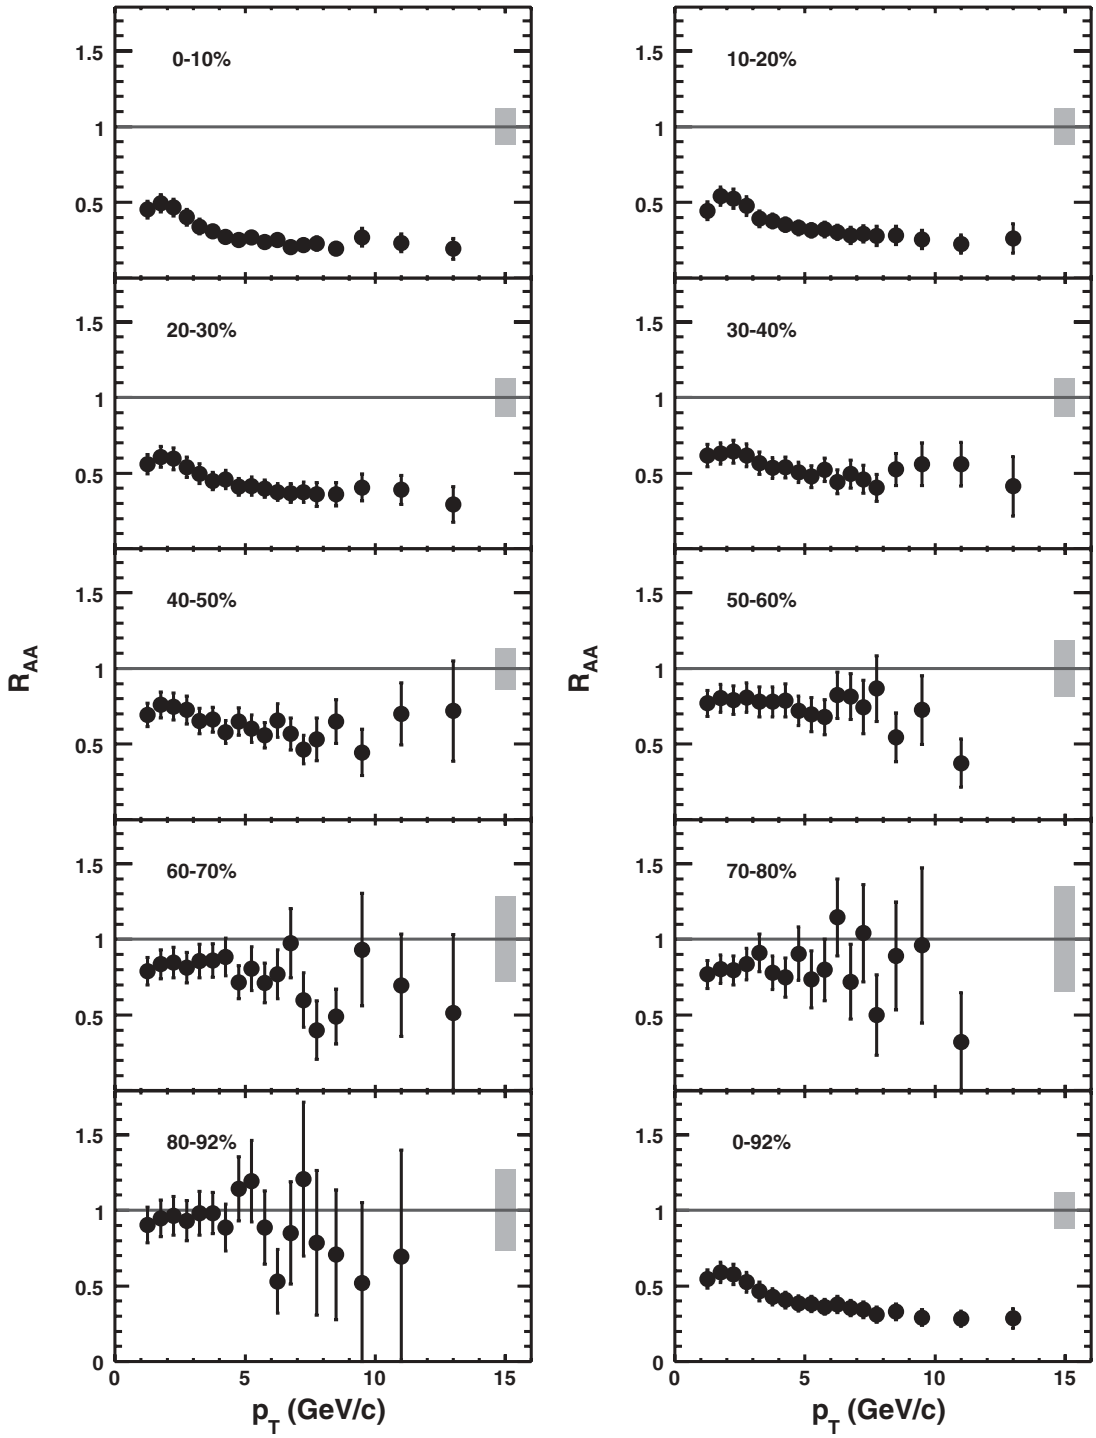

FIG. 9. Nuclear modification factor R_{AA} for neutral pions as a function of p_T for different centralities. The shaded error band around unity indicates the uncertainty in scaling factor T_{AA} and an overall scale uncertainty in the $p+p$ reference.

dependence of the data for $p_T > 3$ GeV/c. The suppression is commonly expressed by taking R_{AA} the ratio of the point-like scaled semi-inclusive yield to the reference distribution [Eq. (6)].

As illustrated in Fig. 10, instead of viewing the suppression in the nuclear modification factor as "vertical" reduction of the Au + Au yields, it can equally well be taken as a "horizontal" shift in the $\langle T_{\mathrm{AA}}\rangle$ scaled Au+Au spectrum, such that

$$\frac{\left(1/N_{\mathrm{AA}}^{\mathrm{evt}}\right)d^2N_{\mathrm{AA}}(p_T)/dp_Tdy}{\langle T_{\mathrm{AA}}\rangle} = \frac{d^2\sigma_{pp}[p'_T{=}p_T{+}S(p_T)]}{dp'_Tdy} \times [1 + dS(p_T)/dp_T], \quad (12)$$

where the last term in parenthesis is the Jacobian, dp'_T/dp_T.

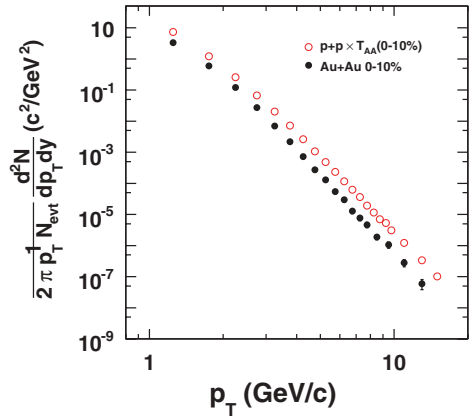

FIG. 10. (Color online) Log-log plot of central Au+Au and scaled $p+p$ π^0 p_T distributions.

Furthermore, owing to the pure power law of the $p+p$ reference spectrum, $Ed^3\sigma/dp^3 \propto p_T^{-n}$ with $n = 8.10 \pm 0.05$ above $p_T \approx 4$ GeV/c, the relative shift of the spectra—assumed to be the result of energy loss for the Au+Au spectrum—is easily related to the equivalent ratio, $R_{\rm AA}(p_T)$:

$$R_{\rm AA}(p_T) = \frac{[p_T + S(p_T)]^{-n+1}}{{p_T}^{-n+1}}[1 + dS(p_T)/dp_T] \qquad (13)$$

$$= [1 + S(p_T)/p_T]^{-n+1}[1 + dS(p_T)/dp_T]$$

where the exponent is $n-1$ because the relevant shift is in the $d\sigma/dp_T$ spectrum rather than in $d\sigma/p_T\,dp_T$. The fact that the Au+Au and reference $p+p$ p_T spectra are parallel in Fig. 10 provides a graphical illustration that the fractional p_T shift in the spectrum, $S(p_T)/pt = S_0$, is a constant for all $p_T > 3$ GeV/c, which also results in a constant ratio of the spectra, $R_{\rm AA}(p_T)$. For the constant fractional shift, the Jacobian is simply $dS(p_T)/dp_T = S_0$ and Eq. (13) becomes:

$$R_{\rm AA}(p_T) = (1 + S_0)^{-n+2}, \qquad (14)$$

$$R_{\rm AA}(p_T)^{1/(n-2)} = \frac{1}{1 + S_0}. \qquad (15)$$

The effective fractional energy loss, $S_{\rm loss}$, is related to the fractional shift in the measured spectrum, S_0. The hadrons that would have been produced in the reference $p+p$ spectrum at transverse momentum $p_T + S(p_T) = (1 + S_0)p_T$, were detected with transverse momentum, p_T, implying a fractional energy loss:

$$S_{\rm loss} = 1 - 1/(1 + S_0) = 1 - R_{\rm AA}(p_T)^{1/(n-2)}. \qquad (16)$$

The fractional energy loss $S_{\rm loss}$ as a function of centrality expressed as $N_{\rm part}$ is shown in Fig. 11 for two different p_T ranges, $3 < p_T < 5$ GeV/c and $5 < p_T < 7$ GeV/c. There appears to be a small decrease of $S_{\rm loss}$ with increasing p_T, but the main observation from Fig. 11 is that $S_{\rm loss}$ increases approximately like $N_{\rm part}^{2/3}$, as suggested by GLV [54] and PQM [55].

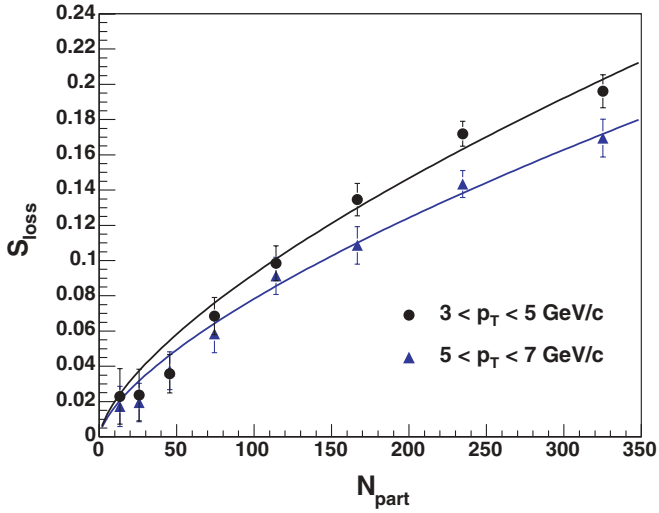

FIG. 11. (Color online) Fractional energy loss $S_{\rm loss}$ obtained from Eq. (16) versus centrality given by $N_{\rm part}$. The lines are fits of the form $\propto N_{\rm part}^{2/3}$ for each p_T range.

It is important to realize that the effective fractional energy loss, $S_{\rm loss}$ estimated from the shift in the p_T spectrum, is actually less than the real average energy loss at a given p_T, i.e., the observed particles have p_T closer to the original value than to the average. The effect is similar to that of "trigger bias" [56] where, due to the steeply falling spectrum, the $\langle z \rangle$ of detected single inclusive particles is much larger than the $\langle z \rangle$ of jet fragmentation, where $z = \vec{p}_{\pi^0} \cdot \vec{p}_{\rm jet}/p_{\rm jet}^2$. Similarly for a given observed p_T, the events at larger p_T' with larger energy loss are lost under the events with smaller p_T' with smaller energy loss.

It should be noted that fluctuations due to the variation of the path length and densities traversed by different partons also contribute to the difference between the true $S_{\rm loss}$ ($S_{\rm loss}^{\rm true}$) and that which is observed ($S_{\rm loss}^{\rm obs}$). However, as long as the dependencies of the induced energy loss on path length and parton energy approximately factorize, these fluctuations will also produce a p_T-independent reduction in $S_{\rm loss}^{\rm obs}$ compared to $S_{\rm loss}^{\rm true}$.

C. Angle dependence of high p_T suppression

To try to separate the effects of the density of the medium and path length traversed, we study the dependence of the π^0 yield with respect to the reaction plane. For a given centrality, variation of $\Delta\phi$ gives a variation of the path length traversed for fixed initial conditions, whereas varying the centrality allows determination of the effect of varying the initial conditions.

Figures 12 and 13 show the nuclear modification factor $R_{\rm AA}$ as a function of $\Delta\phi$ integrated over $3\,{\rm GeV}/c < p_T < 5\,{\rm GeV}/c$ and $5\,{\rm GeV}/c < p_T < 8\,{\rm GeV}/c$, respectively. For all centralities (eccentricities) considered, there is almost a factor of 2 more suppression out-of-plane ($\Delta\phi = \pi/2$) than in-plane ($\Delta\phi = 0$), something that is immediately apparent in viewing the data in this fashion—explicitly displaying information that is implicit only in $R_{\rm AA}$, v_2, or the combination thereof.

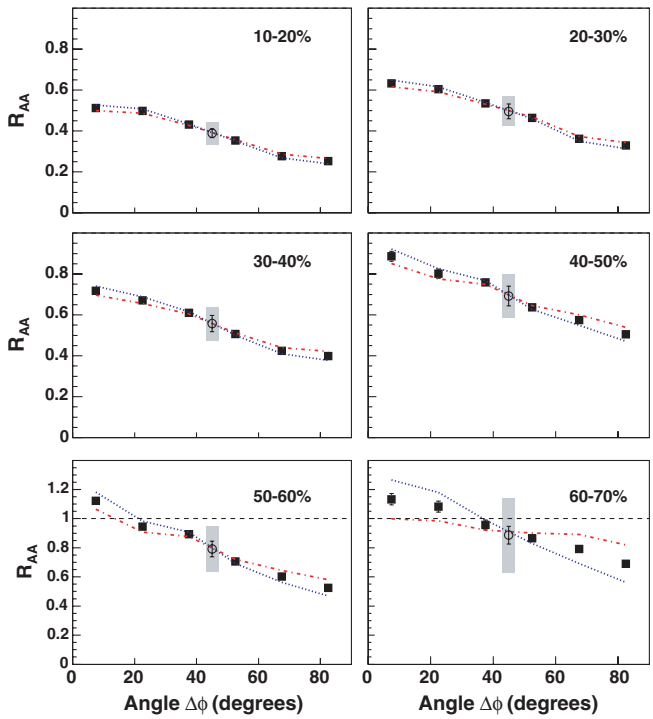

FIG. 12. (Color online) R_{AA} versus $\Delta\phi$ for π^0 yields integrated over $3 < p_T < 5$ GeV/c. Most statistical errors are smaller than the size of the points. The lines following the data points show the bin-to-bin errors resulting from the uncertainty in the reaction plane resolution correction (Fig. 1) and from bin-to-bin uncertainties in the R_{AA} values. The shaded band indicates the overall R_{AA} uncertainty.

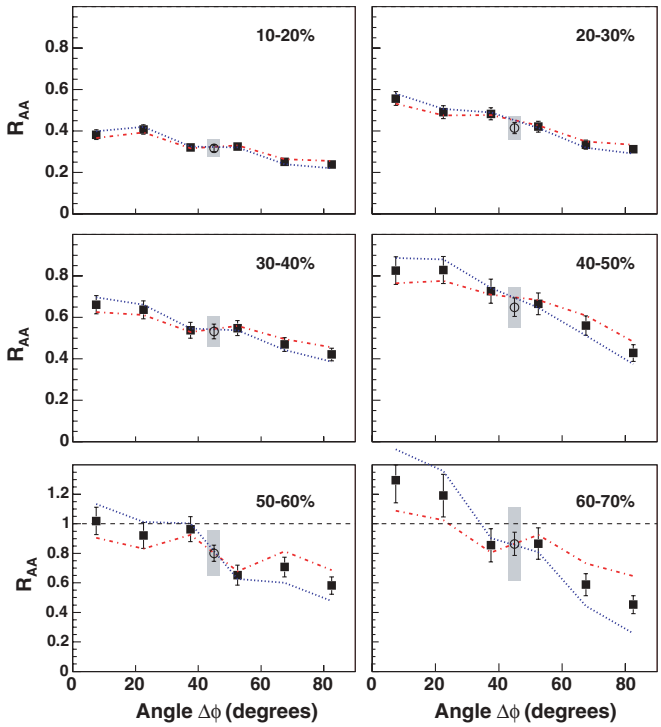

FIG. 13. (Color online) R_{AA} versus $\Delta\phi$ for π^0 yields integrated over $5 < p_T < 8$ GeV/c. The error lines and band are the same as in Fig. 12.

Strikingly, in contradiction to the data the variation in R_{AA} with respect to the reaction plane expected by parton energy loss models [29,57] should be much smaller for the more peripheral bins than for the central bins. As a result, the suppression vanishes (and perhaps an enhancement is observed) for smaller $\Delta\phi$ in the peripheral bins, corresponding to small path length traversed in the medium. Although collective elliptic flow effects, usually not included in those models, are known to boost in-plane (compared to out-of-plane) particle production [2,42], it is unclear how such collective effects can still play such an important role at the high-p_T bins considered. This may point to the possible need for a formation time before suppression can occur [58] and which could also explain why attempts to describe the azimuthal asymmetry v_2 solely in terms of purely geometrical energy loss have failed. Figures 14 and 15 give the angular dependence in terms of the fractional energy loss $S_{\rm loss}$, and provide essentially the same information as shown in the plots of $R_{AA}(\Delta\phi)$ in Figs. 12 and 13. Once again we see a large variation in energy loss as a function of angle. All the measurements of R_{AA} or equivalently $S_{\rm loss}$ vs. reaction plane and centrality, provide new constraints to models of jet quenching. To better understand the implications of the results shown in these figures, we will attempt in the next section to find a common geometric description of the angle and centrality dependences in terms of an estimated path length of the parton in the medium.

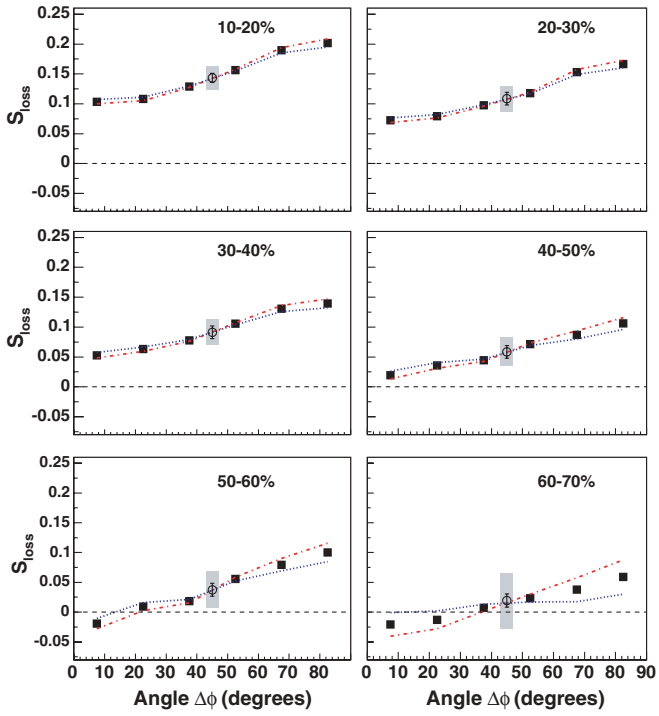

FIG. 14. (Color online) $S_{\rm loss}$ versus $\Delta\phi$ for π^0 yields integrated over $3 < p_T < 5$ GeV/c. The statistical errors are smaller than the size of the points. The lines following the data points show the bin-to-bin errors resulting from the uncertainty in the reaction plane resolution correction (Fig. 1) and from bin-to-bin uncertainties in the $S_{\rm loss}$ values. The shaded band indicates the overall $S_{\rm loss}$ uncertainty.

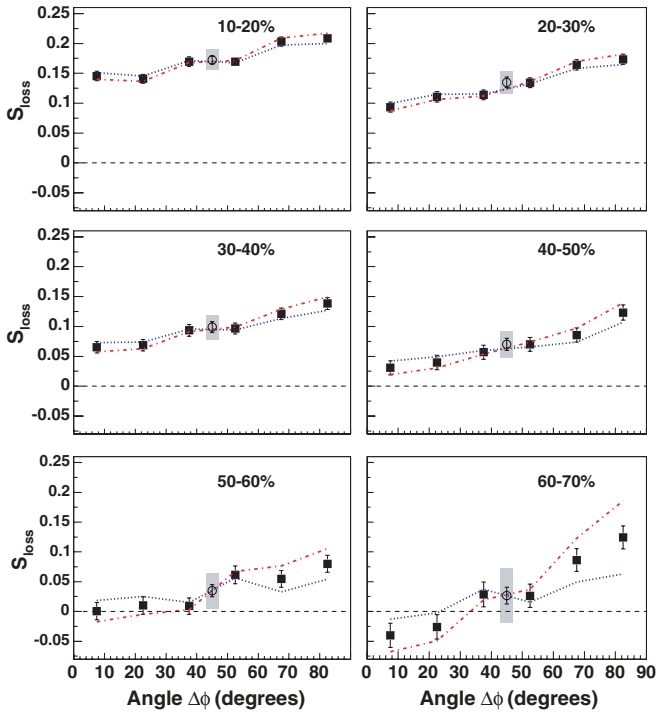

FIG. 15. (Color online) $S_{\rm loss}$ versus $\Delta\phi$ for π^0 yields integrated over $5 < p_T < 8$ GeV/c. The error lines and band are the same as in Fig. 14.

D. Path-length dependence of energy loss

To analyze the path-length dependence of parton energy loss using the data presented here we will use different methods for estimating the path lengths of partons in the medium as a function of centrality and $\Delta\phi$. The "standard" approach would be to evaluate a length-weighted integral of the participant charge density in the medium along the parton path. We will adopt such an approach, described by the parameter L_{xy} defined below, but we will also consider two other simplified approaches that may help indicate which physics is most relevant in determining the observed suppression. We first consider, simply, L_ε, the distance from the edge to the center of the elliptical overlap zone of the Au+Au collision to represent the average path length of a parton in the medium. Then we try to weight the path length (or length-squared) traversed by a parton from the center of the ellipse by the participant density in the transverse plane: $\rho L(\Delta\phi)$ [$\rho L^2(\Delta\phi)$]. Finally, we do the same path-length weighting for partons produced across the overlap ellipse, with hard-scattering production points weighted by $T_{\rm AA}(x, y)$: ρL_{xy} (ρL_{xy}^2). It is obvious that such a $\Delta\phi$-dependent analysis is not possible from just a simple combination of $R_{\rm AA}$ and v_2.

In detail, the three approaches considered here are as follows:

(i) The simplest picture for the angular dependence of the energy loss in noncentral collisions is that it is due to the asymmetric shape of the overlap region of the colliding nuclei. Taking this idea to its extreme, only the simplest length scale, the length of the overlap region in a particular direction, matters.

To evaluate this length, we first estimated the root-mean-square radius and eccentricity of an ellipse approximating the shape of the overlap region from the transverse distribution of the participant density calculated using standard Glauber Monte Carlo techniques in which all variations of impact parameter, etc., for a given centrality class are taken account in the quoted errors of the geometrical quanties [51]. Only the errors on the averages are considered; for instance, the fluctuations in the event-by-event participant eccentricity are taken into account in the quoted error of the centrality averaged ε. We then estimated the path length, L_ε, of partons emitted at a given angle $\Delta\phi$ by evaluating the distance from the center of ellipse to the edge. For each centrality, the value of L_ε is calculated as a function of $\Delta\phi$:

$$L_\varepsilon = \frac{b\sqrt{1+\varepsilon}}{\sqrt{1+\varepsilon\cos(2\Delta\phi)}}, \tag{17}$$

where $b = \sqrt{\langle x^2\rangle}$, the root-mean-square semiminor axis (conventionally taken in the x direction) and $\varepsilon = (\langle y^2\rangle - \langle x^2\rangle)/(\langle y^2\rangle + \langle x^2\rangle)$ are taken from the Monte Carlo Glauber calculation. The errors on b and ε are propagated through Eq. (17) for the error on L_ε. A plot of L_ε as a function of centrality and $\Delta\phi$ is shown in Fig. 16.

As described previously in Section III F, the effect and associated uncertainties of reaction plane resolution are

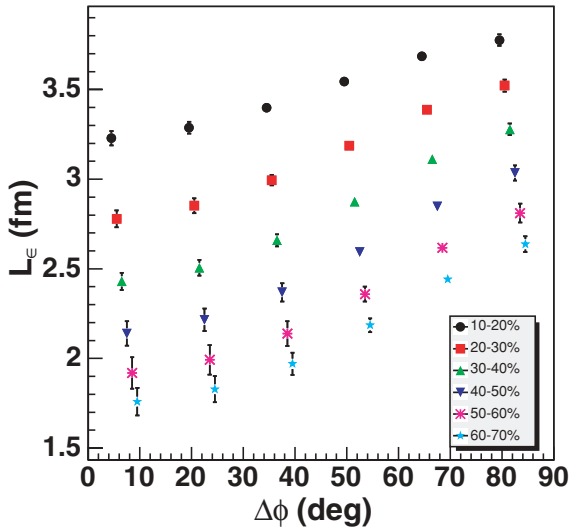

FIG. 16. (Color online) Simple geometrical length estimator L_ε with uncertainties plotted *vs.* angle with respect to reaction plane, plotted for the six centralities considered as indicated in the legend. The angle with respect to reaction plane, $\Delta\phi$, is for the center of the bins (7.5°, 22.5°, 37.5°, 52.5°, 67.5°, and 82.5°), the same for all centralities. For visual clarity a centrality dependent offset is introduced.

taken into account (i.e., corrected for) in the values and quoted errors of $R_{AA}(\Delta\phi)$. Thus detector effects of reaction plane resolution should not be considered in the evaluation of L_ε.

(ii) Although the participant density is used to evaluate the dimensions of the ellipse, the above analysis ignores the dependence of participant density on position in the transverse plane. Thus as a natural extension of the simple length scale in (i), for another analysis of the dependence of energy loss on $\Delta\phi$, we assume that the color-charge density in the medium is proportional to participant density (see Refs. [29,59]) and evaluate ρL, the integral of this density along the path length of the particle. This quantity is proportional to the opacity of the medium ($n = L/\lambda$) divided by some undetermined cross section. Although the integral in principle extends to infinity the participant density naturally cuts off the integral outside the collision zone.

$$\rho L = \int_0^\infty dr\ \rho_{\text{part}}(r, \Delta\phi). \tag{18}$$

To account for the possible role of LPM coherence in the energy loss process, we evaluate a similar quantity, including an extra factor of r in the integrand.

$$\rho L^2 = \int_0^\infty dr\ r\rho_{\text{part}}(r, \Delta\phi). \tag{19}$$

We note that a Bjorken $1/\tau$ expansion of the medium would approximately cancel one power of r in the above expressions. Then, ρL, might represent LPM energy

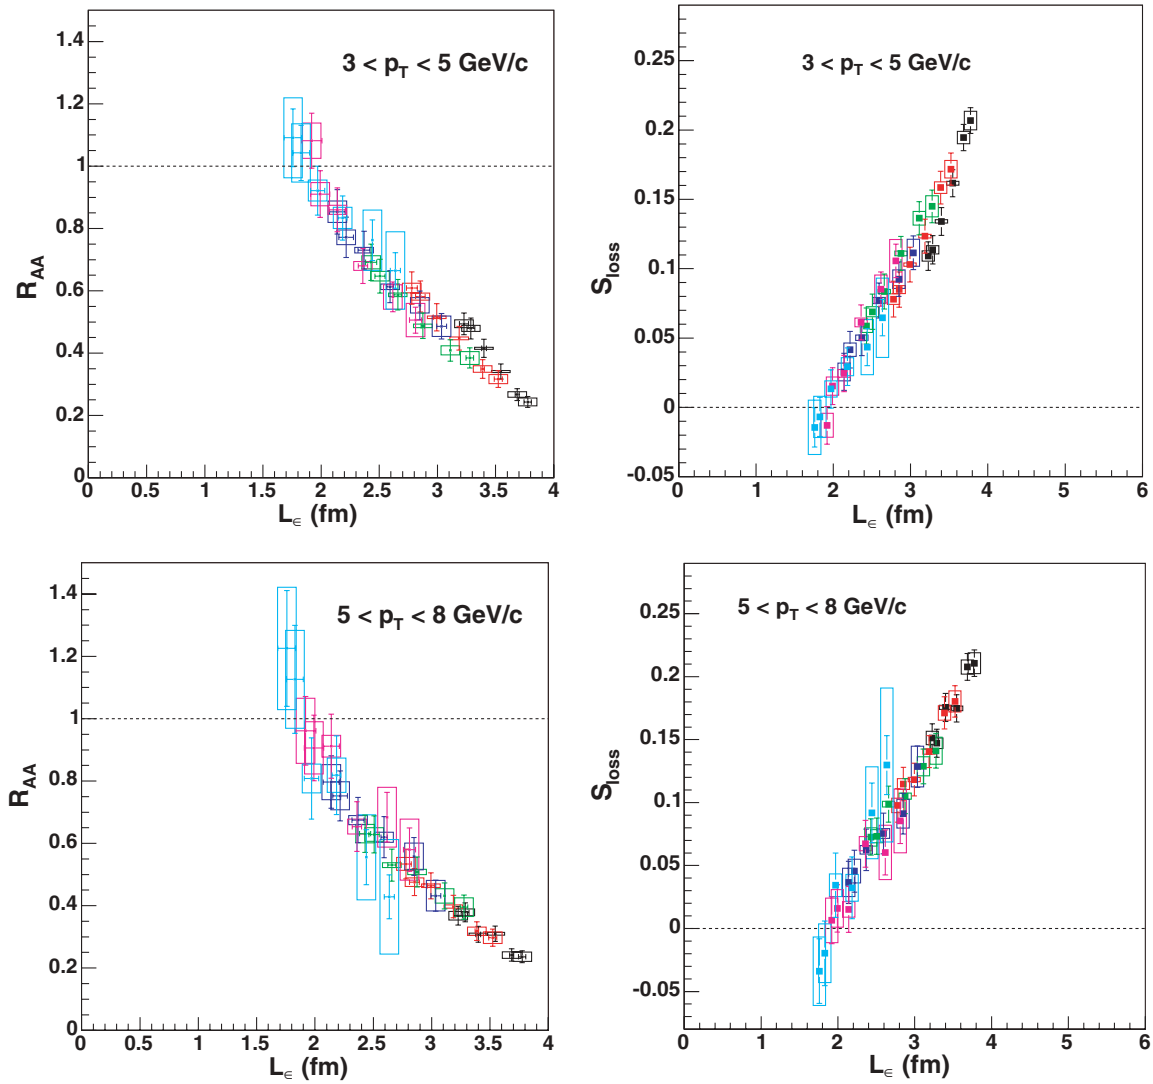

FIG. 17. (Color online) R_{AA} and S_{loss} versus L_ε whose definition is explained in the text. Each data point represents a centrality bin and $\Delta\phi$ (azimuth defined *w.r.t.* the reaction plane) bin combination. The six centrality bins are denoted by different colors as follows: cyan, 60–70%; mauve, 50–60%; blue, 40–50%; green, 30–40%; red, 20–30%; black, 0–10%. Within each centrality group, the six different data points correspond to the same $\Delta\phi$ bins as in Figs. 12–15. The height of the bars around each data point represent the systematic error in $R_{AA}(\Delta\phi)$ (S_{loss}) corresponding to L_ε.

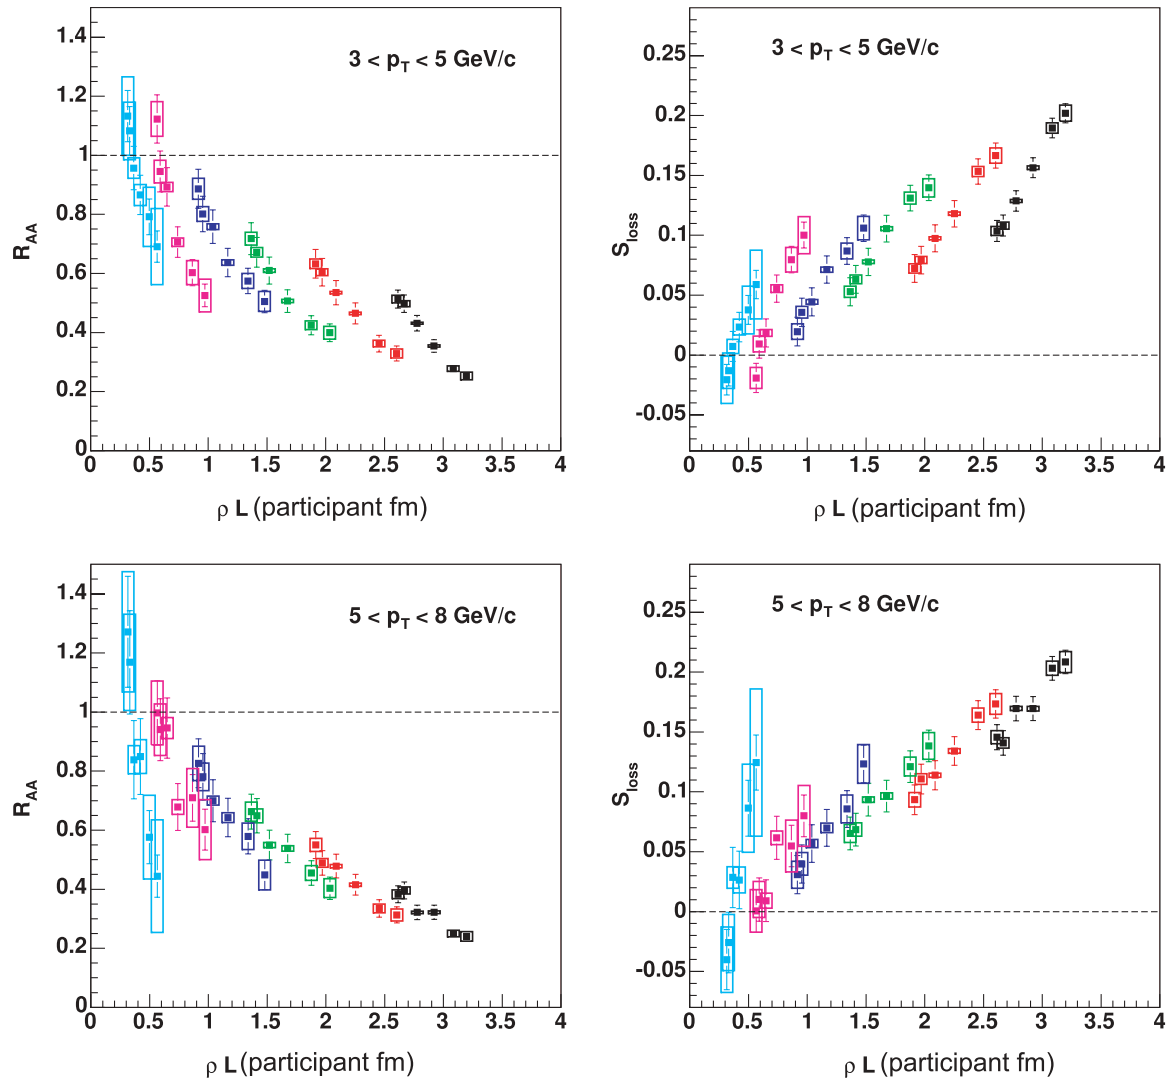

FIG. 18. (Color online) R_{AA} and S_{loss} versus ρL, the participant density-weighted path length. The units of ρL are (nucleon) participants times fm. Colors/data points as in Fig. 17.

loss in the presence of one-dimensional expansion. In the above integrals we assume all jets originate at the center of the collision region similar to our assumption for L_ε.

(iii) A final refinement on our geometrical calculation evaluates integrals like those in Eq. (18) for jet production points distributed over the collision region to better account for geometric fluctuations. We are using a Monte Carlo algorithm to sample jet production points (x_0, y_0) according to $T_{AA}(x, y)$ weighting and $\Delta\phi$ angles from a uniform distribution. For each jet, we evaluate the integral of the color-charge density (assumed $\propto$ participant density as above) along the path of the parton out of the medium,

$$\rho L_{xy} = \int_0^\infty dl\ \rho_{\text{part}}(x_0 + l\cos\Delta\phi,\ y_0 + l\sin\Delta\phi). \tag{20}$$

The above Monte Carlo sampling yields a distribution of ρL_{xy} values for each centrality. The larger values of ρL_{xy} correspond to larger energy loss, which means these jets will have smaller contribution to the observed yield. To take this into account, a weighting factor is applied when evaluating $\langle \rho L_{xy} \rangle$. We assume that the energy loss can be represented by our empirical energy loss, S_{loss} which we take to be proportional to ρL_{xy} but with an undetermined multiplicative constant, κ. We determine this constant in each centrality bin by relating S_{loss} to R_{AA} using Eq. (16) and then evaluating the survival probability of each jet through

$$P_{\text{surv}}(\rho L_{xy}) = 1 - (\kappa \rho L_{xy})^{(n-2)} \tag{21}$$

and requiring that the resulting suppression summed over all sampled jets agrees with the measured $\Delta\phi$-integrated R_{AA} for that centrality bin. This determines the constant $\kappa(N_{\text{part}})$ and allows us to

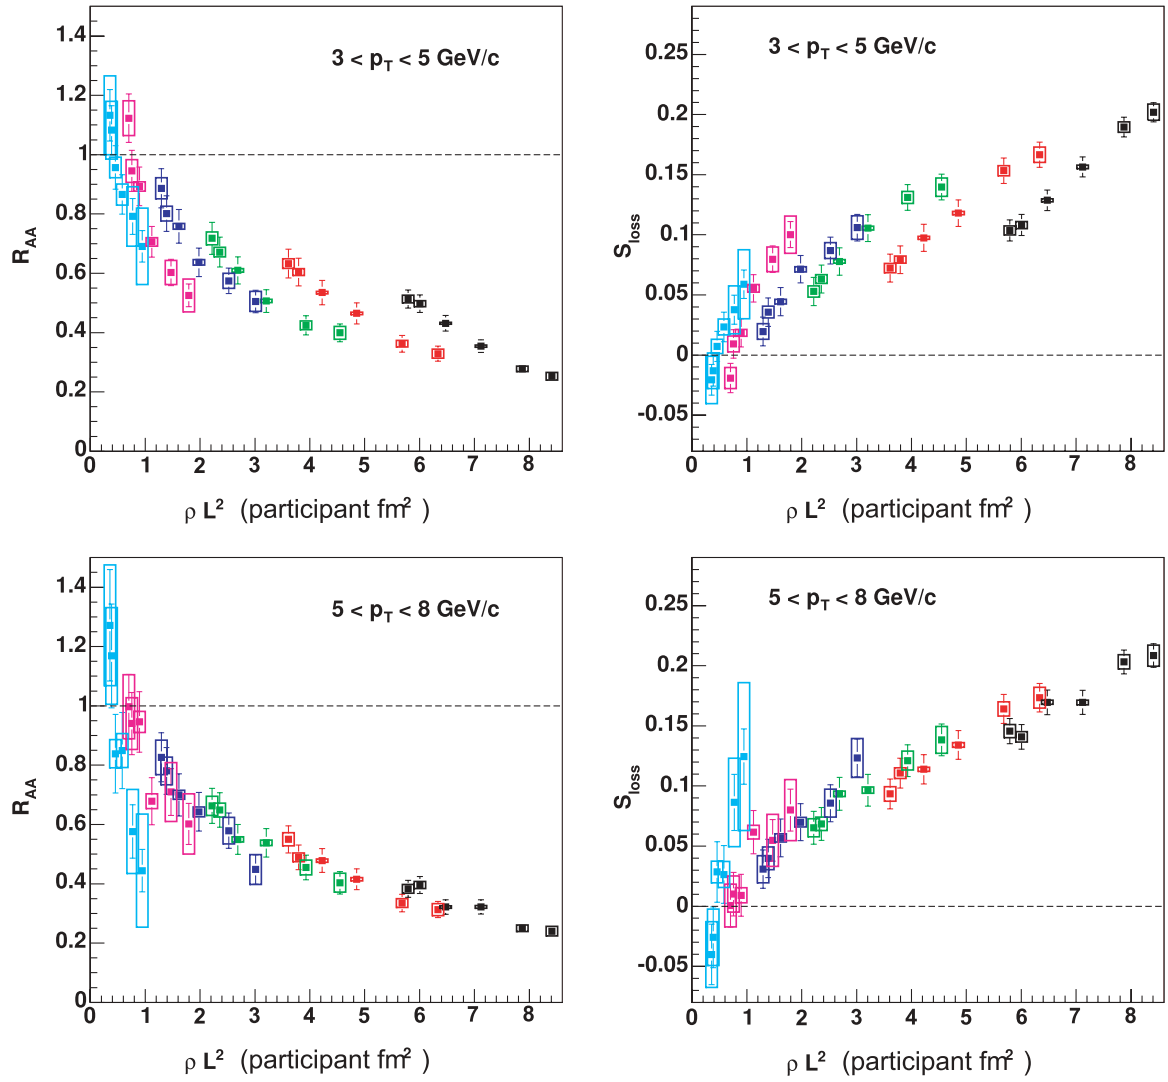

FIG. 19. (Color online) R_{AA} and S_{loss} versus ρL^2, the density-weighted path length squared. The units of ρL^2 are (nucleon) participants times fm squared. Colors/data points as in Fig. 17.

evaluate a survival probability weighted average for ρL_{xy}.

We now evaluate how well the three above-described treatments of the geometry of the parton propagation in the medium perform in providing a consistent description of the $\Delta\phi$ *and* centrality dependence of π^0 suppression.

The plots shown in Figs. 17–21 illustrate the path-length and path-density line-integral dependence of suppression using our empirical estimators. The integral of the ρ_{part} density (i.e., its normalization) is commonly called the "number of participants" N_{part}. The systematic error, mostly from N_{part}, in the estimators due to the uncertainty of the overlap geometry parameter in a centrality class is approximately 10–20%, decreasing with centrality and is not included in the figures. This uncertainty is derived by propagating the impact parameter and eccentricity uncertainties from the PHENIX Glauber MC itself [1,41].

From Figs. 17–21 it is evident that the individual centrality bins exhibit roughly parallel linear dependencies of the variables vs ρL_{xy}, etc. For the $3 < p_T < 5$ GeV/c bin these slopes are such that the curves are disjoint due to the steeper value of the slopes in each centrality group (each color in the plots) compared to the bin-to-bin trend. For the higher $5 < p_T < 8$ GeV/c bin, the slopes in the individual centralities flatten such that they follow the bin-to-bin trend much better. These are meant to be qualitative statements. We defer further quantitative tests, e.g., statistical tests, to subsequent data sets (e.g., the larger PHENIX 2004–2005 Run4 data set) with which we can improve statistical precision.

In this spirit, we note several other interesting qualitative dependencies:

(i) R_{AA} is universal as a function of L_ε for all centrality classes and both p_T ranges.

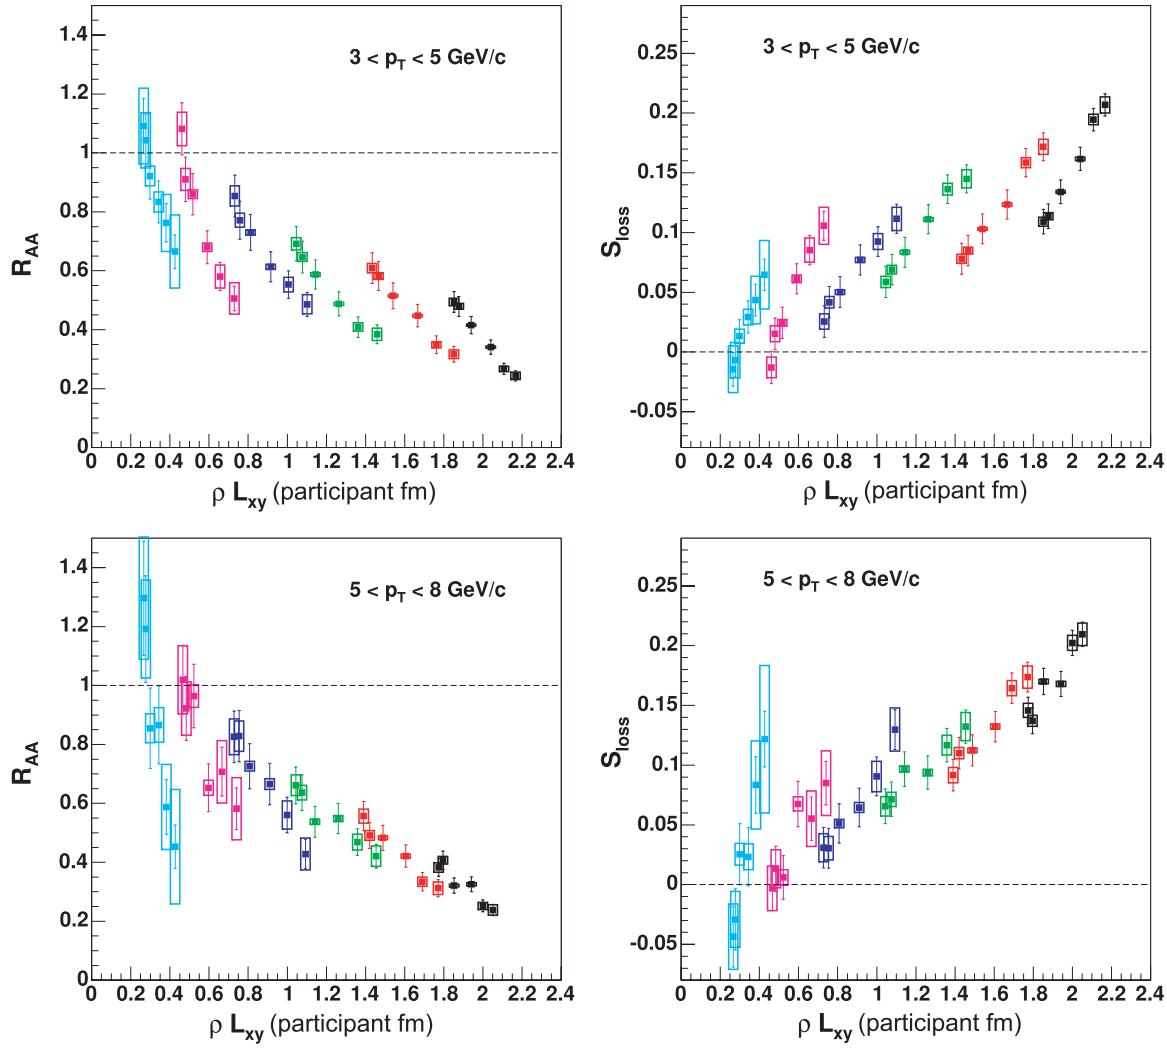

FIG. 20. (Color online) $R_{\rm AA}$ and $S_{\rm loss}$ versus ρL_{xy} whose definition is explained in the text. The units of ρL_{xy} are (nucleon) participants times fm. Colors/data points as in Fig. 17.

(ii) $S_{\rm loss}$ is universal and is a linear function of L_ε for all centrality classes and both p_T ranges.

(iii) Within our errors, we see no suppression $R_{\rm AA} \approx 1$, hence no apparent fractional energy loss $S_{\rm loss}$ for $L_\varepsilon \leqslant 2$ fm.

(iv) Neither $R_{\rm AA}$ nor $S_{\rm loss}$ is universal as a function of ρL, ρL^2, or ρL_{xy} for $3 < p_T < 5$ GeV/c.

(v) For the higher $5 < p_T < 8$ GeV/c p_T bin, $S_{\rm loss}$ ($R_{\rm AA}$) approaches universality as a function of ρL^2, ρL, and ρL_{xy} (possibly to a lesser extent for the latter two) but does not achieve the level of universality found for L_ε. The largest deviations from universality in these quantities are toward the longer axis (perpendicular to the event plane) in the more peripheral events. The dependence of $S_{\rm loss}$ is reasonably linear as a function of ρL but tends to level off at larger values of ρL^2.

(vi) When ρL is normalized by the central density $\rho_{\rm part}(0, 0) = \rho_{\rm cent}$, then $S_{\rm loss}$ ($R_{\rm AA}$) become universal in the quantities $\rho L/\rho_{\rm cent}$ for both p_T ranges with a linear dependence. The universality appears to become more exact in the higher p_T range. A similar improvement (not shown) of the qualitative universality for ρL^2 and ρL_{xy} is also observed when these quantities are scaled in the same way by $\rho_{\rm cent}$. The fact that scaling by $\rho_{\rm cent}$ improves the universality suggests that simple geometry may be more important than the details of the participant density.

The most important of these observations is the absence of suppression for the same value of $L_\varepsilon \leqslant 2$ fm for both p_T ranges, $3 \leqslant p_T \leqslant 5$ GeV/c and $5 \leqslant p_T \leqslant 8$ GeV/c. This may suggest a "formation time effect" (see Ref. [58], also considering mechanisms suggested in Ref. [60]) or some other type of emission zone which has generally not been taken into account in parton energy-loss models. The level of universal scaling with this simple geometric quantity is surprising.

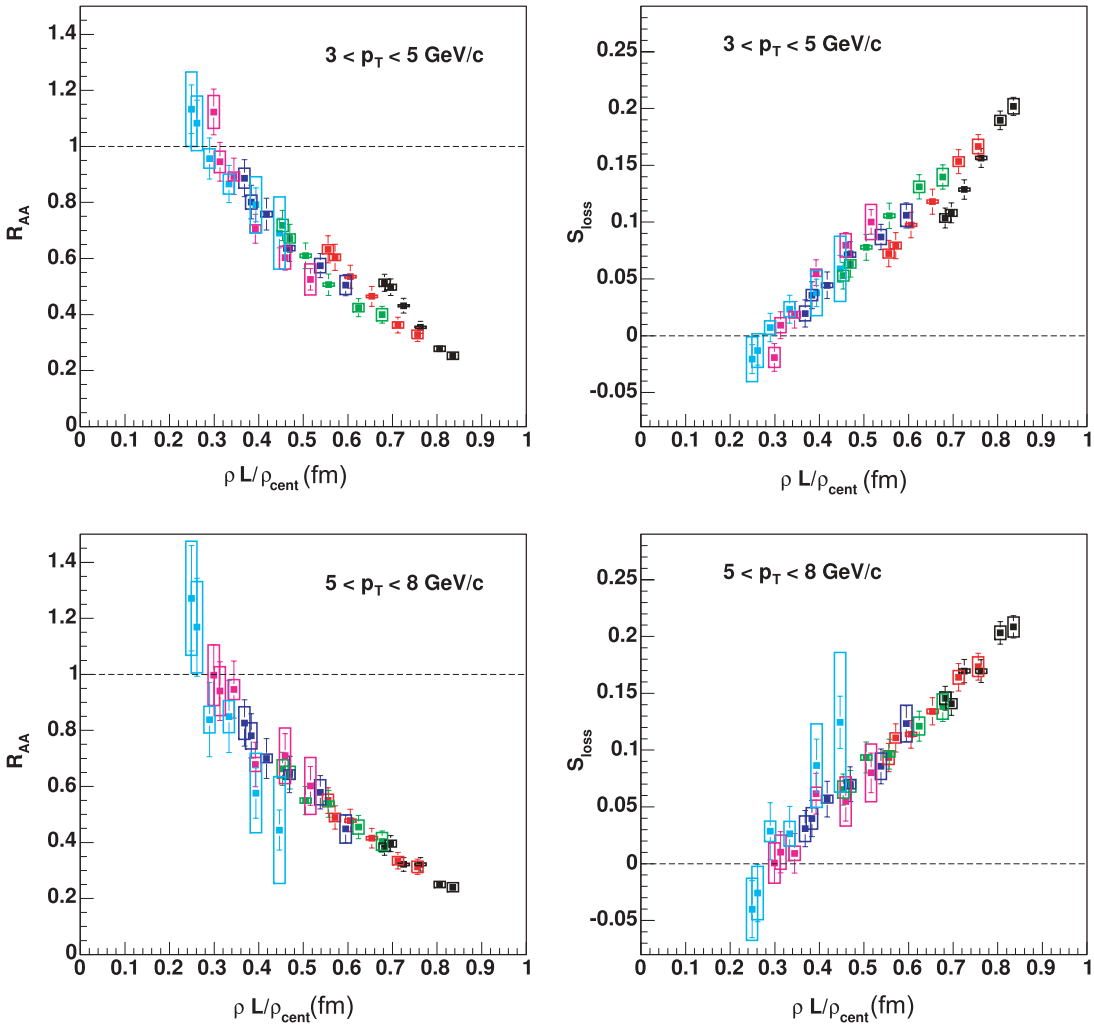

FIG. 21. (Color online) R_{AA} and S_{loss} versus ρL normalized by the most central ($b_x = b_y = 0$) density ρ_{cent}. Colors/data points as in Fig. 17.

V. SUMMARY AND CONCLUSIONS

We have presented a detailed analysis of high-p_T neutral pion suppression as a function of transverse momentum, centrality, and angle with respect to reaction plane in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The π^0 yields have been measured in the range $p_T \approx 1$–$14\,\mathrm{GeV}/c$ in nine centrality bins and compared to the π^0 differential cross sections measured in $p+p$. The ratio of Au+Au over $p+p$ spectra (scaled by the number of equivalent nucleon-nucleon scatterings) is reduced more and more for larger centralities. The resulting suppression factor is, however, independent of p_T above $p_T \approx 4$ GeV/c for all centralities. This observation can be interpreted as an indication of a constant effective fractional energy loss, fixed S_{loss} "p_T shift," in the Au+Au compared to the $p+p$ yields. The dependence of S_{loss} in the centrality as given by the number of participating nucleons N_{part} follows an approximately $N_{\mathrm{part}}^{2/3}$ law as predicted by parton energy loss models.

To constrain the "jet quenching" models with more differential observables, we have experimentally tested the path-length (L) dependence of the energy loss by exploiting the spatial azimuthal asymmetry of the system produced in noncentral nuclear collisions. Due to the characteristic almondlike shape of the overlapping matter produced in $A+A$ reactions with finite impact parameter, partons traversing the produced medium along the direction perpendicular to the reaction plane ("out-of-plane") will comparatively go through more matter than those going parallel to it ("in-plane") and therefore are expected to lose more energy.

We have studied the suppression pattern along different $\Delta\phi$ trajectories with respect to the reaction plane determined with the beam-beam counters at high rapidities. The measured $R_{\mathrm{AA}}(\Delta\phi)$ curves show clearly a factor of $\sim$2 more suppression out-of-plane ($\Delta\phi = \pi/2$) than in-plane ($\Delta\phi = 0$) for all the centralities (eccentricities) considered. Theoretical calculations of parton energy loss in an azimuthally asymmetric medium predict a significantly smaller difference between the suppression patterns for partons emitted at $\Delta\phi = 0$ and $\Delta\phi = \pi/2$ [29,32,33]. The discrepancy is stronger for more peripheral centralities (with correspondingly larger eccentricities) and challenges the underlying in-medium path-length

dependence of non-Abelian parton energy loss. Although elliptic flow effects are responsible for extra boost of in-plane (compared to out-of-plane) pions, it is unclear how such collective effects persist up to p_T values as high as $\sim$8 GeV/c. We have analyzed the observed reaction-plane and centrality dependence of the nuclear modification factor with three different versions of a Monte Carlo model with an increasing level of refinement in the description of the azimuthal propagation of the parton in the medium. For all three approaches we observe that the π^0 suppression tends to vanish for values of the path-length $L \approx 2$ fm in the two p_T ranges considered, $3 \leqslant p_T \leqslant 5$ GeV/c and $5 \leqslant p_T \leqslant 8$ GeV/c. Such a result suggests either a formation time effect or a surface emission zone that results in a p_T-independent suppression and puts additional constraints to parton energy-loss models.

(Received 6 November 2006; published 27 February 2007)

Inclusive transverse momentum spectra of η mesons in the range $p_T \approx 2$–12 GeV/c have been measured at midrapidity ($|\eta| < 0.35$) by the PHENIX experiment at RHIC in $p+p$, d+Au, and Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The η mesons are reconstructed through their $\eta \to \gamma\,\gamma$ channel for the three colliding systems as well as through the $\eta \to \pi^0\pi^+\pi^-$ decay mode in $p+p$ and d+Au collisions. The nuclear modification factor in d+Au collisions, $R_{d\mathrm{Au}}(p_T) \approx 1.0$–1.1, suggests at most only modest p_T broadening ("Cronin enhancement").

In central Au+Au reactions, the η yields are significantly suppressed, with $R_{\mathrm{AuAu}}(p_T) \approx 0.2$. The ratio of η to π^0 yields is approximately constant as a function of p_T for the three colliding systems in agreement with the high-p_T world average of $R_{\eta/\pi^0} \approx 0.5$ in hadron-hadron, hadron-nucleus, and nucleus-nucleus collisions for a wide range of center-of-mass energies ($\sqrt{s_{NN}} \approx$ 3–1800 GeV) as well as, for high scaled momentum x_p, in e^+e^- annihilations at $\sqrt{s} = 91.2$ GeV. These results are consistent with a scenario where high-p_T η production in nuclear collisions at the Relativistic Heavy Ion Collider is largely unaffected by initial-state effects but where light-quark mesons (π^0, η) are equally suppressed due to final-state interactions of the parent partons in the dense medium produced in Au+Au reactions.

DOI: 10.1103/PhysRevC.75.024909 PACS number(s): 25.75.−q, 12.38.Mh, 13.85.−t, 13.87.Fh

I. INTRODUCTION

Single-hadron production at large transverse momenta ($p_T \gtrsim 2$ GeV/c) in high-energy hadronic and nuclear collisions results from the fragmentation of quarks and gluons issuing from parton-parton scatterings with large momentum transfer Q^2. Because the cross sections for such hard processes can be calculated perturbatively within quantum chromodynamics (QCD) [1], inclusive high-p_T hadrons (as well as jets, real and virtual direct photons, and heavy quarks) have long been considered sensitive, well-calibrated probes of the small-distance QCD processes. The study of inclusive hadron production at large p_T in proton-proton interactions provides valuable information about perturbative QCD (pQCD), parton distribution functions (PDF) in the proton, and fragmentation functions (FF) of the partons [2]. Furthermore, the use of polarized beams ($\vec{p} + \vec{p}$) allows one to investigate the spin structure of the proton [3]. High-energy collisions of protons or deuterons on nuclear targets (p, d+A) also provide interesting insights on initial- and final-state QCD effects such as modifications of the nuclear PDFs [4,5] and parton rescattering in the cold nuclear medium [6]. Both effects are sensitive to physics such as parton structure and evolution at small values of fractional momentum x in the hadronic wave functions [7] and the dynamics of hadronization in cold nuclei [8,9]. Last, high-p_T hadron production in nucleus-nucleus (A+A) reactions is a sensitive probe of the properties of the strongly interacting QCD matter produced in the collision. Indeed, because perturbative processes happen at time scales $\tau \approx 1/p_T \lesssim 0.1$ fm/c, the hard-scattered partons traverse and are potentially modified by the bulk matter formed shortly after the collision. In this context, the suppression of leading hadrons has been postulated [10] as a signal of "jet quenching" in a quark-gluon-plasma (QGP) due to medium-induced energy-loss of the parent parton [11–13].

All the aforementioned research topics have been addressed in detail by the rich physics program carried out at the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory (BNL) during its first 6 years of operation (2000–2006). For example, the study of inclusive high-p_T neutral pion production at midrapidity in $p+p$ [14], $\vec{p} + \vec{p}$ [15], d+Au [16,17], and Au+Au [18–21] collisions at $\sqrt{s_{NN}} =$ 200 GeV has provided valuable information respectively on (i) the gluon-to-pion FF [14,22], (ii) the gluon contribution to the proton spin [23–25], (iii) initial-state effects in cold nuclear matter such as shadowing of the nuclear PDFs [26–29], Cronin broadening [30–32], and gluon saturation [33–35], and (iv) the thermodynamical and microscopic properties of hot and dense QCD matter [36], such as the initial gluon rapidity density dN^g/dy [37] and the transport coefficient $\langle \hat{q} \rangle$ [38,39] of the produced medium; and the mechanism of hadronization in a dense parton medium [40].

In this article, we extend previous PHENIX analyses of high-p_T hadron production in $p+p$ [14,15], d+Au [16], and Au+Au [19–21,41] collisions at $\sqrt{s_{NN}} = 200$ GeV to include an additional identified particle, the η meson, measured in the range $p_T =$ 2–12 GeV/c. The spectra presented here are the hardest (i.e., have the highest p_T) ever measured for the η meson[1] in $p+p$, p+A, and A+A collisions. The high p_T reach of the η helps to characterize the mechanisms of truly perturbative parton-parton scatterings and parton fragmentation in different QCD environments ($p+p, d$+A, and Au+Au). The η data from $p+p$ collisions are presented here as a baseline for medium effects in d+Au and Au+Au. Once a parametrization of the η FF in e^+e^- is performed (see Sec. IV E2), the observed $p+p$ cross section will additionally allow a test of pQCD predictions. Such a FF parametrization would be useful in particular in the light of upcoming high-p_T η asymmetry data obtained with polarized beams of relevance for the proton spin program [44].

For d+Au and Au+Au reactions, we present the single η spectra, the η nuclear modification factors, and the η-to-π^0 ratio measured as a function of p_T in different centralities. Within uncertainties, the d+Au spectra for all centralities are consistent with the $p+p$ yields scaled by the corresponding number of incoherent nucleon-nucleon (NN) collisions. The maximum amount of p_T broadening seen in the η data is 10%, $R_{dAu}(p_T) \approx$ 1.0–1.1. Such a result confirms the limited influence of cold nuclear matter effects, such as shadowing, Cronin broadening or recombination, on high-p_T meson production at midrapidity at RHIC [16,17]. However, the factor of ∼5 deficit of inclusive η yields observed above $p_T \approx$ 4 GeV/c in central Au+Au compared to binary-scaled $p+p$ collisions, $R_{\mathrm{AuAu}}(p_T) \approx 0.2$, is the same as that found for

*Deceased.
†Electronic address: zajc@nevis.columbia.edu.

[1]Before this measurement, only the ISR AFS Collaboration $p+p \to \eta$+X measurement for $p_T =$ 3–11 GeV/c at $\sqrt{s} =$ 62.4 GeV [42] and the single CDF η/π^0 point measured at $p_T =$ 12 GeV/c in $\bar{p}+p$ collisions at $\sqrt{s} = 1800$ GeV [43] had comparable maximum p_T values.

high-p_T π^0 [19,21] and for inclusive charged hadrons [41,45]. Such a common suppression pattern for π^0, η and $h^{\pm}$ is expected if the energy loss takes place at the parton level in the dense medium formed in the reaction *prior* to its fragmentation into a given hadron in the vacuum. Indeed, in this case the high-p_T deficit will just depend on the energy lost by the parent light-quark or gluon (i.e., on the initial density of scatterers in the produced medium) and not on the nature of the final leading hadron whose production will be described by the same *universal* probabilities (fragmentation functions) that govern vacuum hadron production in more elementary systems. Such an interpretation is supported by the fact that the ratio of p_T-differential cross sections of η mesons with respect to π^0 in Au+Au, d+Au, and p+p collisions is approximately constant, $R_{\eta/\pi^0} \approx 0.40$–$0.48$, which is consistent with the world average measured: (i) in hadron-hadron, hadron-nucleus, and nucleus-nucleus collisions above $p_T \approx 3$ GeV/c; as well as (ii) in electron-positron annihilations at the Z pole ($\sqrt{s} = 91.2$ GeV) for *energetic* η and π^0 with scaled momenta $x_p = p_{\text{hadron}}/p_{\text{beam}} \gtrsim 0.35$. Comparison of our data to a world compilation of η/π^0 ratios is done in the last section of the article.

In addition to their interest as a *signal* in their own right, reliable knowledge of the production of η mesons in p+p, d+Au, and Au+Au reactions is also required to determine and statistically remove the *background* of secondary $e^{\pm}$ and γ for other measurements such as single electrons (from heavy-quark decays) [46,47], dielectrons [47], and direct photons [48,49]. Indeed, η mesons constitute the second most important source after the π^0 of decay electrons (Dalitz and conversion) and photons contributing to these backgrounds.

The article is organized as follows. Section II presents a description of the experimental setup and detector systems used in this work. Section III provides an explanation of the analysis methods employed to obtain the η data. Section IV presents and compares the η results (p_T spectra, nuclear modification factors, and η/π^0 ratios) measured in p+p, d+Au, and Au+Au at $\sqrt{s_{NN}} = 200$ GeV and discusses the relative role of cold nuclear (d+Au) and hot and dense medium (Au+Au) effects on high-p_T meson production. In particular, Sec. IV E discusses the measured η-to-π^0 ratios in the context of different phenomenological models of high-p_T hadron production as well as in comparison to other experimental results measured in high-energy particle collisions at different center-of-mass energies. A less detailed presentation of a subset of these η results has already been published in [20].

II. EXPERIMENTAL SETUP

The PHENIX experiment at the RHIC facility [50] at BNL is specifically designed to measure hard QCD probes such as high-p_T hadrons, direct photons, leptons, and heavy flavor production. PHENIX achieves good mass and particle identification (PID) resolutions as well as small granularity by combining 13 detector subsystems (~350,000 channels) divided into (i) two central arm spectrometers for electron, photon, and hadron measurements at midrapidity ($|\eta| < 0.35$, $\Delta\phi = \pi$); (ii) two forward-backward ($|\eta| = 1.2$–2.2, $\Delta\phi = 2\pi$) spectrometers for muon detection; and (iii) two global (inner) detectors for trigger and centrality selection. A detailed description of the complete detector can be found elsewhere [51]. The data presented in this article were obtained during the Run-2 (2001–2002, Au+Au) and Run-3 (2003, d+Au, p+p) operations at RHIC. The layout of the PHENIX detector during these run periods is shown in Fig. 1. The primary detectors used to obtain the present results are the PHENIX central arm spectrometers, particularly the electromagnetic calorimeters (EMCal) [52] and the charged-particle tracking devices [the drift chamber (DC) [53] and pad chambers (PC) [54]]. In addition, the beam-beam counters (BBC) [55] and the zero-degree calorimeters (ZDC) [56] are used for triggering, event characterization and (Au+Au and d+Au) centrality determination.

A. Electromagnetic calorimeter (EMCal)

The η mesons are detected in PHENIX via their $\gamma\gamma$ (branching ratio BR = 39.43%) and $\pi^0\pi^+\pi^-$ (BR = 22.6%) decays [57]. Photons from the direct $\gamma\gamma$ channel as well as from the secondary (daughter) π^0 decays are measured in the PHENIX EMCal, which has a pseudorapidity acceptance of $-0.35 < \eta < 0.35$ and covers π radians in azimuth. The electromagnetic calorimeter is divided into eight sectors with two distinct detection technologies (see Fig. 1). A lead-scintillator calorimeter (PbSc) consists of 15,552 individual lead-scintillator sandwich modules ($5.54 \times 5.54 \times 37.5$ cm, $18X_0$), grouped in six sectors located at a radial distance of 5.1 m from the beam line, covering a total solid angle of $\Delta\eta \approx 0.7$ and $\Delta\phi \approx 3\pi/4$. A lead-glass Čerenkov calorimeter (PbGl) comprising two sectors, with a total of 9,216 modules ($4 \times 4 \times 40$ cm, $14.4X_0$), is located at a radial distance of ~5 m from the beam pipe and covers a total solid angle at midrapidity of $\Delta\eta \approx 0.7$ and $\Delta\phi = \pi/4$. The corresponding $\Delta\eta \times \Delta\phi$ acceptance of a single tower at $\eta = 0$ is 0.011×0.011 and 0.0075×0.0075 for the PbSc and PbGl calorimeters, respectively. The chosen transverse size of the towers is not much larger than their corresponding Molière radius ($\rho_M = 3.0$ cm and 3.7 cm for PbSc and PbGl, respectively) so that most of the electromagnetic showers extend over several modules, resulting in an improved position resolution based on a "center of gravity" reconstruction of the impact point of the photon clusters.

The energy calibration of the PbSc modules was obtained from the original beam-test values and redundantly confirmed with (i) the position of the reconstructed π^0 mass peak, (ii) the energy deposit from minimum-ionizing charged particles traversing the calorimeter, as well as with (iii) the expected $E_{\text{PbSc}}/p_{\text{tracking}} \sim 1$ value measured for electrons and positrons identified in the Ring-Imaging Čerenkov (RICH) detector and whose momentum was measured in the tracking detectors. In the PbGl modules, the reference energy calibration from the original beam-test values is corrected with the time-dependent gain corrections obtained with a light-emission-diode (LED) system for the lead-glass calorimeter. The LEDs emit light with known intensity, so gain fluctuations can be detected. The final

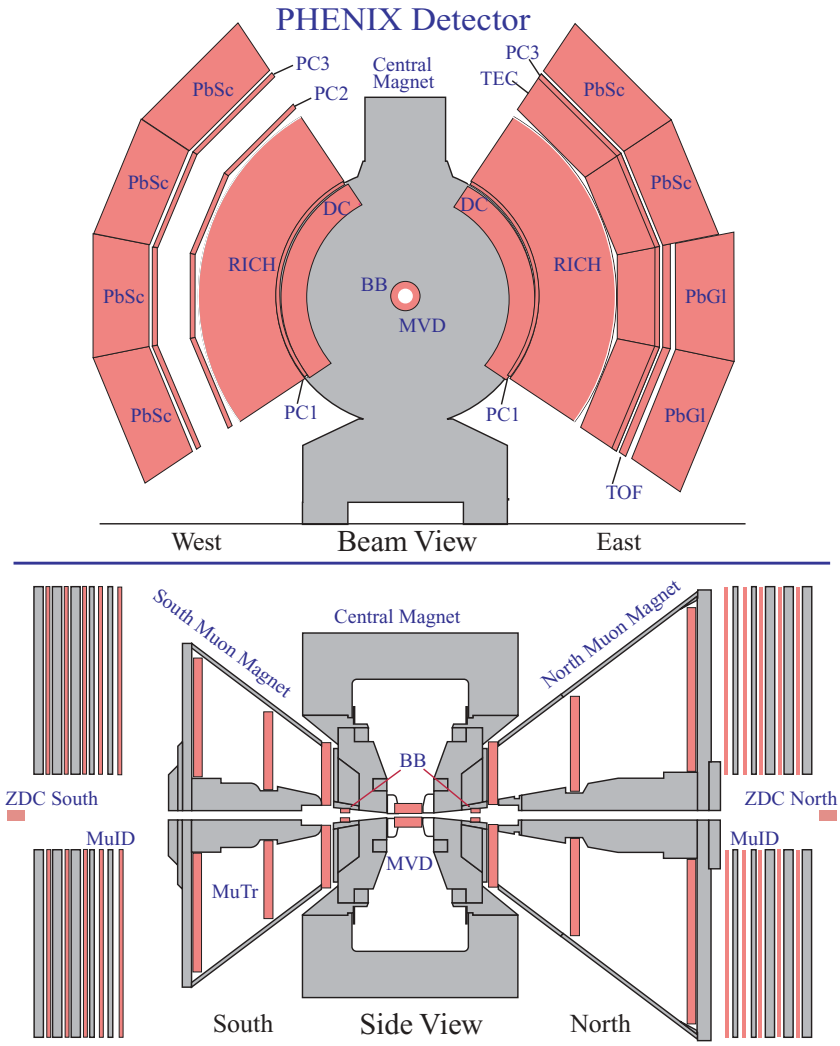

FIG. 1. (Color online) The PHENIX experimental setup during Run-2 and Run-3 at RHIC. The detectors used in the present analysis are the 8 EMCal (PbSc, PbGl) sectors for photon detection ($\eta \to \gamma\,\gamma$), the drift chamber (DC), and two layers of multiwire proportional chambers with pad readout (PC) for charged pion detection ($\eta \to \pi^0\pi^+\pi^-$); as well as the two beam-beam counters (BBC) and the two zero-degree calorimeters (ZDC) for global event characterization.

PbGl calibration is obtained by comparing the measured π^0 peak position to its nominal value.

B. Central arm tracking

Charged pions are measured with the PHENIX central tracking system combining information from the drift and pad chambers. The momenta of the $\pi^{\pm}$ are measured at a radius of 2.0 m from the event vertex by the DC. The DC, located outside the field of PHENIX central magnets, uses several layers of wires to reconstruct the angle of the track, which is inversely proportional to its momentum. The DC momentum resolution is determined to be $0.7 \oplus 1.1\% p_T$ (GeV/c). The polar angle of the track is measured by pad chamber 1 (PC1), a multiwire proportional chamber located just beyond the DC. The last pad-chamber layer, PC3, at a radius of 5.0 m and directly in front of the EMCal, is used in this analysis for two purposes: to confirm the track by matching to a PC3 hit, as well as to veto an EMCal cluster produced by a charged particle track.

The DC momentum scale is checked by the reconstruction of the correct mass of (i) $\pi^{\pm}$, $K^{\pm}$, p, $\bar{p}$ identified with the time-of-flight (TOF) system [58] and (ii) ω, ϕ, J/Ψ mesons decaying into the e^+e^- channel identified with the RICH and EMCal. The momentum scale is thus known with an accuracy better than 0.2%. Because at low p_T, the momentum resolution is better when measured with the tracking system than that using the energy measured via calorimetry, and given that the momentum range of the three η decay products has a relatively low p_T, the uncertainties in the tracking system calibration are less important in the $\pi^0\pi^+\pi^-$ measurement than in the $\gamma\gamma$ decay channel. As a result, the tracking devices provide better accuracy for the η mass reconstruction than the EMCal.

C. Global detectors

Triggering and global event characterization is achieved using the BBC and the ZDC. The two BBC are placed around the beam pipe 1.44 m in each direction from the nominal interaction point. Each BBC consists of 64 hexagonal quartz Čerenkov radiators closely packed in an approximately azimuthally symmetric configuration. The BBC are used to count the charged particle multiplicity in the pseudo-rapidity range $3.0 < |\eta| < 3.9$, to provide the start time for TOF

TABLE I. Events sampled and integrated luminosity (after vertex cuts) in the η analyses for $p+p$, d+Au, and Au+Au collisions. The equivalent $p+p$ luminosities in d+Au (Au+Au) have been obtained normalizing their corresponding luminosities by 2 A (A^2) factors as expected for hard cross-section scaling.

Collision system	Events sampled		Total integrated luminosities		BBC attributes	
	MB (LVL1) trigger	High-p_T (γ) trigger	Absolute	Equivalent $p+p$	Cross section	Efficiency
$p+p$	25.2×10^6	49.3×10^8	216 nb^{-1}	216 nb^{-1}	23.0 mb $\pm$ 9.7%	(55 $\pm$ 5)%
d+Au	58.3×10^6	29.2×10^8	1.5 nb^{-1}	590 nb^{-1}	1.99 b $\pm$ 5.2%	(88 $\pm$ 4)%
Au+Au	34×10^6	30×10^6	9 μb^{-1}	230 nb^{-1}	6.315 b $\pm$ 8.4%	(92 $\pm$ 3)%

measurement, and to give the collision vertex position along the interaction diamond with a typical resolution of 0.6 (2) cm in Au+Au ($p+p$) collisions [55]. In d+Au collisions, the centrality of the collision is determined by measuring the charge deposited in the BBC in the *Au* beam direction [59]; whereas in Au+Au reactions, the correlation between the BBC charge sum and the ZDC total energy is used for centrality determination [60] (see the next section). The ZDC are small hadronic calorimeters that measure the energy carried by spectator neutrons at very forward angles. They are placed 18 m up- and downstream of the interaction point along the beam line ($|\theta| < 2$ mrad). Each ZDC consists of three modules with a depth of 2 hadronic interaction lengths read out by a single photomultiplier tube (PMT). Both time and amplitude are digitized for each PMT along with the analog sum of the three PMT signals for each ZDC.

III. DATA ANALYSIS

In this section, we describe the event selection criteria, the reaction centrality determination in d+Au and Au+Au collisions, the η identification and reconstruction procedures in the $\eta \to \gamma\gamma$ and $\eta \to \pi^0\pi^+\pi^-$ channels and the various corrections (geometrical acceptance, reconstruction efficiency, trigger, absolute cross-section normalization) applied to the raw data. The systematic uncertainties of the measurements are discussed at the end of the section.

A. Event selection

The data presented in this article were collected under two general trigger conditions. The first sample, consisting of minimum-bias (MB) events with vertex position along the beam axis $|z| < 30$ cm, was conditioned on a local-level-1 (LVL1) trigger generated by coincidences between the two BBC (in the case of $p+p$ and d+Au) or by coincidences between the BBC and ZDC detectors (in the case of Au+Au). The MB trigger cross sections measured by the BBC in $p+p$ and d+Au collisions are, respectively, 23.0 mb $\pm$ 9.7% mb and 1.99 b $\pm$ 5.2% [61], whereas the Run-2 Au+Au minimum bias trigger has some inefficiency for the most peripheral interactions and records only $92.2^{+2.5}_{-3.0}$% of $\sigma_{\mathrm{Au\ Au}}$ [19]. In other words, the LVL1 triggers accept, respectively, (55$\pm$5)%, (88$\pm$4)%, and (92$\pm$3)% of the total inelastic cross sections: $\sigma_{pp}^{\mathrm{inel}} = 42 \pm 3$ mb, $\sigma_{dAu}^{\mathrm{inel}} = 2260 \pm 100$ mb, and $\sigma_{\mathrm{Au\ Au}}^{\mathrm{inel}} = 6850 \pm 540$ mb. A second "photon-triggered" sample, requiring electromagnetic showers above a given threshold in the EMCal (with or without the MB BBC requirement), has been used to extend the η measurements to higher p_T. The details of this level-2 (LVL2) software trigger are described in Ref. [21]. The total number of events collected in the MB and photon-triggered samples (after vertex cuts) as well as the integrated luminosities for each collision system are listed in Table I.

B. Centrality determination (d+Au, Au+Au)

The events in d+Au collisions are classified into four different centrality classes given in percentiles of the total cross section: 0–20%, 20–40%, 40–60% and 60–88%, with the latter being the most peripheral. The reaction centrality is related to the number of hits in the south beam-beam counter (BBCS), which is proportional to the number of participant nucleons in the gold nucleus [59]. The distribution of the normalized charge in the BBCS and the classification into different centrality classes is shown in Fig. 2. To obtain reasonably large

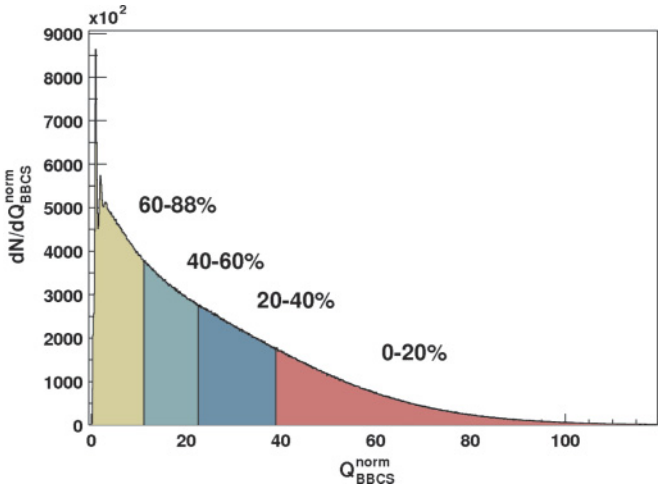

FIG. 2. (Color online) Distribution of the normalized charge in the south beam-beam counter (BBCS) in d+Au collisions at $\sqrt{s_{NN}} =$ 200 GeV. The normalization is done such that the normalized charge corresponds to the number of hits.

TABLE II. Values of the average nuclear overlap function $\langle T_{dA}\rangle$ and $\langle T_{AA}\rangle$ for the different centralities considered in d+Au and Au+Au reactions, respectively.

Centrality bin	$\langle T_{dA}\rangle$ (mb^{-1})	$\langle T_{AA}\rangle$ (mb^{-1})
Min bias	0.20 ± 0.01	6.14 ± 0.45
0–20%	0.36 ± 0.02	18.5 ± 1.3
20–40%	0.25 ± 0.017	—
20–60%	—	4.6 ± 0.4
40–60%	0.17 ± 0.014	—
60–88%	0.073 ± 0.007	—
60–92%	—	0.3 ± 0.1

statistics in each Au+Au centrality class, three centralities are used in the current Au+Au analysis: 0–20% (central), 20–60% (semicentral), and 60–92% (peripheral), determined by cuts in the correlated distribution of the charge detected in the BBC and the energy measured in the ZDC [60]. A Glauber Monte Carlo model combined with a simulation of the BBC (plus ZDC) response allows determination of the mean value of the associated nuclear overlap function $\langle T_{dA}\rangle$ ($\langle T_{AA}\rangle$) for each d+Au (Au+Au) centrality bin. Table II lists the mean value of the nuclear overlap function for different centralities in both systems.

C. $\eta \to \gamma\,\gamma$ Reconstruction

The main mode of η-meson reconstruction in PHENIX is via the electromagnetic channel $\eta \to \gamma\,\gamma$. PHENIX has published the results of a number of $\pi^0 \to \gamma\,\gamma$ measurements in the EMCal for different colliding systems [14–21]. The technique for identifying the photons and reconstructing the π^0 yields as a function of p_T and centrality is now well established and is exactly the same one used here to obtain the corresponding η yields. Although the reconstruction methods are identical, the p+p and d+Au analyses do not suffer from the large particle multiplicity background that the Au+Au η reconstruction faces, and there are a few differences between Au+Au and the other studies. In the Au+Au case, the applied analysis cuts (photon identification, invariant mass reconstruction, and other cuts) are tighter than in the p+p and d+Au cases. Additionally, to deal with cluster overlap effects appropriately, the Au+Au analysis uses a full GEANT [62] Monte Carlo (MC) simulation, in which the simulated single η are embedded into real events rather than a tuned fast MC simulation without embedding. These differences are explained in separate subsections below.

1. Photon reconstruction in EMCal

Electromagnetic clusters are reconstructed in the EMCal sectors by finding contiguous calorimeter towers with pulse heights above the ADC pedestal value. The energy of each EMCal cluster is corrected for angular dependence and nonlinearity based on test-beam results and simulation. The linearity correction for the two detector types is different, with the PbGl having a stronger dependence on the energy. The correction factors for a photon with a detected energy of 1 GeV (10 GeV) are 1.00 (0.95) for the PbSc and 1.05 (0.975) for the PbGl, respectively. The PbGl calorimeter also shows a stronger variation of the measured photon energy with the angle of incidence on the detector surface: at 20° the measured energy is reduced by 5% compared to perpendicular incidence (0°), whereas in the PbSc this reduction is only of the order of 2%.

Because we are interested in high-p_T η production, only EMCal clusters with energy above 1 GeV are selected for further analysis. In addition, fiducial cuts excluding the edges of each EMCal sector, as well as an area of 3×3 towers around the towers that have been determined to be hot or dead, were applied to exclude clusters with incorrectly reconstructed energies. Among the clusters passing the cuts, photon candidates are identified by applying standard particle identification (PID) cuts based on TOF and shower profile. Both cuts are applied to reject slower and broader showers that are mostly of hadronic origin. For the PbSc we require the measured cluster TOF to be $t_{\rm clust} < L/c \pm 1.2$ ns where L is the straight-line path from the collision vertex to the reconstructed cluster centroid. For the PbGl we require reconstructed clusters to have times, $t_{\rm clust} < L/c \pm 2$ ns; the difference is due to the difference in intrinsic timing resolution of the two calorimeter technologies. Shower profile cuts are based on rejecting those clusters whose energy deposition among the modules, and in particular in the most central tower of the cluster, is not consistent, within a given χ^2-test limit, with the shower shape expected for electromagnetic showers as parametrized from test-beam data [52].

In the most central Au+Au events, the EMCal typically detects $\gtrsim$300 clusters, corresponding to a detector occupancy of $\sim$10% in terms of hit towers, resulting in a non-negligible probability of particles making clusters which overlap. To minimize the effects of cluster overlaps due to high multiplicity, two methods are used to determine the cluster energy. First the energy of each cluster in the PbSc calorimeter is determined from the sum of all contiguous towers with deposited energy above a given threshold ($E_{\rm tower} = 15$ MeV, typically). Alternatively, an extrapolation (using a standard electromagnetic shower profile for an event with zero background) from the measured core energy (*ecore*) in the four central towers to the full cluster energy is used. For the latter case, the *ecore* energy was computed from the experimentally measured center of gravity, central shower energy, and impact angle in the calorimeter using a parametrized shower profile function obtained from electromagnetic showers measured in the beam tests. Such an *ecore* energy represents an estimate of the true energy of a photon impinging on the PbSc unbiased by background contributions from other particles produced in the same event and depositing energy in the neighborhood of a given cluster. The use of *ecore* instead of the total cluster energy for photon reconstruction helped considerably to minimize the effects of cluster overlaps in central Au+Au collisions.

2. Raw η yield extraction (p+p and d+Au)

The η yields are obtained by an invariant mass analysis of photon candidate pairs having asymmetries $\alpha = |E_{\gamma_1} -$

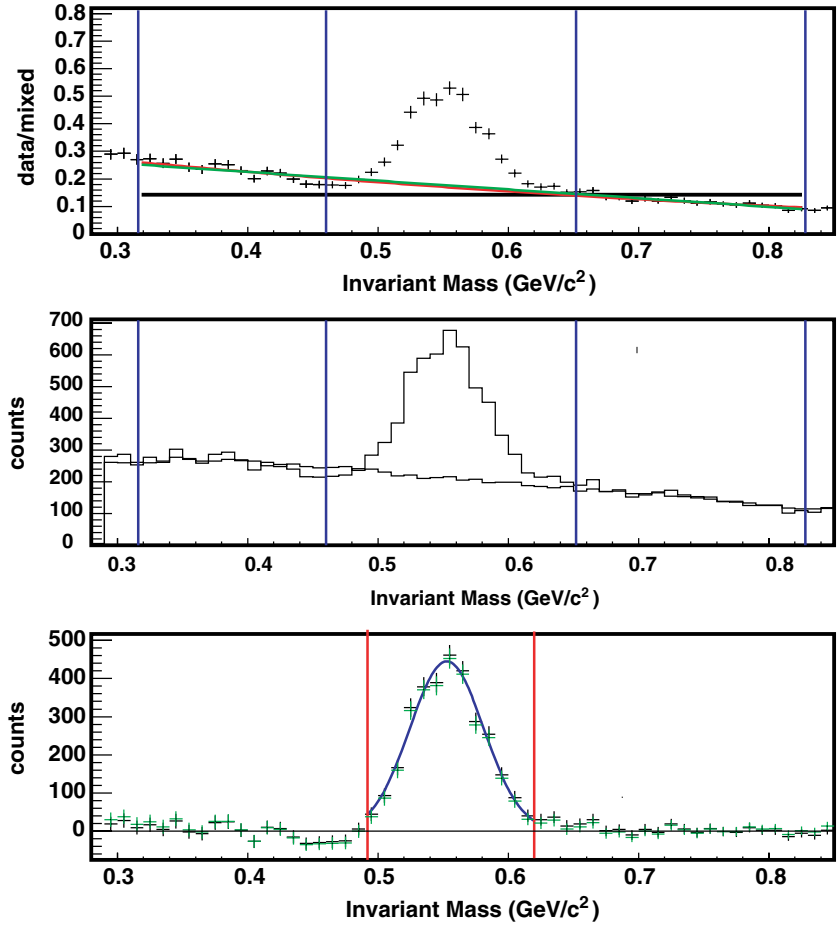

FIG. 3. (Color online) Invariant mass distribution of photon candidate pairs measured in $p+p$ collisions for the default PID cuts with pair transverse momenta 4.0 GeV/c < p_T < 4.5 GeV/c. (Top) Ratio of real and mixed event distributions, and background fits. The red fit is used for the background parametrization and the green fit for estimating the systematic uncertainty. (Middle) Real invariant mass spectrum and scaled background. (Bottom) Final distribution with the scaled background subtracted from the real event distribution (black entries); the green entries result from the background fit for estimating the systematic error. Additionally, the peak is fitted with a Gaussian to get its mean and σ.

$E_{\gamma_2}|/(E_{\gamma_1} + E_{\gamma_2}) < 0.7$. The cut on the asymmetry α reduces the background because high-p_T combinatorial pairs are strongly peaked near $\alpha = 1$ due to the steeply falling spectrum of single-photon candidates. The resulting invariant mass spectra obtained for proton-proton and deuteron-gold collisions are shown in Figs. 3 and 4, respectively, for two typical p_T bins. A peak is seen at about 550 MeV/c^2, the expected mass of the η meson. The measured peak position is modified by detector effects that lead to energy smearing. The combined effects of the energy resolution of the detector, the steeply falling single-photon spectrum, and the finite size of the energy bins lead to a smearing of the measured photon energies that widens the η signal. As a result the average peak position in the invariant mass spectra is about 9 MeV/c^2 larger than the nominal mass of the η meson, an effect that is well reproduced by the simulation.

The combinatorial background below the peak signal is estimated with the event mixing method in which clusters from different events with similar event vertex (and centrality class in d+Au) are combined to produce a "background" invariant mass distribution. This background is normalized to the real invariant mass spectrum and then subtracted from the invariant mass spectrum of the real events. To estimate the normalization of the background, the distribution of the real events is first divided by the mixed event distribution. This ratio is shown in the upper panel of Figs. 3 and 4. The normalization function is estimated by a fit in the region outside the peak. The spectrum, fitted to a second-degree polynomial, is shown in the region denoted by the vertical lines in the upper and the middle panels of Figs. 3 and 4. The final real event mass distribution after the background subtraction is shown in the lower panel of Figs. 3 and 4.

The interval over which the background is adjusted is limited by two considerations: the expected η peak position m and width σ. Both were estimated in a first analysis of the spectra and set to $m = 556$ MeV/c^2 and $\sigma = 32$ MeV/c^2. The background interval includes the region between $m - 7.5\sigma$ and $m + 8.5\sigma$ (320 and 830 MeV/c^2) excluding the peak region $m \pm 3\sigma$ (460 MeV/c^2 < m_{inv} < 650 MeV/c^2). For higher transverse momenta, the background almost vanishes and thus the estimation of the normalization by a fit leads to large errors. Hence an alternative method is used where the fit function is replaced by the ratio of the number of photon pairs in the normalization region in the real and the mixed event distributions.

Finally, the total number of η in a given p_T bin is obtained by integration of the invariant mass distribution within 3σ around the η peak position. The statistical error of the peak extraction is estimated as done for the π^0 and described in Ref. [21]. The uncertainty of the background parametrization is estimated by calculating the error on the ratio of the integrals of the real and the mixed event distributions in the region of the background fit. Above $p_T = 10$ GeV/c in $p+p$ collisions, the mixed event background does not work as expected as there

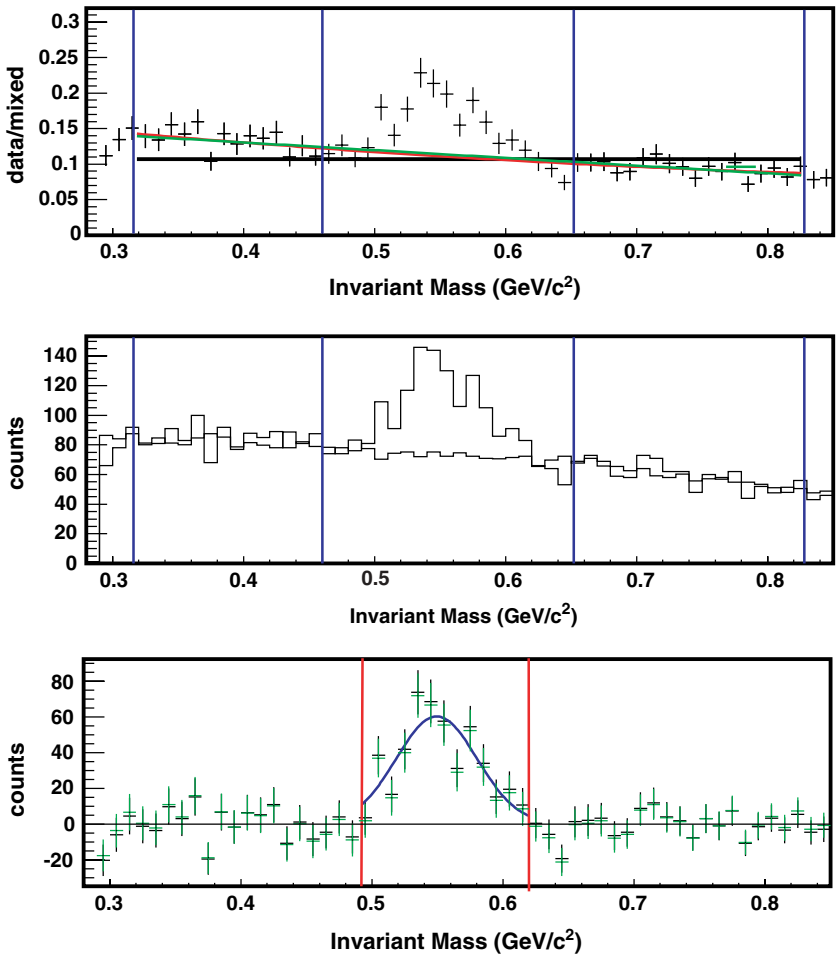

FIG. 4. (Color online) Invariant mass distribution of photon candidate pairs measured in minimum bias d+Au collisions for the default PID cuts with pair transverse momenta 3.5 GeV/c < p_T < 4.0 GeV/c. (Top) Ratio of real and mixed event distribution and background fits (the red fit is used for the background parametrization, the green fit for estimating the systematic uncertainty). (Middle) Real invariant mass spectrum and scaled background. (Bottom) Final distribution with the scaled background subtracted from the real event distribution (black entries). The green entries result from the background fit for estimating the systematic error. Additionally, the peak is fitted with a Gaussian to get its mean and sigma.

are some entries in the mixed event background but not in the η region. For these cases, the background was estimated by integrating the real event distribution outside the peak (in the fit region mentioned above) and scaling this to the η integration region. This background is then subtracted from the real event distribution to get the number of η. The error in this case is estimated with $\sigma^2_{\mathrm{Sig}} = S + 2B$, S being the η signal and B being the background. The integral of the invariant mass distribution after the background subtraction is calculated in a reduced interval $m - 2\sigma; m + 2\sigma$ (492–620 MeV/c^2).

3. *Raw η yield extraction (Au+Au)*

The η yields for Au+Au are determined by calculating the invariant mass of photon pairs with asymmetries $\alpha = |E_{\gamma 1} - E_{\gamma 2}|/(E_{\gamma 1} + E_{\gamma 2}) < 0.5$, a value tighter than that used for the p+p and d+Au cases to reduce the larger uncorrelated background in Au+Au collisions, and binned in p_T. The η yield in each p_T bin is determined by integrating the background-subtracted $\gamma\,\gamma$ invariant mass distribution around the η peak. The combinatorial background is obtained by combining uncorrelated photon pairs from different events with similar centrality and vertex and normalizing the distribution in a region below ($m_{\mathrm{inv}} = 400$–450 MeV/c^2) and above ($m_{\mathrm{inv}} = 750$–1000 MeV/c^2) the η mass peak (Fig. 5 top). After the mixed background subtraction, the resulting distribution is fitted to a Gaussian plus an exponential (or linear, see below) function to account for the residual background—more important at low p_T—not completely removed by the event-mixing technique. The bottom plot in Fig. 5 depicts the η signal after mixed (and residual) background subtraction. To estimate the uncertainty in the subtraction of the residual background, different pair asymmetries and an alternative linear parametrization were used (see Sec. III F). The signal-to-background (S/B) ratio in peripheral (central) Au+Au collisions is approximately 1.3 (1.5) and 0.05 (0.002) for the highest and lowest p_T, respectively. The signal-to-background ratio is comparable for central and peripheral collisions at the highest p_T because the spectrum in the central data extends to higher p_T than that in the peripheral.

The scaled mixed-event distribution is subtracted from the real-event distribution to produce a statistical measure of the true η yield. The result of such a subtraction procedure is shown in the bottom plot of Fig. 5. The raw η yield is obtained by integrating the subtracted invariant mass distribution in a range determined by the mean and the width of the η peak and given by $m_{\mathrm{inv}} \in [m_\eta - 2\sigma_\eta, m_\eta + 2\sigma_\eta]$. The analysis described above is applied in bins of $\Delta p_T = 1$ GeV/c for p_T = 2–4 GeV/c and $\Delta p_T = 2$ GeV/c above. We cease attempting to extract η yields at high p_T when the number of pairs within the

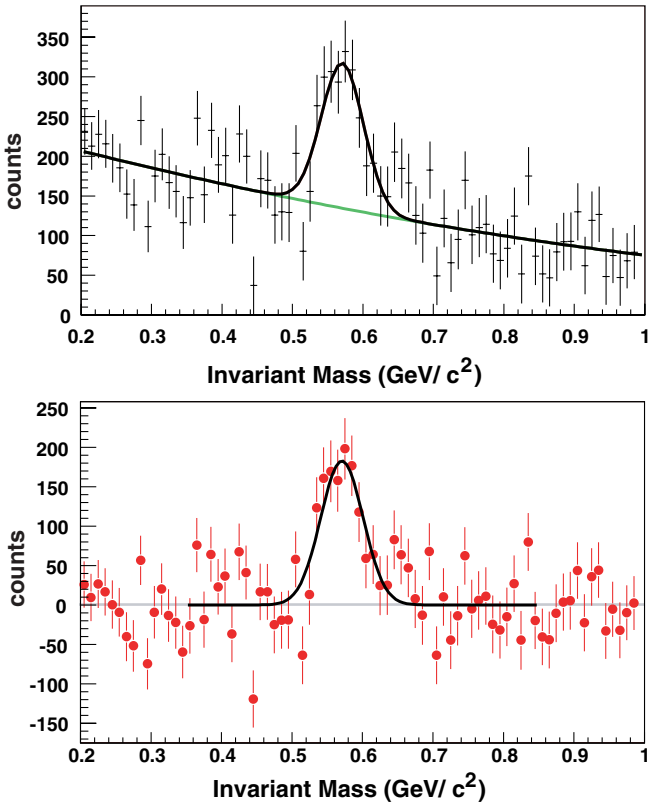

FIG. 5. (Color online) (Top) Invariant mass distribution of pairs of photon candidates measured in minimum bias Au+Au with pair momenta $p_T = 3.5$–4.5 GeV/c around the η mass fitted to a Gaussian plus exponential. (Bottom) Final η signal after mixed-event (and residual) background subtraction.

selected (background-subtracted) η mass window falls below 4 counts.

4. Acceptance correction

The geometric acceptance is evaluated using a fast Monte Carlo (fastMC) program based on routines from the JETSET library [64] to simulate the $\eta \to \gamma\gamma$ decays and determine the geometric acceptance of the calorimeter for the decaying photons. The acceptance correction accounts for the fraction of produced η mesons whose decay photons will not actually hit the detector due to the finite solid angle covered by the detector. A decay photon will be accepted by the EMCal in the fastMC when it hits the active surface of the detector covering the pseudorapidity range $-0.35 < \eta < 0.35$ (computed using a realistic distribution of event vertices within $|z| < 30$ cm) and $2 \times 90^\circ$ in azimuth. The acceptance shows a strong dependence on the transverse momentum because the opening angle of the decay photons decreases with increasing p_T. Thus, the probability that both decay photons hit the detector decreases for small values of p_T. The acceptance for $p+p$ and $d+$Au collisions is shown in Fig. 6. The acceptance is influenced by the geometry of the whole detector as well as by dead and hot modules in the $p+p$ and $d+$Au cases (for Au+Au the efficiency losses due to dead and hot modules are computed from the full GEANT3 simulation plus "embedding" and

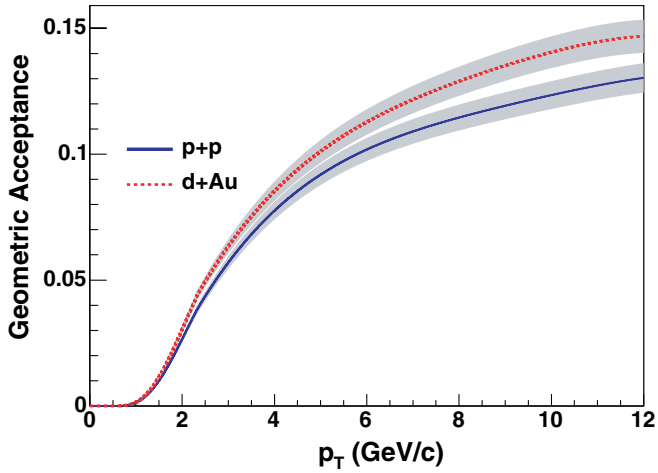

FIG. 6. (Color online) Geometric acceptance (including dead channels) for the η meson as a function of p_T measured in the EMCal in both $d+$Au (dashed curve) and $p+p$ (solid curve) collisions at PHENIX in Run-3.

are accounted for in the *efficiency* loss correction). Due to a different number of masked out modules, the acceptance is not exactly the same in $p+p$ and $d+$Au collisions.

5. Efficiency corrections of the raw η yields ($p+p$, $d+$Au)

a. Reconstruction efficiency correction. The reconstruction efficiency takes into account that the measured η spectrum in the detector is different from the real physical spectrum, i.e., the reconstruction efficiency is defined as the ratio between the output and the input η spectra:

$$\varepsilon(p_T) = \frac{dN_\eta/dp_T|_{\text{output}}}{dN_\eta/dp_T|_{\text{input}}} \tag{1}$$

as obtained using the fastMC, which parametrizes all the detector effects on the input spectrum (EMCal energy and position resolution, efficiency losses due to γ identification cuts and $\gamma\gamma$ reconstruction procedure, etc.). A realistic input η spectrum $dN/dp_T|_{\text{input}}$ is used as an initial spectrum for the efficiency calculation and an iterative procedure is performed, in which the corrected output spectrum is used as the input spectrum of the next iteration. To simulate detector effects, the smeared energies and hit positions of the decay photons are parametrized in the fastMC. The energy smearing has a constant and an energy-dependent term and follows the functional form

$$\sigma_E/E = \frac{A}{\sqrt{E/\text{GeV}}} \oplus B\,. \tag{2}$$

The parameters for Eq. (2) are given in Table III for the different collision systems and the two EMCal detector types. The initial values have been taken from the detector response obtained in the beam tests [52] and retuned for real run conditions in previous π^0 analyses [14,15]. During the cross-checks between simulated and real data it was found that the energy scale of the EMCal was slightly shifted compared to the parametrized results. Because the energy

TABLE III. Parameters for energy smearing, Eq. (2), as used in the fastMC for the different EMCal detector types and the different collision systems.

Collision system	Detector type	Energy-dependent term (A)	Constant term (B)
$p+p$	PbGl	0.085	0.059
$p+p$	PbSc	0.082	0.050
d+Au	PbGl	0.085	0.059
d+Au	PbSc	0.082	0.050

scale is estimated experimentally by fitting the location of the π^0 peak, and the position of the peak is also affected by reconstructed secondary neutral pions from K_s^0 decays that themselves decay off vertex, an additional correction is applied in the fastMC shifting the energy scale by 0.7%. After this correction, the position and the width of the simulated η peaks are confirmed to be consistent with the position and the width measured in the data for all p_T bins.

The efficiency correction also takes into account the different cuts used for particle identification. The simulation must consider the loss of photons and thus of η due to the applied shower shape (or "dispersion") and energy threshold cuts. The effect of the dispersion cut is estimated by a comparison of uncorrected spectra without a PID cut with the spectra obtained with the different PID cuts. The spectra are obtained with a sharp asymmetry (α) cut and as a function of $(E_1 + E_2)/2$. The resulting loss of η is translated into a photon loss probability, which is then used in the simulation. The energy cut is reproduced by rejecting photon hits according to an energy-dependent survival probability in the simulation. Finally, the simulation reconstructs the invariant mass and the transverse momentum of the η from the reconstructed (smeared) information. Only particles inside the interval used for the integration of the real peak are accepted. The overall η efficiency losses obtained by this method are of the order of $\varepsilon_{\eta\to\gamma\gamma} = 76\% \pm 3\%$ (dominated by the asymmetry cut and the invariant mass yield extraction procedure) and are flat within 1–2% in the whole p_T range measured for both ($p+p$ and d+Au) colliding systems.

b. Photon conversion correction. Some of the produced η are not reconstructed due to conversions of one or both decay photons in the inner regions of the PHENIX detector. Such an effect is not included in the fastMC and is computed independently using a full simulation of the detector including a realistic description of the material in front of the EMCal. The correction factors obtained from this analysis are 1.067 ± 0.003 for PbSc West, 1.052 ± 0.004 for PbSc East, and 1.076 ± 0.005 for PbGl, as the material between the collision vertex and the EMCal is different in the east and the west arm and between PbGl and PbSc.

6. *Efficiency corrections of the raw η yields (Au+Au)*

In the Au+Au case, the detection efficiency is determined using a full PISA (PHENIX Integrated Simulation Application) GEANT3-based Monte Carlo (MC) program of the PHENIX detector to simulate the complete response of the calorimeter to single η decays. The nominal energy resolution was adjusted in the simulation by adding an additional p_T-independent energy smearing of ~3% for each PbSc tower. The shape, position, and width of the η peak measured for all p_T and centralities were thus well reproduced by the simulated data. The data from each simulated η is embedded into real Au+Au events and the efficiency for detecting the embedded η is evaluated analyzing the merged events with the same analysis cuts used to obtain the real yields. Using this technique we determine efficiency corrections that account not only for the energy resolution and position resolution of the calorimeter but also for the losses due to overlapping clusters in a real Au+Au event environment. The embedding also permits a precise determination of the effect of edge cuts and bad modules. Though these effects can in principle be considered as geometric acceptance corrections (as done in the $p+p$ and d+Au analyses), they depend not only on the geometry but also on the energy deposition of an electromagnetic shower in the different calorimeter towers. Last, in the full-simulation plus embedding procedure we additionally have control over the effects of photon conversions, as the GEANT simulation considers the material in front of the EMCal and the information whether a decay-photon converts is kept for evaluation in the efficiency determination.

The input η spectrum embedded in real events is weighted to match a functional form fit to the measured η spectrum so that the correct folding of the η spectrum with the resolution is obtained. This procedure is iterated, with the fit of the p_T dependence of the input weights adjusted as the estimate of the efficiency correction improves, until the procedure converges within the nearly p_T-independent statistical error of the embedded sample, approximately 3%. The final overall η yield reconstruction efficiency correction factor was ~3 with a centrality dependence of $\lesssim$20%. The losses were dominated by fiducial and asymmetry cuts.

D. $\eta \to \pi^0\pi^+\pi^-$ Reconstruction

1. *Raw η yield extraction*

The second mode of η-meson reconstruction in PHENIX is via the three-body decay channel $\eta \to \pi^0\pi^+\pi^-$ with branching ratio BR = 22.6% ± 0.4%. This mode has been used for the $p+p$ and d+Au data but not for the Au+Au where the large detector occupancy makes the signal very difficult to extract. Reconstruction starts with identifying the π^0 candidates among the pairs of EMCal γ clusters with energy $E_\gamma > 0.2$ GeV in the same way described in the previous section for the direct $\eta \to \gamma\gamma$ channel. The mass of a candidate is required to be within two standard deviations from the peak position of π^0. The peak position and its width are determined by the π^0 decay kinematics and EMCal resolution for each of the clusters and its position. These parameters were found to be consistent with the expected values. Selected π^0 candidates with transverse momentum $p_T > 1.0$ GeV/c are assigned the exact mass of the meson and measured p_T of the pair. These candidates are further combined into triplets with

positive and negative particle tracks measured by DC and PC1 to have momentum in the range $0.2\ \text{GeV}/c < p_T < 4.0\ \text{GeV}/c$. No particle identification was used on the charged tracks.

To extract the raw η yields the mixed-event subtraction technique was not used in this case because it does not adequately reproduce the shape of the background in the real events. The most important physical reason for this is that there are a significant number of correlated tracks among the $\pi^+\pi^-$ pairs coming from various heavier particle decays. The yield extraction was done by simultaneous fitting of the peak and the background in the adjacent region. The characteristic peak in the three-particle mass distribution is shown in the top panel of Fig. 7. The position of the peak is consistent with the nominal mass of the η meson within the statistical error of the fit shown in the figure. The measured 8 MeV/c^2 width of the peak is narrower than in the $\eta \to \gamma\,\gamma$ decay channel. Unlike the $\gamma\,\gamma$ channel, where the full width of the peak is defined

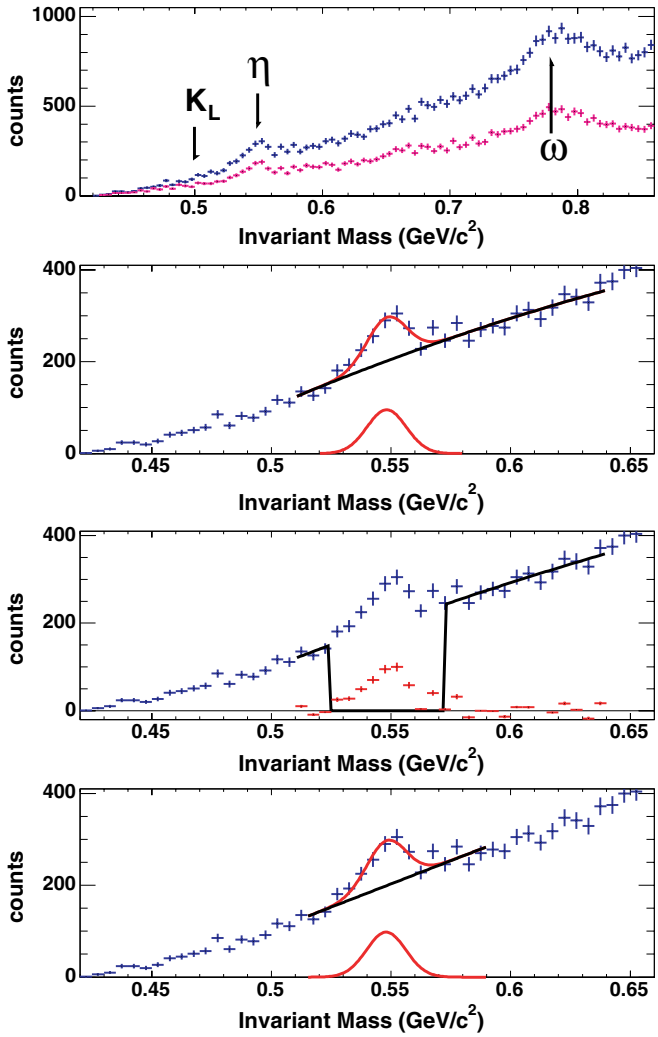

FIG. 7. (Color online) Invariant mass distribution of pion triplets ($\pi^0\pi^+\pi^-$) measured in $p+p$ collisions at $\sqrt{s} = 200$ GeV in the range $m_{\text{inv}} = 0$–0.9 GeV/c^2 (top panel) showing η- and ω-meson peaks. Lower panels showing η-mass region $m_{\text{inv}} = 0.42$–0.66 GeV/c^2 demonstrate three different methods of the extraction of the raw yields. See text for a detailed explanation of each method.

by the EMCal resolution alone, in $\pi^0\pi^+\pi^-$ only 1/4 of the measured mass is derived from an EMCal-based measurement. Given the relatively low p_T of the decay products, tracking has better resolution than the calorimeter. These two effects result in higher accuracy of the mass measurement and smaller width of the peak compared to the $\eta \to \gamma\,\gamma$ analyses.

The raw yield numbers were extracted by simultaneously fitting the signal with a Gaussian function and the background to a quadratic function. The fit was limited to the mass window of 510 MeV/$c^2 < m_{3\pi} <$ 640 MeV/c^2. The lower limit is chosen to avoid the region where the $K^0_L \to \pi^0\pi^+\pi^-$ decay (branching ratio BR = 13%) yields an additional signal at and above $m_{K^0_L} = 498$ MeV/c^2. The upper limit is chosen at a safe distance from the $\omega \to \pi^0\pi^+\pi^-$ (BR = 89.1%) peak at 782 MeV/c^2 with a width of 20–25 MeV/c^2. An example of the fit is shown in the second panel in Fig. 7. We also compared the result of such a combined signal+background fit with separate fitting of the background. For that, the region under the peak, 530 MeV/$c^2 < m_{3\pi} <$ 570 MeV/c^2, was rejected from the fit and the background was approximated by the quadratic function. The function was interpolated and subtracted from the histogram in Fig. 7 (third panel). The histogram counts in the region initially rejected were summed up to calculate the yield.

In addition, simultaneous fitting was done in the restricted window below $m_{3\pi} <$ 580 MeV/c^2, with the background approximated by a linear function. The same three fits were repeated applying an additional condition in the analysis. Each charged track was required to match a hit in PC3 or in the EMCal in case a track missed the active area of PC3. The resultant invariant mass spectrum is shown by the lower curve in the top panel of Fig. 7. The amplitude of the signal is reduced by about a factor of 2 because many tracks fall outside the acceptance of these two detectors, but the background is also reduced and, more importantly, modified in its shape. The overall significance of the results with and without matching is approximately the same. Signal loss due to matching can be corrected with the simulation with small systematic uncertainty and the results can be compared to deduce the accuracy of the yield extraction procedure. Thus, for each p_T point we obtain six statistically correlated measurements of the raw yields. The first measurement with its statistical error is used in further analysis and the variance of the six measurements provides the estimate of the systematic errors of the yield extraction.

2. *Acceptance and efficiency corrections of the raw η yields*

Similar corrections as described for the $\gamma\,\gamma$ decay channel need to be applied to the $\eta \to \pi^0\pi^+\pi^-$ raw yields. However, for the three-pion analysis, we use the full detector simulation and both corrections, namely the acceptance and the efficiency corrections, are computed at the same time. A MC hadron decay generator was used to produce initial η mesons with a p_T distribution providing satisfactory statistical significance in all bins after acceptance and trigger losses. The full GEANT-based PISA simulation was updated with the three-body decay of the η meson and used to decay η mesons. PISA also performs the full simulation of the PHENIX detector and generates the response of all its subsystems up to the electronics-signal

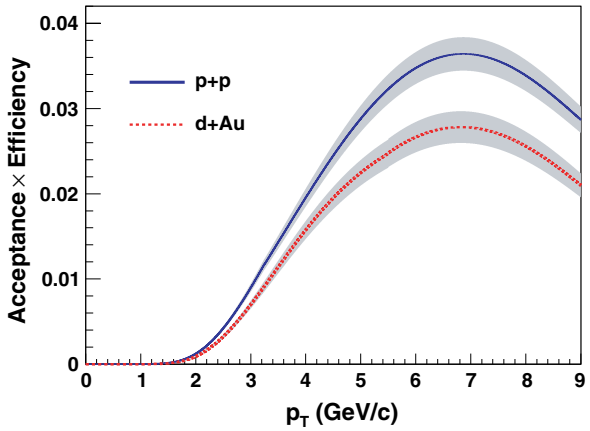

FIG. 8. (Color online) Acceptance×efficiency for the $\eta \to \pi^0\pi^+\pi^-$ as a function of p_T in both d+Au (dashed curve) and p+p (solid curve) collisions at PHENIX in Run-3.

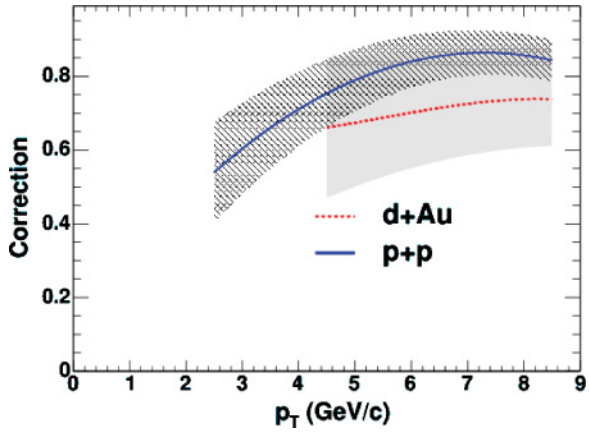

FIG. 10. (Color online) Phase-space density correction for p+p (solid curve) and d+Au (dashed curve) event samples as a function of p_T.

level, which was then processed by standard PHENIX reconstruction software. Special attention was paid to verify that the simulation code represented the real configuration of the detector, and that the π^0 peak parameters in the real data and simulation were consistent with each other. The reconstruction of the simulated data was carried out using the same steps and tools as the real data.

Figure 8 shows the combined efficiency×acceptance as a function of p_T for the three-pion decay analysis. To compare this with the $\gamma\,\gamma$ decay channel reconstruction efficiency one needs to multiply the acceptance curve shown in Fig. 6 with the obtained $\varepsilon_{\eta\to\gamma\,\gamma} = 76\% \pm 3\%$ overall efficiency loss. The three-body decay combined acceptance is significantly lower than the acceptance of the $\gamma\,\gamma$ decay channel. With comparable branching ratios of the two modes the resulting statistics in the three-body decay mode is expected to be smaller. The decrease of the efficiency at high p_T is due to the momentum cut on the $\pi^{\pm}$ to be below 4.0 GeV/c. Above that threshold the track sample is contaminated by products of in-flight decays of long-lived particles with mismeasured momentum.

3. *Phase-space density correction*

The $\eta \to \pi^0\pi^+\pi^-$ decay channel required an additional correction to take into account the uneven distribution of the momenta of the three pions within the kinematically allowed region. Such a distribution, taken from Refs. [65–67], is shown in the left panel of Fig. 9. The vertical axis is the fraction of kinetic energy carried by the π^0 in the η-meson rest frame. The horizontal axis shows the difference between kinetic energies of π^- and π^+ divided by the total in the same system. The left plot of Fig. 9 shows that on average the π^0 meson carries less kinetic energy, and thus momentum, than the two charged π mesons. The right panel shows the PHENIX reconstruction efficiency including geometrical acceptance, high-p_T trigger efficiency (see the next section), and analysis cuts. The latter two effectively select higher momentum π^0 and lower momentum $\pi^{\pm}$ in the lab frame. In the η-meson rest frame these translate into the effect opposite of what is shown in the left panel. To correct for that we used the following approach. The uniform distribution of the phase-space density produced by the simulated event generator was weighted according to the known probabilities of the π-meson momenta to be observed in the η-meson decay. The corresponding correction was deduced by comparing the reconstruction efficiencies with and without applying weights. The systematic uncertainties associated with the measurement of the phase-space density accuracy were thus obtained. This correction is shown in Fig. 10. The correction factor is calculated in the range where data is available.

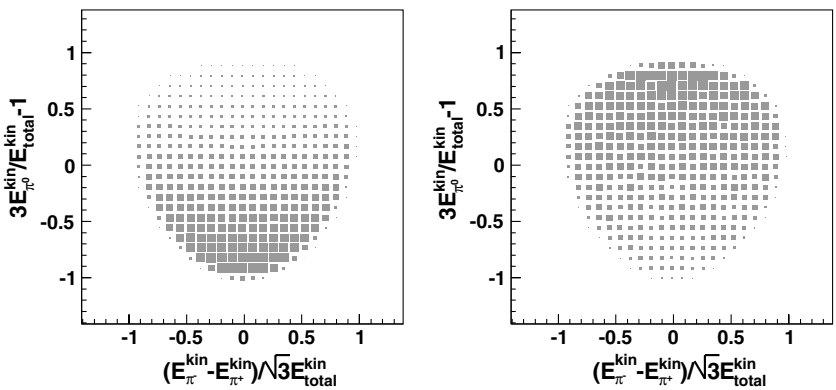

FIG. 9. The phase-space density of the $\eta \to \pi^0\pi^+\pi^-$ decay [65–67] (left panel). PHENIX reconstruction and trigger efficiencies in p+p for the $\eta \to \pi^0\pi^+\pi^-$ decay (right panel).

TABLE IV. Correction factors ($\varepsilon_{\rm trig}/\varepsilon_\eta$), due to the efficiency of the MB trigger for different d+Au centralities [59].

Collision system	Correction factor
d+Au 0–20% central	0.95
d+Au 20–40% semicentral	0.99
d+Au 40–60% semiperipheral	1.03
d+Au 60–88% peripheral	1.04

E. Trigger corrections and absolute cross-section normalization

1. Minimum-bias trigger efficiency

The minimum bias trigger does not detect every collision; only a certain fraction $\varepsilon_{\rm trig}$ of the inelastic collisions and a fraction ε_η of the η mesons can be observed. The spectra have to be corrected for both of these effects. The correction factors $\varepsilon_{\rm trig}/\varepsilon_\eta$, determined in Ref. [59] for d+Au collisions, are shown in Table IV. In the case of p+p collisions, as well as in MB d+Au collisions, one can directly determine the inelastic η cross section. Therefore, one does not apply the correction factors mentioned above but rather multiplies the spectra by the total cross section observed by the BBC, found to be 23.0 mb ± 9.7% in Run-3 p+p collisions and 1.99 b ± 0.10 b in Run-3 d+Au collisions [63]. An additional correction has to be applied for the bias of the BBC to high-p_T η. It is found to be 0.79 for p+p [17] and 0.94 for d+Au [63] collisions.

2. High-p_T γ-trigger efficiency

The efficiency of the high-p_T trigger has to be studied as well to get η spectra for the γ-triggered data at high transverse momenta, as previously performed for PHENIX π^0 analyses [14,21]. The γ triggers in PHENIX are implemented by adding together amplitudes in 4×4 adjacent EMCal towers during data taking and comparing them to a preset threshold. In the case of p+p the threshold was set to correspond to $E_\gamma = 1.5$ GeV, whereas for d+Au it was set at $E_\gamma = 3.5$ GeV. In the case of Au+Au, triggering was performed by a LVL2 software algorithm run over the MB-triggered events during data taking, such that the number of rejected minimum bias events were recorded. This allowed two different threshold triggers to be employed based on event centrality in Au+Au: $E_\gamma = 1.5$ GeV for the 60–92% peripheral sample and $E_\gamma = 3.5$ GeV for the more central event selections.

The trigger efficiency curves versus the energy of a single photon for two different threshold settings used in p+p and d+Au collisions are shown in the top panel of Fig. 11. Based on these curves, the 2-γ efficiency is calculated as for the previous π^0 analyses [14,21] using the fastMC calculation. For this calculation, the single-photon trigger turn-on curve is represented by an integrated Gaussian for the d+Au analysis and by the integrated sum of two Gaussians for the p+p analysis. In the case of the Au+Au LVL2 triggers, the high-statistics measurement of the single-photon efficiency, which

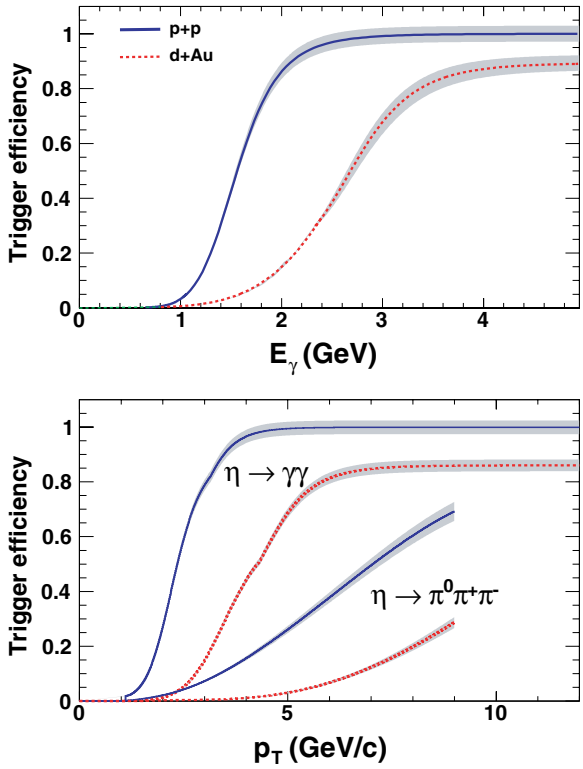

FIG. 11. (Color online) Simulation result for the efficiency of the γ trigger in d+Au collisions. The γ trigger efficiency for a single γ is shown in the top panel for p+p (solid curve) and d+Au (dashed curve). The gray band is the error of the measurement. The lower panel shows the recalculated trigger efficiency for $\gamma\,\gamma$ and $\pi^0\pi^+\pi^-$ channels for both collision systems.

for the central trigger reaches ∼100% above threshold, is used itself as shown in the top panel of Fig. 12. The derived π^0 efficiency is checked by comparing the ratio of the number of π^0 in MB events that carry the trigger flag to the number of π^0 in all MB events. In this way the normalization of the LVL2 data sample relative to the MB data sample is confirmed to be accurate to 2%.

In the same way we determine the $\eta \to \gamma\gamma$ trigger efficiency, which is shown in the lower panels of Figs. 11 and 12. In the $\eta \to \pi^0\pi^+\pi^-$ decay channel where the statistics is very limited, we use the measured single-photon trigger efficiency curves shown in the top panel and full detector MC to determine the efficiency of the trigger. The derived curves for p+p and d+Au are also shown in the lower panel of Fig. 11. One can see that the trigger efficiency plateaus at a p_T of the η about twice the energy of the threshold in the case of the $\gamma\gamma$ decay channel, but in the three-body decay mode where the trigger can only be fired by one of the γ from $\pi^0 \to \gamma\gamma$, it requires the p_T of the η to be approximately four times the threshold. In central Au+Au the η efficiency reaches 50% (∼100%) for η above $p_T = 5$ (7–8) GeV/c, as shown in Fig. 12 (bottom panel). The LVL2 data were used only for p_T regions where the trigger had better than ∼50% η efficiency: $p_T > 5$ GeV/c for the central trigger and $p_T > 2$ GeV/c for peripheral.

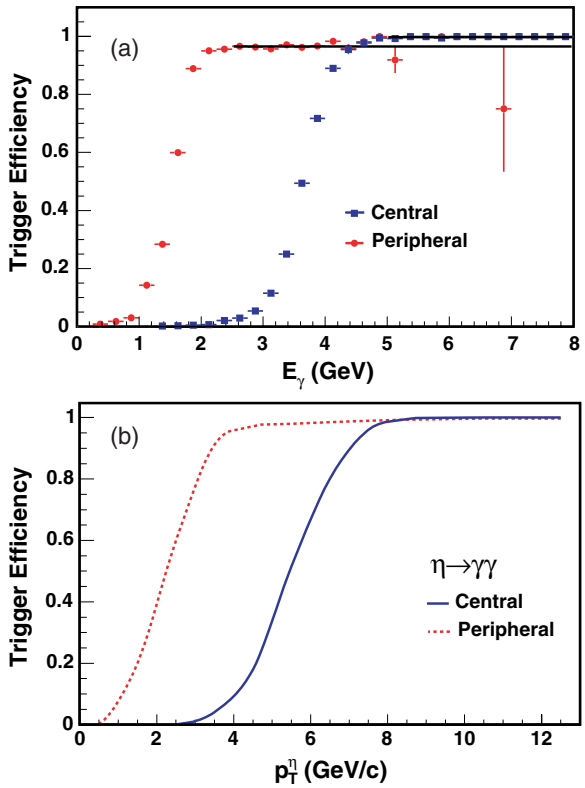

FIG. 12. (Color online) Level-2 trigger photon (top) and η (bottom) efficiencies for central Au+Au ($E_\gamma = 3.5$ GeV threshold) and peripheral Au+Au ($E_\gamma = 1.5$ GeV) collisions as in Fig. 11. For deriving the η efficiencies, the histograms in the top panel were directly used, with the black lines denoting constant fits to the above-threshold asymptotic value, at >99.7% for the central trigger. The central (peripheral) LVL2 η sample was used only above $p_T >$ 5 (2) GeV/c.

3. *Cross-section normalization*

The invariant cross sections for η production as a function of p_T in MB $p+p$ and $d+$Au collisions are obtained from the measured number of counts in each p_T bin via

$$E\frac{d^3\sigma}{d^3p} \equiv \frac{1}{2\pi\, p_T N_{\rm evt}} \frac{1}{\mathcal{L}} \frac{1}{BR} \frac{1}{Acc(p_T)\varepsilon(p_T)\varepsilon_{\rm trig}(p_T)} \frac{N(\Delta p_T)}{\Delta p_T \Delta y}, \tag{3}$$

where Acc, ε, and $\varepsilon_{\rm trig}$ are the acceptance, reconstruction efficiency, and trigger efficiency, respectively, determined in the previous section; $BR = 0.3943 \pm 0.0026$ is the known $\gamma\gamma$ decay branching ratio of the η meson, and $\mathcal{L}$ is the integrated luminosity obtained using the absolute inelastic cross-section normalization (see Sec. III A). The invariant *yields* as a function of p_T for a given bin in collision centrality in $d+$Au and Au+Au collisions are obtained via

$$\frac{1}{2\pi\, p_T}\frac{d^2N_{\rm cent}}{dp_T dy} \equiv \frac{1}{2\pi\, p_T N_{\rm cent}^{\rm event}} \frac{1}{BR} \times \frac{1}{Acc(p_T)\varepsilon(p_T, {\rm cent})\varepsilon_{\rm trig}(p_T)} \frac{N(\Delta p_T, {\rm cent})}{\Delta p_T \Delta y}. \tag{4}$$

A final bin-shift correction is needed to take into account the fact that the data points of the η spectra are plotted at the center of each given p_T interval (bins whose width is as large as $\Delta p_T = 2$ GeV/c), which, due to the exponentially falling spectrum, does not represent the true physical value of the yield in the interval [68]. Usually, either the correction is applied displacing the x values horizontally (i.e., the center of the p_T bin is decreased) keeping their y value, or the y values are moved vertically (i.e., the yields are decreased) keeping the p_T values at the center of the bin. The second method (yield correction) is preferred here because it facilitates taking bin-to-bin p_T ratios of spectra (with slightly different shapes) from different collisions systems. The net effect of this recipe is a small (few %) shift downwards of the invariant η yields in each p_T bin.

F. Systematic uncertainties

1. $\eta \to \gamma\,\gamma$ *analysis (p+p and d+Au)*

All systematic errors for the $p+p$ and the $d+$Au analysis are summarized in Table V. Hereafter, the errors are categorized by type:

(i) (**A**) point-to-point error uncorrelated between p_T bins,
(ii) (**B**) p_T correlated, all points move in the same direction but not by the same factor,
(iii) (**C**) an overall normalization error in which all points move by the same factor independent of p_T.

The cross-section measurement of the MB trigger has a type-C uncertainty of 9.7% in $p+p$ and 5.2% in $d+$Au. All other systematic errors are of type B, i.e. they are p_T correlated.

The error of the raw yield (peak) extraction was estimated, as described in Ref. [21], calculating the error of the ratio of the integrals of the real and the mixed event distributions in the region of the background fit. The systematic error in peak extraction differs from the systematic error estimated for neutral pions in Ref. [21] because the background in the η region cannot be estimated as well as the background in the π^0 region. This type-B error, estimated to be 4% higher than for pions, becomes dominant at very low transverse momenta due to the small S/B ratio. The error on the acceptance correction includes fiducial cuts on the edges of the EMCal sector as well as cuts around towers that have been determined to be hot or dead. The uncertainty in the MC (GEANT) description of the detector geometry is estimated varying these cuts slightly in the fastMC and in the embedded events (Au+Au). Those variations are found to result in differences in the yields of less than 5%. Different combinations of particle ID cuts were used in the analysis to estimate the uncertainty related to the photon identification. The differences among the various samples are less than 4% for all the different PID cuts for $p+p$ as well as for $d+$Au reactions. The error in the reconstruction efficiency contains this difference. The most important source of uncertainty at high p_T is related to the energy scale. The η peak positions and widths observed in the data are not reproduced to better than 1.5%. An error in the energy scale of 1.5% leads to an error of 4% in the yield at $p_T = 2$ GeV/c
