TABLE V. Systematic errors of the η measurement in $p+p$ and $d+$Au (Run-3) for different p_T bins. The error of the peak extraction has a very steep slope at low p_T.

Error source	p_T independent	3 GeV/c	5 GeV/c	10 GeV/c	type
Peak extraction		14.5% ($p+p$), 9.5% ($d+$Au)	6%	6%	B
Geometric acceptance		4.5%	4.5%	4.5%	B
η reconstruction efficiency		1.3%	2.3%	3.6%	B
Global energy scale		5.5%	7.0%	8.4%	B
Energy scale linearity		1.5%	0.4%	4.3%	B
γ-trigger efficiency		9% ($p+p$), - ($d+$Au)	0% ($p+p$), 2.5% ($d+$Au)	0%	B
Conversion correction	2.0%				B
Absolute cross-section normalization	9.7% ($p+p$), 5.2% ($d+$Au)				C

and of 8% at $p_T = 10$ GeV/c. The error of the high-p_T trigger efficiency in $p+p$ is different from in $d+$Au: it amounts to 7.5% at $p_T = 3.5$ GeV/c and becomes negligible at $p_T = 5$ GeV/c (see Sec. III E2).

2. $\eta \to \gamma\gamma$ analysis (Au+Au)

The sources of systematic errors in the Au+Au analysis are listed in Table VI. The main sources of systematic errors in the η measurement are the uncertainties in the yield extraction (10–30%), the yield correction (∼10%), and the energy scale (a maximum of ∼8%). The energy scale uncertainty is basically the same as discussed before for the $p+p$ and $d+$Au analyses. The uncertainty on the raw yield extraction was studied by varying the normalization region of the mixed event background and by comparing yields extracted from 2σ and 3σ integration windows. The yields were found to vary within 10% of the expectation for all centralities. The final results obtained with different PID cut combinations are found to be consistent within ∼8%, and this was the assigned systematic uncertainty for the photon identification procedure. The final combined systematic errors on the spectra are at the level of ∼10–15% (type-A, point to point) and ∼10–15% (type-B, p_T correlated).

TABLE VI. List of systematic uncertainties in the PbSc η measurement in Au+Au collisions (Run-2). Ranges generally correspond to uncertainties from the lower p_T to the higher p_T values of the measurement.

Error source	Percentage error	Type
Raw yield (peak) extraction (point to point)	0–31%	A
Raw yield (peak) extraction (p_T correlated)	10–20%	B
Energy scale	3–8%	B
PID cuts	8%	A
Geometric acceptance	4–2%	B
Trigger efficiency	5–2%	B
Reconstruction efficiency	2%	A

3. $\eta \to \pi^0\pi^+\pi^-$ analysis ($p+p$ and $d+$Au)

Systematic errors for the $\pi^0\pi^+\pi^-$ channel are summarized in Table VII. The $p+p$ and $d+$Au data samples have different systematic errors which are usually larger in $d+$Au. This is due to the larger high-p_T trigger threshold set during $d+$Au data taking. The PC3-EMCal matching uncertainty is used to evaluate peak extraction uncertainty. The dominant systematic uncertainties in the $p+p$ ($d+$Au) measurement are in the yield extraction and the phase-space corrections, with uncertainties of 10–30% (10–30%) and ∼10% (∼25%), respectively. The final combined systematic errors on the spectra are at the level of ∼30% ($p+p$) and ∼40% ($d+$Au).

IV. RESULTS AND DISCUSSION

In this section, the fully corrected spectra for η production differential in p_T in $p+p$, $d+$Au and Au+Au are presented, as well as the nuclear modification factors for $d+$Au and Au+Au collisions. The measured η/π^0 ratio as a function of p_T for the three colliding systems is presented and discussed in comparison with a compilation of world data for hadron-hadron, hadron-nucleus, nucleus-nucleus, and e^+e^- collisions and to phenomenological (PYTHIA and "m_T-scaling") expectations.

A. Transverse momentum spectra ($p+p$, $d+$Au, Au+Au)

The fully corrected spectra for the η meson are shown in Fig. 13 for MB events in proton-proton and deuteron-gold collisions at $\sqrt{s_{NN}} = 200$ GeV. The figure shows the spectra obtained in both the $\eta \to \gamma\gamma$ and $\eta \to \pi^0\pi^+\pi^-$ decay channels. For the $\gamma\gamma$ result, the error bars represent the total error, given by the quadratic sum of the statistical and the systematic uncertainties. For the pion-triplet spectra, the error bars (bands) represent the statistical (systematic) uncertainties. These results agree well in spite of very different analysis approaches and sources of systematic uncertainties. Due to higher acceptance and lower trigger threshold (see Figs. 6, 8, and 11), the $\gamma\gamma$ channel has superior statistics and therefore these results alone are used henceforth.

The invariant yields measured in four different centrality classes in $d+$Au collisions at $\sqrt{s_{NN}} = 200$ GeV are shown

TABLE VII. Systematic errors of the $\eta \to \pi^0\pi^+\pi^-$ measurement in $p+p$ and $d+$Au collisions (Run-3). The first number corresponds to the $p+p$ data and the number in parentheses to $d+$Au in cases where it is different from $p+p$.

in Fig. 14. In Fig. 15 the fully corrected invariant spectra for MB and three different centrality classes in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV are shown. The error bars represent the quadratic sum of the statistical and the point-to-point systematic uncertainties.

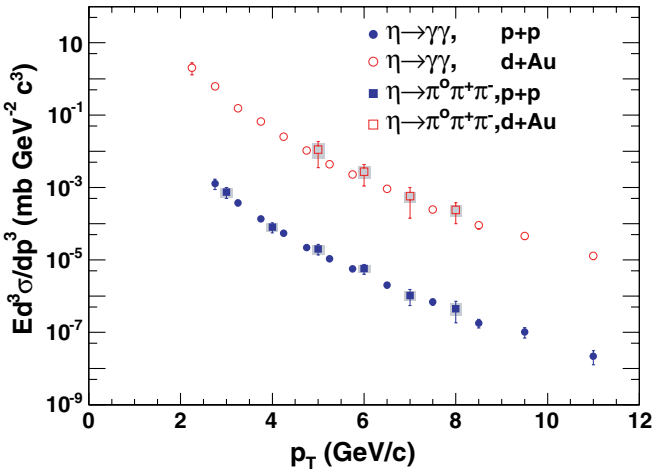

FIG. 13. (Color online) Invariant η cross section as a function of transverse momentum in $p+p$ and $d+$Au collisions at $\sqrt{s_{NN}} = 200$ GeV measured in the $\eta \to \gamma\gamma$ (circles) and $\eta \to \pi^0\pi^+\pi^-$ (squares) decay channels. The error bars of the $\eta \to \gamma\gamma$ are the quadratic sum of statistical and systematic uncertainties. The error bars (bands) of the $\pi^0\pi^+\pi^-$ spectra represent the statistical (systematic) uncertainties of the measurement.

B. Nuclear modification factor in $d+$Au, $R_{d\mathrm{Au}}(p_T)$

Medium effects in $d+$A collisions are quantitatively determined using the *nuclear modification factor* given as the ratio of the measured $d+$A invariant yields, d^2N_{dA}/dp_Tdy, over the measured $p+p$ cross sections, $d^2\sigma_{pp}/dp_Tdy$, scaled by the nuclear thickness function $\langle T_{dA}\rangle$ in the centrality bin under

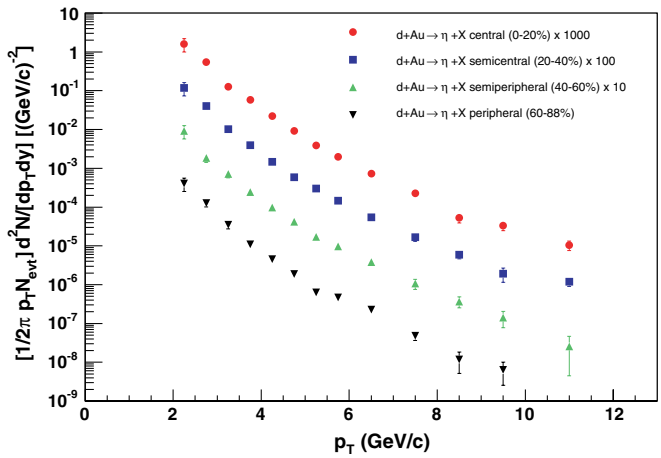

FIG. 14. (Color online) Invariant η yields as a function of transverse momentum in $d+$Au collisions at $\sqrt{s_{NN}} = 200$ GeV in four different centralities (0–20, 20–40, 40–60, 60–88%). The error bars are the quadratic sum of statistical and all systematic uncertainties. For clarity, the data points are scaled vertically as noted in the figure.

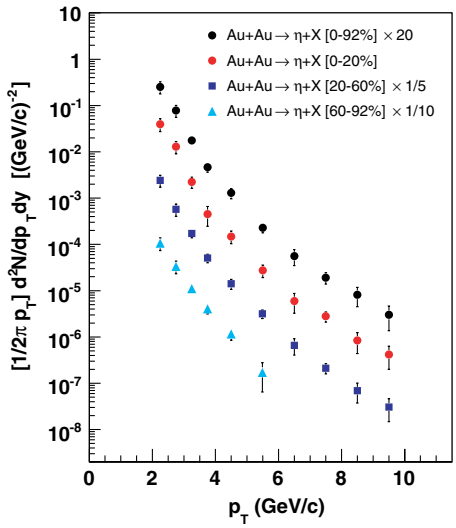

FIG. 15. (Color online) Invariant η yields as a function of transverse momentum in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV for MB and three centralities (0–20, 20–60, 60–92%). The error bars are the quadratic sum of statistical and point-to-point systematic uncertainties. For clarity, the data points are scaled vertically as noted in the figure.

consideration:

$$R_{dA}(p_T) = \frac{d^2N_{dA}/dy\,dp_T}{\langle T_{dA}\rangle \cdot d^2\sigma_{pp}/dy\,dp_T}. \tag{5}$$

Deviations from $R_{dA}(p_T) = 1$ quantify the degree of departure of the hard d+A yields from an incoherent superposition of *NN* collisions. The values of the nuclear thickness function for different centralities are obtained in a Glauber MC calculation and tabulated in Table II. The resulting $R_{dA}(p_T)$ for η mesons in d+Au collisions is plotted for different centralities in Fig. 16.

The data points at lower transverse momenta have large statistical errors. This is caused by the poor S/B ratio of the η peak in the sample that is not triggered with the γ trigger. The systematic uncertainties shown in the plot are computed propagating the experimental uncertainties in the p+p and d+Au measurements described in Sec. III F. Some of these uncertainties cancel out when calculating the nuclear modification factor [Eq. (5)]. The error due to the η reconstruction efficiency as well as the error due to uncertainties in the energy scale are very similar for the measurement of η mesons in p+p and d+Au collisions as the measured data have been taken in the same experimental run, and they cancel almost completely in the ratio.

In the case of *minimum bias* d+Au collisions, the nuclear modification factor, shown in Fig. 17, is more simply defined as the ratio of d+Au over p+p *cross sections* normalized by the total number of nucleons ($2 \cdot A$ for a d+A collision) with $A = 197$ for a gold nucleus:

$$R_{dA}(p_T) = \frac{d\sigma_{dA}}{2 \cdot A \cdot d\sigma_{pp}}. \tag{6}$$

All the d+Au nuclear modification factors shown in Figs. 16 and 17 are approximately 1 and show a very weak p_T and/or centrality dependence. Similar trends have been observed for π^0 production [17]. As shown in the comparison plot of Fig. 18, the π^0 nuclear modification factors indicate

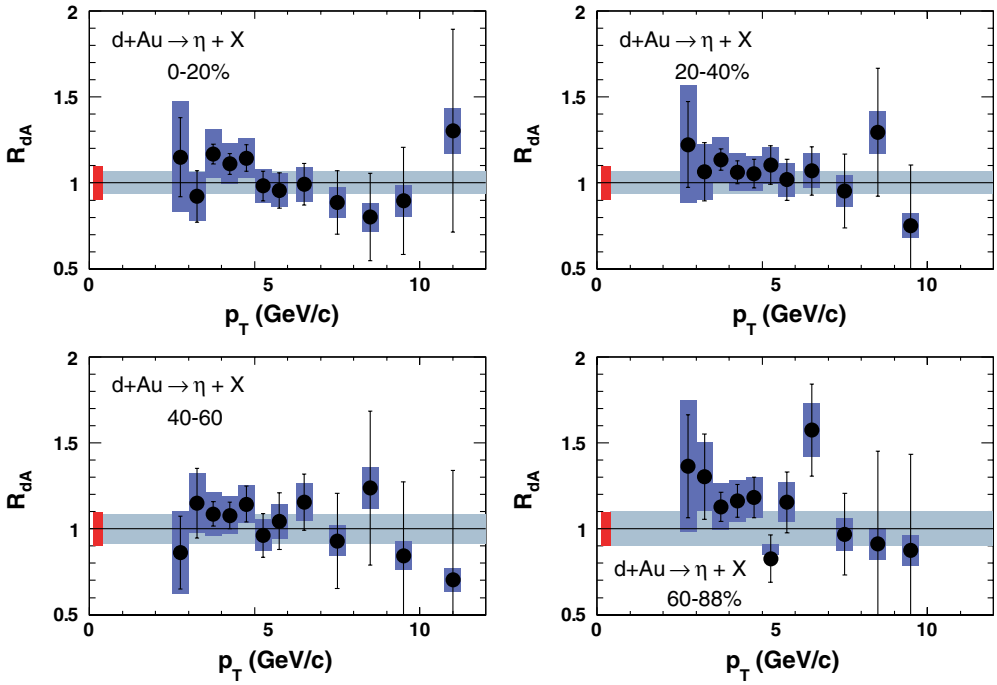

FIG. 16. (Color online) Nuclear modification factors for η production for four d+Au centralities: 0–20, 20–40, 40–60, 60–88%. The error bars (bands) around each point are the statistical (type-B systematic) uncertainties. The error band at $R_{dA} = 1$ indicates the uncertainty in $\langle T_{dA}\rangle$ for each centrality. The error box at $R_{dA} = 1$ indicates the p+p cross-section uncertainty of 9.7%.

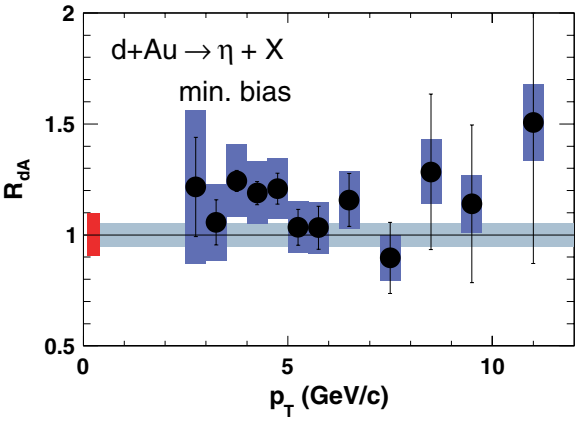

FIG. 17. (Color online) Nuclear modification factor R_{dA} for η mesons as a function of p_T for minimum-bias $\sqrt{s_{NN}} = 200$ GeV d+Au collisions. The uncertainties are the same described in Fig. 16.

small shape modifications with centrality, with a possible Cronin enhancement on the level of 10% around 4 GeV/c disappearing for $p_T > 10$ GeV/c. At high p_T the π^0 MB result can be described well by next-to-leading-order pQCD calculations [27,69] without implementation of the Cronin effect. The contribution of (anti-)shadowing effects [26,27] in the η or π^0 production is very small, as expected for this kinematical region with $x_T = 2p_T/\sqrt{s} \approx 0.02$–$0.2$.

The small role of initial-state cold nuclear effects observed in the midrapidity spectra of neutral mesons at high p_T is also consistent with other similar observations in d+Au reactions at $\sqrt{s_{NN}} = 200$ GeV such as (i) the absence of significant nuclear modifications in the yields of J/Ψ compared to p+p collisions [63] and (ii) the very similar characteristics of near-side and away-side jetlike correlations in p+p and d+Au [70]. Those results indicate that the nuclear medium has little influence on the hard processes in d+Au collisions at top RHIC energies and $y = 0$.

C. Nuclear modification factor in Au+Au, $R_{AA}(p_T)$

The nuclear modification factor, $R_{AA}(p_T)$, for η production in each centrality class in Au+Au collisions is computed using the standard formula:

$$R_{AA}(p_T) = \frac{d^2N_{AA}/dydp_T}{\langle T_{AA}\rangle \cdot d^2\sigma_{pp}/dydp_T}, \qquad (7)$$

where (i) the Au+Au spectra $d^2N/dydp_T$ are used in the numerator (Fig. 15), (ii) the p+p invariant spectrum $d^2\sigma/dydp_T$ (Fig. 13) is used in the denominator, and (iii) $\langle T_{AA}\rangle$ are the values of the average Glauber overlap function for each Au+Au centrality (Table II). The $R_{AA}(p_T)$ is computed taking the bin-to-bin ratio of Au+Au and p+p spectra and propagating the corresponding uncertainties. Only the acceptance uncertainty (~5%) cancels in the Au+Au/p+p ratio of spectra. Figure 19 compares the nuclear modification factor for η measured in central (0–20%), semicentral (20–60%) and peripheral (60–92%) Au+Au collisions. The error bars are the total point-to-point errors (including type-**A** systematic and statistical uncertainties) of the Au+Au and p+p measurements. The error bands on the left are the uncertainties in $\langle T_{AuAu}\rangle$ for each centrality class. The error box on the right is the Run-3 p+p cross-section uncertainty of 9.7%. As observed for high-p_T π^0 [19,21], the Au+Au η yields are consistent with the expectation of independent NN scatterings in peripheral reactions ($R_{AA} \approx 1$) but they are increasingly depleted with respect to this expectation for more central collisions. There is no p_T dependence of R_{AA}, as seen also for neutral pions.

Figure 20 contrasts the nuclear modification factors measured in central Au+Au at $\sqrt{s_{NN}} = 200$ GeV for η, π^0 [19,21], and γ [48]. Whereas direct photons are unsuppressed compared to the scaled reference given by a NLO pQCD calculation [48,71] that reproduces the PHENIX p+p γ results well [49], neutral pions and η are suppressed by a similar factor of ~5 compared to the corresponding cross sections measured in p+p. Within the current uncertainties, light-quark neutral mesons at RHIC show a flat suppression in the range $p_T \approx 4$–15 GeV/c, independent of their mass (note that the η is ~4 times heavier than the π^0). Those results are in agreement with parton energy loss calculations in a system with initial effective gluon densities of the order $dN^g/dy \sim 1000$ (solid curve in the figure) [37]. The equal suppression of η and π^0 mesons and the agreement with parton energy loss calculations suggest that the final fragmentation of the quenched parton into a leading meson occurs in the vacuum according to the same probabilities (fragmentation functions) that govern high-p_T hadroproduction in more elementary systems (p+p, e^+e^-). This conclusion is examined in more detail in the next two sections.

D. Ratio of η to π^0 (p+p, d+Au, Au+Au)

A useful way to determine possible differences in the suppression pattern of π^0 and η is to study the centrality dependence of the η/π^0 ratio, $R_{\eta/\pi^0}(p_T)$, in d+Au and Au+Au reactions and compare it with the values measured in more elementary systems (p+p, e^+e^-). The "world" η/π^0 ratio in hadronic and proton-nucleus collisions increases rapidly with p_T and flattens out above $p_T \approx 2.5$ GeV/c at values R_{η/π^0} ~0.40–0.50 (see Sec. IV E1). Likewise, in electron-positron annihilations at the Z pole ($\sqrt{s} = 91.2$ GeV), $R_{\eta/\pi^0} \sim 0.5$ for *energetic* η and π^0 (with $x_p = p_{\rm hadron}/p_{\rm beam} > 0.4$, consistent with the range of scaled momenta $\langle z\rangle = p_{\rm hadron}/p_{\rm jet}$ considered here), as discussed in Sec. IV E2. It is interesting to test if this ratio is modified in any way by initial- and/or final-state effects in d+Au and Au+Au collisions at RHIC energies.

The production ratio of η and π^0 mesons is shown in Fig. 21 for p+p and in Fig. 22 for d+Au (MB and four centrality classes). The ratio is calculated point by point for the d+Au measurements, propagating the corresponding errors. In the p+p case, a fit to the π^0 spectrum [21] was used. All the ratios are consistent with the PYTHIA [72] curve for p+p at $\sqrt{s} = 200$ GeV (dashed line, see discussion in Sec. IV E1) with an asymptotic $R^{\infty}_{\eta/\pi^0} = 0.5$ value.

Figure 23 shows the $R_{\eta/\pi^0}(p_T)$ ratio for MB and three Au+Au centralities, obtained using the latest PHENIX π^0 spectra [21] and removing those systematic uncertainties that

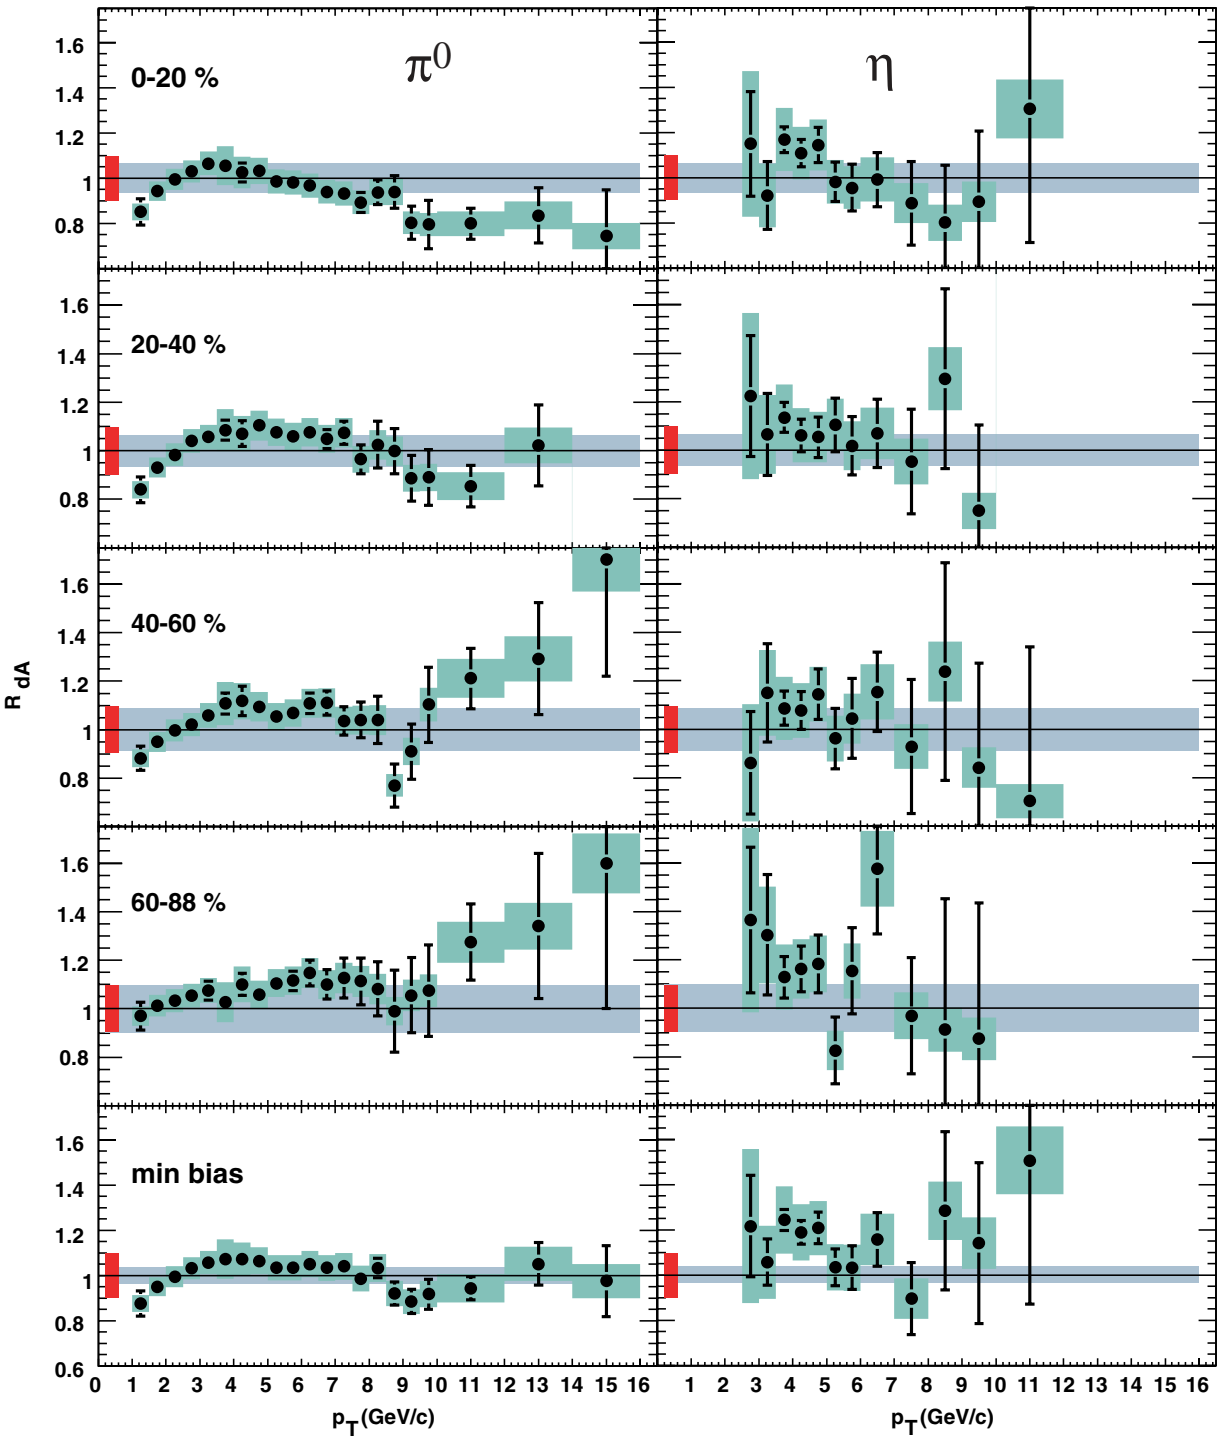

FIG. 18. (Color online) Nuclear modification factor $R_{\rm dA}(p_T)$ for π^0 (left) and η (right) production in different centrality selections and MB d+Au data. The bands around the data points show systematic uncertainties which can vary with p_T (type-B errors). The shaded band around unity indicates the $\langle T_{dA}\rangle$ uncertainty and the small box on the left side of the data points indicates the normalization uncertainty of the p+p total inelastic cross section.

cancel in the ratio. The $R_{\eta/\pi^0}(p_T)$ data for Au+Au is compared to a PYTHIA [72] calculation that reproduces the hadronic collision data well (see the next section). Within uncertainties, all the ratios are consistent with $R_{\eta/\pi^0} \approx 0.5$ (dashed line) and show no collision system, centrality, or p_T dependence. A simple fit to a constant above $p_T = 2$ GeV/c yields the following ratios:

(i) R_{η/π^0} (Au+Au cent) $= 0.40 \pm 0.04$ (stat) ± 0.02 (syst), χ^2/ndf $= 0.48$

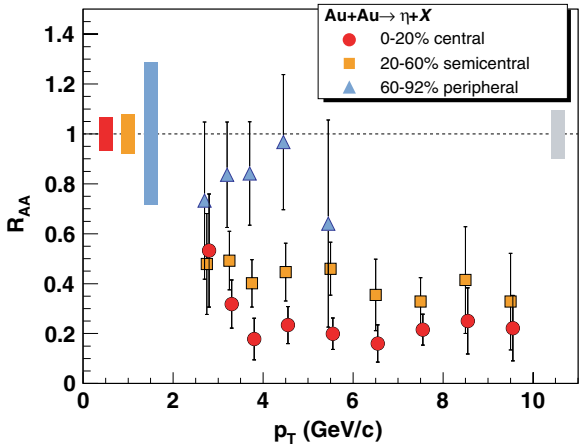

FIG. 19. (Color online) Nuclear modification factors for η in three Au+Au centralities (0–20, 20–60, 60–92%). The errors bars are point-to-point uncertainties. The absolute normalization error bands at $R_{AA} = 1$ are (i) the uncertainties in $\langle T_{AA} \rangle$ for each centrality (left side) and (ii) the p+p cross-section normalization uncertainty of 9.7% (right side). The $R_{AA}(p_T)$ for peripheral/central Au+Au have been slightly displaced to the left/right (±50 MeV/c) along the p_T axis to improve the clarity of the plot.

(ii) R_{η/π^0} (Au+Au semicent) = 0.39 ± 0.03 (stat) ± 0.02 (syst), χ^2/ndf = 0.26

(iii) R_{η/π^0} (Au+Au periph) = 0.40 ± 0.04 (stat) ± 0.02 (syst), χ^2/ndf = 0.42

(iv) R_{η/π^0} (p+p)= 0.48 ± 0.02 (stat) ± 0.02 (syst), χ^2/ndf = 0.89

(v) R_{η/π^0} (d+Au)= 0.47 ± 0.02 (stat) ± 0.02 (syst), χ^2/ndf = 0.84.

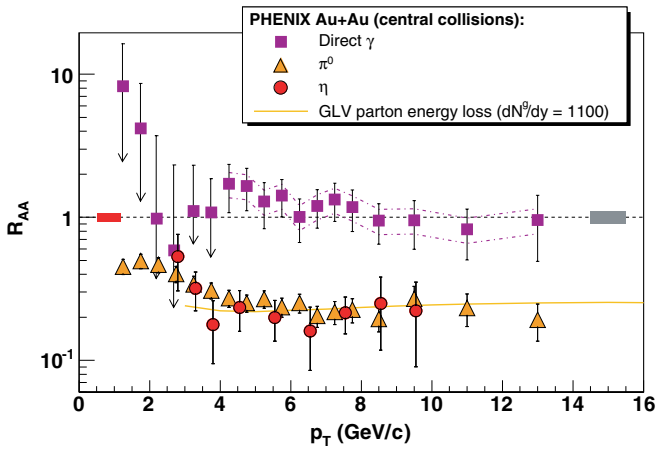

FIG. 20. (Color online) $R_{AA}(p_T)$ measured in central Au+Au at $\sqrt{s_{NN}} = 200$ GeV for η, π^0 [19,21], and for direct γ [48]. The error bars include all point-to-point uncertainties. The error bands at $R_{AA} = 1$ have the same meaning as in Fig. 19. The baseline p+$p \rightarrow \gamma + X$ reference used is a NLO pQCD calculation [48,71] that reproduces our own data well [49], with theoretical (scale) uncertainties indicated by the dash-dotted lines around the points. The solid yellow curve is a parton energy loss prediction for the suppression factor of leading pions in a medium with initial gluon density $dN^g/dy = 1100$ [37].

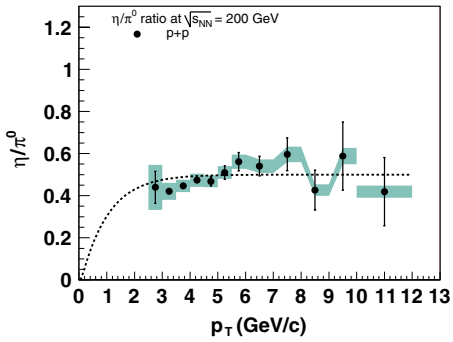

FIG. 21. (Color online) Ratio η/π^0 measured in p+p collisions at $\sqrt{s} = 200$ GeV. The error bars represent the point-to-point errors; the boxes represent the systematic uncertainties. The dashed line is the prediction of PYTHIA [72] for p+p at this center-of-mass energy.

E. World data on the η/π^0 ratio in high-energy particle collisions

In this last section of the article, we present a compilation of experimental η/π^0 ratios as a function of transverse momentum, $R_{\eta/\pi^0}(p_T)$, measured in different hadronic and nuclear colliding systems in a wide range of center-of-mass energies ($\sqrt{s_{NN}} \approx$ 3–1800 GeV). The collected world data on η/π^0 ratios includes (i) hadron-hadron collisions (26 p+p, p+$\bar{p}$, $\pi^{\pm}$+p data sets), (ii) hadron-nucleus collisions (17 $p, \pi^{\pm}$+A sets), and (iii) nucleus-nucleus collisions (7 A+A data sets).

In addition, we present also the $R_{\eta/\pi^0}(x_p)$ ratio obtained from inclusive π^0 and η cross sections in e^+e^- as a function of scaled momentum $x_p = 2\, p_{\rm had}/\sqrt{s}$ measured by the four LEP experiments at the Z pole ($\sqrt{s} = 91.2$ GeV). In all cases, the ratio R_{η/π^0} increases rapidly with p_T (or x_p) and saturates at $R_{\eta/\pi^0} \approx 0.4$–$0.5$ above $p_T \approx 3$ GeV/c ($x_p \approx 0.3$). The experimental $R_{\eta/\pi^0}(p_T)$ ratios are also compared to PYTHIA and to m_T-scaling expectations. PHENIX p+p, d+Au, and

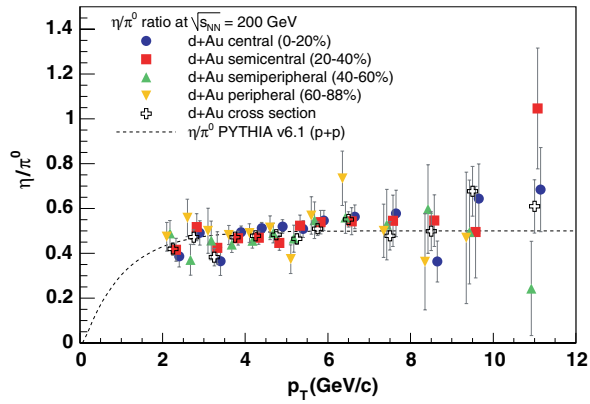

FIG. 22. (Color online) Ratio η/π^0 measured in different centralities in d+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The error bars represent all point-to-point uncertainties. The dashed line is the prediction of PYTHIA [72] for p+p at this center-of-mass energy. A few $R_{\eta/\pi^0}(p_T)$ ratios have been slightly displaced to the left or right (±<150 MeV/c) along the p_T axis to improve the clarity of the plot.

TABLE VIII. Hadron-hadron collisions with a published η/π^0 ratio and/or η and π^0 spectra. For each reaction we quote: the center-of-mass energy $\sqrt{s}$ (and $p_{\rm lab}$ for fixed-target experiments), the p_T and $x_T = 2p_T/\sqrt{s}$ ranges of the measurement (the x_T values are not quoted for "soft" spectra below $p_T = 1$ GeV/c), and the average η/π^0 ratio above $p_T = 2$ GeV/c obtained by fitting $R_{\eta/\pi^0}(p_T > 2\ \text{GeV}/c)$ to a constant.

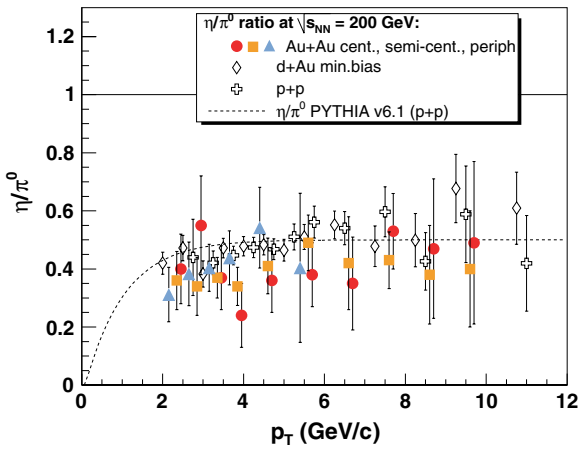

FIG. 23. (Color online) Au+Au R_{η/π^0} ratio in MB and three centrality classes (0–20, 20–60, 60–92%) as a function of p_T compared to the ratio in d+Au and $p+p$ collisions. The error bars include all point-to-point errors. The dashed line is the prediction of PYTHIA [72] for $p+p$ at this center-of-mass energy. A few $R_{\eta/\pi^0}(p_T)$ ratios have been slightly displaced to the left or right ($\pm$50 MeV/c) along the p_T axis to improve the clarity of the plot.

Au+Au η/π^0 ratios at $\sqrt{s} = 200$ GeV are found to be consistent with the obtained world data on R_{η/π^0}.

1. η/π^0 ratio in hadron-hadron, hadron-nucleus, and nuclear collisions ($\sqrt{s} \approx$ 3–1800 GeV)

In Tables VIII, IX, and X we list all data sets with published η and π^0 spectra and/or published $R_{\eta/\pi^0}(p_T)$ ratios in hadron-hadron, hadron-nucleus, and nucleus-nucleus collisions that we have found in the literature. Most of those measurements are performed around midrapidity. Roughly half of the $R_{\eta/\pi^0}(p_T)$ listed have been directly taken from the original works whose references are provided in the data tables. A few others have been constructed by taking the ratio of the published π^0 and η invariant cross-section spectra measured at the same $\sqrt{s}$. In the latter case, the error in the ratio has been computed by adding statistical and systematic uncertainties quadratically. There were a few cases where the p_T binning of the η spectrum did not match that of the π^0. In these cases, the π^0 spectrum was fitted with a functional form that reproduced the data well (usually a modified power law of

TABLE IX. Hadron-nucleus collisions with a published η/π^0 ratio and/or η and π^0 spectra. For each reaction we quote: the center-of-mass energy $\sqrt{s_{NN}}$ (and $p_{\rm lab}$ for fixed-target experiments), the p_T and $x_T = 2p_T/\sqrt{s}$ ranges of the measurement (the x_T values are not quoted for "soft" spectra below $p_T = 1$ GeV/c), and the average η/π^0 ratio above $p_T = 2$ GeV/c obtained by fitting $R_{\eta/\pi^0}(p_T > 2\ \text{GeV}/c)$ to a constant.

the form discussed in Ref. [73]) and the η/π^0 ratio was then obtained by dividing the η spectrum data points by the values of the π^0 function at each point. In this case, the error was computed by dividing the quoted η error by the function value at that point. The uncertainty arising from the π^0 spectrum fit was obtained by computing the minimum and maximum ratio values at each point. Both errors were then added in quadrature.

In Tables VIII, IX and X, together with the general info on the collected data sets, we indicate for each measurement the approximate p_T and $x_T = 2p_T/\sqrt{s}$ ranges, as well as the average value of R_{η/π^0} at high p_T, obtained by fitting the data to a constant above $p_T = 2$ GeV/c. With the exception of the higher energy data ($\sqrt{s_{NN}} \gtrsim 100$ GeV), most of the experimental ratios have been measured in a fractional momentum range $x_T \approx 0.1$–0.3 where the parton distribution functions are dominated by valence quarks (rather than gluons) and, hence, the produced high-p_T π^0 and η mesons come largely from $q, \bar{q}$ fragmentation. Figures 24, 25, and 26 show the corresponding $R_{\eta/\pi^0}(p_T)$ ratios for each type of colliding system. All the ratios show a rapid increase with p_T and level off at $R_{\eta/\pi^0} \approx 0.4$–$0.5$ above $p_T \approx 3$ GeV/c. No difference is observed for different colliding systems. The PHENIX $p+p$, d+Au, and Au+Au high-p_T data presented in the previous section are consistent with those ratios. A fit of the PHENIX ratios to a constant gives $R_{\eta/\pi^0} = 0.47 \pm 0.03$ for both $p+p$ and d+Au and, slightly lower but still consistent, $R_{\eta/\pi^0} = 0.40 \pm 0.04$ for Au+Au. Together with the data points in Figs. 24–26, we also plot two phenomenological curves with PYTHIA 6.131 [72] based on the Lund fragmentation model [74,75], and on $m_{\rm T}$-scaling expectations for the η/π^0 ratio in $p+p$ collisions at $\sqrt{s} =$ 200 GeV.

a. Lund string fragmentation. The fragmentation mechanism in PYTHIA is based on the phenomenological Lund string

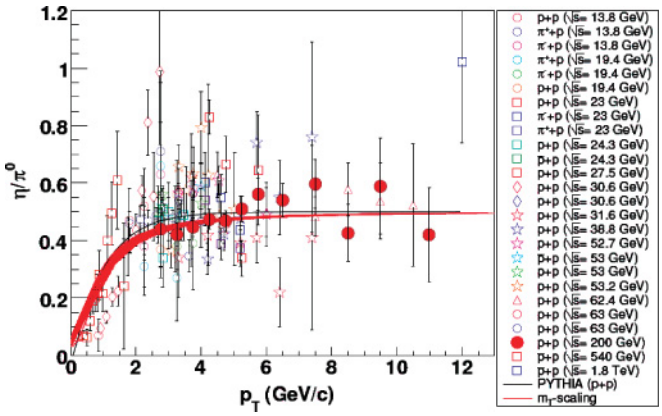

FIG. 24. (Color online) Values of the R_{η/π^0} ratios as a function of p_T measured in the hadron-hadron collisions reported in Table VIII. The black curve is the prediction of PYTHIA [72] for the ratio in $p+p$ at $\sqrt{s} = 200$ GeV, and the red shaded area indicates the empirical m_T-scaling prescription Eq. (10) with fixed $a = 1.2$, power-law exponent $n = 10$–14, and an asymptotic $R^{\infty}_{\eta/\pi^0} = 0.5$ ratio.

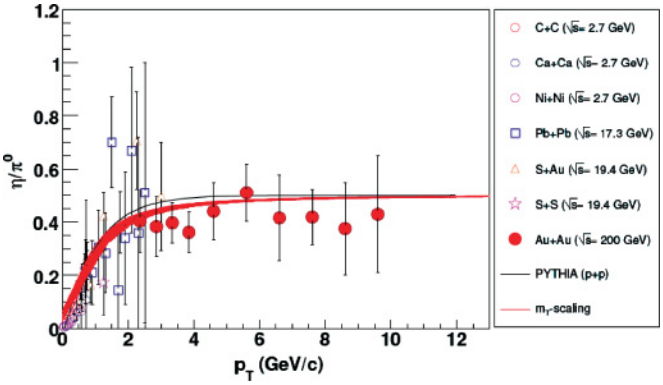

FIG. 26. (Color online) Values of the R_{η/π^0} ratios as a function of p_T measured in the nucleus-nucleus collisions reported in Table X. The black curve is the prediction of PYTHIA [72] for the ratio in $p+p$ at $\sqrt{s} = 200$ GeV, and the red shaded area indicates the empirical m_T-scaling prescription Eq. (10) with fixed $a = 1.2$, power-law exponent $n = 10$–14, and an asymptotic $R^{\infty}_{\eta/\pi^0} = 0.5$ ratio.

scheme [74,75] that considers the color field between the partons to be the fragmenting entity rather than the quarks and gluons themselves. The string is viewed as a color flux tube formed by gluon self-interaction between the partons. As the partons move apart the potential energy stored in the string increases. At some point the string breaks via the production of new $q\bar{q}$ pairs according to the probability of a quantum-mechanical tunneling process, $\exp(-\pi\, m^2_{\mathrm{q,T}}/\kappa)$, which depends on the transverse mass squared ($m^2_{\mathrm{q,T}} = m^2 + {p_T}^2$) and the string tension $\kappa \approx 1$ GeV/fm ≈ 0.2 GeV^2. The string breakup process proceeds repeatedly into color singlet systems as long as the invariant mass of the string pieces exceeds the on-shell mass of a hadron (each hadron corresponding to a small piece of string with a quark at one end and an antiquark at the other). At each branching,

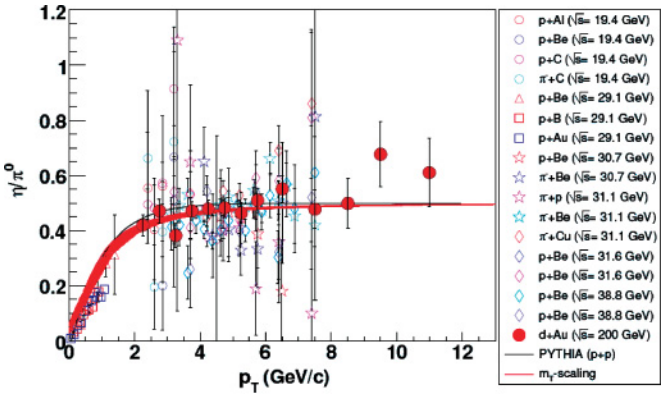

FIG. 25. (Color online) Values of the R_{η/π^0} ratios as a function of p_T measured in the hadron-nucleus collisions reported in Table IX. The black curve is the prediction of PYTHIA [72] for the ratio in $p+p$ at $\sqrt{s} = 200$ GeV, and the red shaded area indicates the empirical m_T-scaling prescription Eq. (10) with fixed $a = 1.2$, power-law exponent $n = 10$–14, and an asymptotic $R^{\infty}_{\eta/\pi^0} = 0.5$ ratio.

probabilistic rules are given for the production of flavors ($u\bar{u} : d\bar{d} : s\bar{s} = 1 : 1 : 0.3$ in the default settings), spin (e.g., a 3:1 mixture between the lowest lying vector and pseudoscalar multiplets is used, suggested by spin counting arguments), and for the sharing of energy and momentum among the products. Regarding the latter, the probability that a hadron picks a fraction z of $E + p_z$ out of the available $E + p$ (p_z is the momentum of the formed hadron along the direction of the quark q) is given by the "Lund symmetric fragmentation function:"

$$f(z) \propto z^{-1}(1-z)^a \exp(-b\, {m_T}^2/z), \tag{8}$$

where a and b are free parameters adjusted to bring the fragmentation into accordance with measured LEP data, e.g., $a = 0.3$ and $b = 0.58$ GeV^{-2} are the current default values for PYTHIA 6.3 [76]. In addition, for the flavor-diagonal meson states $u\bar{u} : d\bar{d} : s\bar{s}$, PYTHIA also includes mixing into the physical mesons. This is done according to a parametrization, based on the mixing angles given in the *Review of Particle Properties* [57]. In particular, the default choices correspond to $\eta = 1/2(u\bar{u} + d\bar{d}) - 1/\sqrt{2}(s\bar{s})$ and $\eta' = 1/2(u\bar{u} + d\bar{d}) + 1/\sqrt{2}(s\bar{s})$. Thus, in the $\pi^0 - \eta - \eta'$ system, no account is taken of the difference in masses, an approximation that seems to lead to an overestimate of η' rates in e^+e^- annihilation [103]. PYTHIA includes therefore parameters to allow an additional "tunable" suppression of η and η' states.

The PYTHIA Monte Carlo simulations of π^0 and η p_T-differential cross sections were carried out with the default settings. In particular, no ad hoc suppression of η was selected. Any uncertainty related to the choice of any (flavor-independent) settings should in principle cancel in the ratio of both p_T spectra. As seen in Figs. 24–26, within the (relatively large in some cases) experimental uncertainties, good agreement between the $R_{\eta/\pi^0}(p_T)$ data and the model prediction is found for all the colliding systems and p_T ranges, despite being at very different center-of-mass energies. We have also run PYTHIA at $\sqrt{s} = 30$ GeV as a reference for lower

energy results, but the resulting η/π^0 curve, though slightly lower at high-p_T ($R_{\eta/\pi^0} \approx 0.44$), is still relatively close to the one obtained at $\sqrt{s} = 200$ GeV. This is an indication that the p_T dependence of the production mechanisms for both neutral mesons is very similar for all systems and center-of-mass energies and, correspondingly, the ratio of p_T-differential cross sections is basically independent of the characteristics of the initial collision process but dominated by the ratio of η and π^0 (vacuum) FF, which is relatively constant in this kinematic range (see discussion in Sec. IV E2).

b. m_T scaling. The red shaded curve shown in Figs. 24, 25, and 26 corresponds to an empirical m_T-scaling observation [77] that assumes that the hadron differential cross sections, plotted as a function of the transverse mass of the produced particle $m_T = \sqrt{m_h^2 + {p_T}^2}$, all have the same shape, $f(m_T)$, with an absolute normalization factor C_h that can vary but is found to be the same for many species:

$$E\frac{d^3\sigma_h}{d^3p} = C_h \cdot f(m_T). \tag{9}$$

Assuming isospin symmetry for pion production, we have combined the measured PHENIX charged $(\pi^+ + \pi^-)/2$ (measured in the range $p_T = 0.2$–2.6 GeV/c) [78] and neutral ($p_T = 1$–14 GeV/c) [17] pion differential m_T cross sections in $p+p$ collisions and fitted them with a modified power-law functional form[2] that reproduces the full spectra well in the range $m_T \approx 0.2$–14 GeV/c^2:

$$f(m_T) = (m_T + a)^{-n}, \quad \text{with } a = 1.2 \quad \text{and } n = 10. \tag{10}$$

If one assumes that m_T scaling holds for η, then its $m_T = \sqrt{m_\eta^2 + {p_T}^2}$ spectrum can also be represented by Eqs. (9) and (10) (with, in principle, a different C_h) and, therefore, the η/π^0 ratio as a function of p_T should follow:

$$R_{\eta/\pi^0}(p_T) = R^{\infty}_{\eta/\pi^0} \cdot \left[\frac{a + \sqrt{m_\eta^2 + {p_T}^2}}{a + \sqrt{m_{\pi^0}^2 + {p_T}^2}}\right]^n, \tag{11}$$

where $R^{\infty}_{\eta/\pi^0} = C_\eta/C_{\pi^0}$ is the asymptotic value of the ratio of η over π^0 for large p_T. Note that because the assumption of m_T scaling is that both m_T-differential cross sections have the same shape, the same parameters $a = 1.2$ and $n = 10$ are valid for both spectra as well as for the ratio [Eq. (11)]. In all figures, the plotted m_T-scaling curve with an asymptotic value of $R^{\infty}_{\eta/\pi^0} = 0.5$ is found to be in good agreement with both the data and the PYTHIA predictions. We note that the agreement between PYTHIA and m_T-scaling is not unexpected in as much as the Lund "fragmentation function," Eq. (8), depends explicitly on the m_T of the produced hadron. The upper red curve shown in all plots is that with the a and n parameters of Eq. (11) that reproduce the power-law shape of the meson spectra at $\sqrt{s} = 200$ GeV. At lower $\sqrt{s}$, the spectra get increasingly steeper and a and n change accordingly [a and n are correlated with $\langle m_T \rangle$ which itself is a logarithmically increasing function of $\sqrt{s}$, i.e., $\langle m_T \rangle = f(\sqrt{s})$]. For illustrative purposes, we have (arbitrarily) fixed the parameter a to the value $a = 1.2$ and refitted the π^0 spectra measured at different center-of-mass energies with n as a free exponent. With fixed a the corresponding values of the power-law exponent increase with decreasing $\sqrt{s}$ as $n \approx 10$, 11.5, 13.5, and 14.0 at $\sqrt{s} = 200$, 63, 27, and 13 GeV, respectively. The shaded red area indicates the range of expected m_T-scaling ratios for power-law exponents $n = 10.$–14. The differences are negligible at large p_T—where the η and π^0 masses are much smaller than their p_T and the ratio Eq. (11) $R_{\eta/\pi^0}(p_T) \approx R^{\infty}_{\eta/\pi^0}$ is independent of n but increases at lower p_T ($p_T \lesssim 3$ GeV/c). Furthermore, it is worth noting that in the low-p_T region below 1 GeV/c, the agreement between the data and the m_T-scaling curve is not always perfect for all data sets, even taking into account different power-law exponents. This is due to the fact that at very low $m_T \approx 0.0$–0.4 GeV/c^2, the pion yield rises due to contributions from multiple resonance decays and the formula [Eq. (10)] does not reproduce the spectral shape of the data anymore. Instead, an exponential behavior of the form $Ed^3\sigma/d^3p = B \cdot \exp(-b\, m_T)$ [99] extrapolates the spectra better in the soft regime all the way down to $m_T = 0$ GeV/c^2. However, for all practical purposes in this analysis focused on high-p_T production, we consider Eq. (10) [(and correspondingly Eq. (11)] to be a good enough approximation.

Last we want to mention that in the case of nucleus-nucleus collisions the existence of a strong collective radial flow ($\beta_{\rm coll} \approx 0.6$ at RHIC [100]), absent in $p+p$ collisions, changes the spectral shape of different hadrons produced at low transverse momenta ($p_T \lesssim 2$ GeV/c) and should result in a violation of the m_T-scaling behavior [101]. Because hydrodynamical flow results in a larger boost for the (heavier) η than for π^0, one expects a comparatively larger $R_{\eta/\pi^0}(p_T)$ ratio in Au+Au than in $p+p$ collisions below $p_T \approx 2$ GeV/c. Unfortunately, we cannot test this assertion with RHIC data since our lowest p_T value ($p_T \approx 2$ GeV/c) is just in the range where radial flow effects start to die out. The same holds true also for the recent proposal [102] to study the η/π^0 ratio as a tool to test different parton recombination scenarios in hadron production in nucleus-nucleus collisions. Lower-p_T η measurements, which are intrinsically more difficult due to the reduced PHENIX acceptance and the larger $\gamma\gamma$ combinatorial background, would be needed to better address the role of collective flow and/or parton recombination effects on the spectral shape and yields of light neutral mesons in Au+Au collisions at RHIC.

2. η/π^0 ratio in e^+e^- collisions at the Z pole ($\sqrt{s} = 91.2$ GeV)

In this last section we are interested in determining the η/π^0 ratio in an elementary colliding system such as e^+e^- and comparing it to the corresponding ratios obtained in hadronic and nuclear collisions. In e^+e^- the dominant high-momentum hadron production mechanism is $q, \bar{q}$ fragmentation because gluon production (and subsequent fragmentation) occurs with a probability that is suppressed by a factor α_S and therefore plays a comparatively less significant role than in the (highest energy) hadronic and nuclear collisions discussed in the

[2]Note that the a and n parameters of Eq. (10) are not independent but strongly correlated. They are actually related to the mean transverse mass of the spectrum via $\langle m_T \rangle = 2a/(n-3)$.

previous section. Some of the experimental interest in the study of η production in e^+e^- collisions was in fact triggered by theoretical expectations that the isoscalar mesons contained a significant $g\,g$ component, and thus that gluon jets should exhibit an anomalously large tendency to fragment into η and $\eta'(958)$ mesons [120–122]. However, this hypothesis was not confirmed by a detailed analysis of the ALEPH e^+e^- gluon fragmentation data [106]. Table XI lists all the existing measurements of inclusive π^0 and η production in e^+e^- collisions at LEP at energies around the Z pole. At lower energies, there are several results on inclusive π^0 production in e^+e^- but few η measurements exist ($\sqrt{s} = 29$ and 35 GeV at SLAC PEP [114,115] and SLC [116–119], respectively), and we could not determine the corresponding ratios.

Figures 27 and 28 show the combined inclusive η and π^0 invariant cross sections measured as a function of the scaled particle momentum $x_p = 2\,p_{\rm had}/\sqrt{s}$. Note that the overall η and π^0 spectra have been measured in x_p ranges which

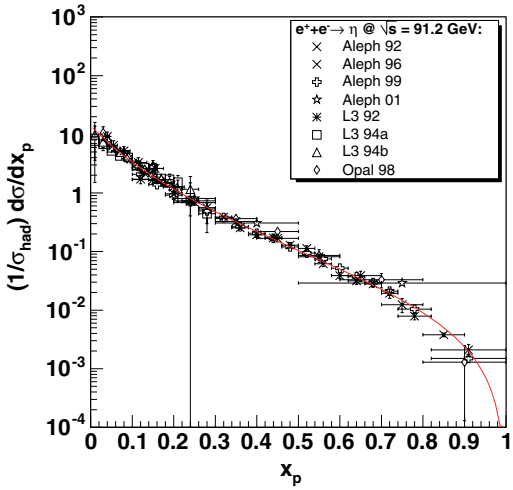

FIG. 27. (Color online) Differential inclusive η cross section as a function of the scaled momentum $x_p = 2\,p_{\rm had}/\sqrt{s}$ measured at the Z pole by the three LEP experiments listed in Table XI, fitted to Eq. (13) (solid curve).

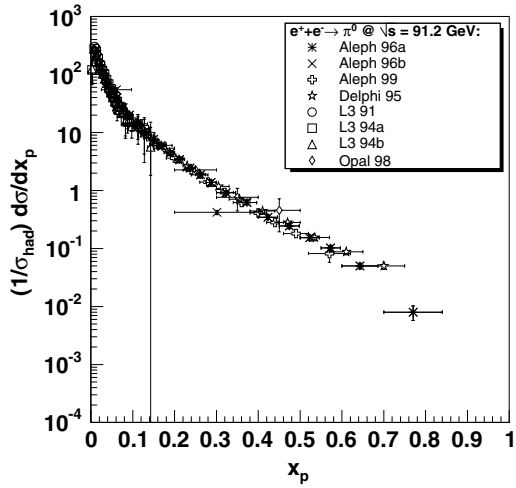

FIG. 28. Differential inclusive π^0 cross section as a function of the scaled momentum $x_p = 2\,p_{\rm had}/\sqrt{s}$ measured at the Z pole by the four LEP experiments listed in Table XI.

are not completely overlapping. There are more experimental measurements on inclusive η (π^0) production at large (small) $x_p \gtrsim 0.7 (x_p \lesssim 0.1)$. For this reason, to obtain the ratio of η over π^0 cross sections, we have parametrized the η cross section as

$$\frac{1}{\sigma_{\rm had}}\frac{d\sigma_\eta}{dx_p} = A \cdot (x_p + b)^n \cdot (1 - x_p)^m \qquad (12)$$

and taken the ratio of the individual π^0 data points over the resulting fit. We note that there is currently no η FF available in the standard FF sets at hand in the literature (BKK [123], KKP [124], Kretzer [125], BFGW [126]). Namely, the LEP data compiled in Fig. 27 have not been fitted and coded so far into any usable format that can be handled within a QCD collinear factorization approach. We are aware of only

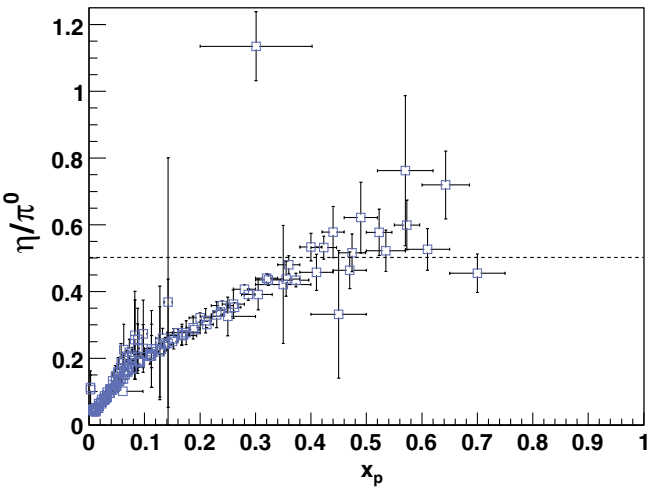

FIG. 29. (Color online) Ratio η/π^0 versus scaled momentum $x_p = 2\,p_{\rm had}/\sqrt{s}$ measured in e^+e^- collisions at LEP energies (Table XI), obtained from the π^0 results of Fig. 28 and the η fit, Eq. (13). The dashed line is the asymptotic $R_{\eta/\pi^0} = 0.5$ measured in hadronic and nuclear collisions.

two works (Rolli *et al.* at NLO [127] and Indumathi and collaborators at LO [128]) that have tried to parametrize the η FF from these data. An updated version of the η FF would be useful as input to a NLO pQCD cross-section calculation for comparison to the results presented here and especially in the light of upcoming high-p_T η asymmetry results using polarized beams of relevance for the proton spin program at RHIC [44]. Fitting all the available η data with Eq. (12), we obtain the following empirical parametrization:

$$\frac{1}{\sigma_{\text{had}}}\frac{d\sigma_\eta}{dx_p} = 0.0975 \cdot (x_p + 0.186)^{-2.953} \cdot (1 - x_p)^{1.507}, \qquad \chi^2/\text{ndf} = 0.37. \tag{13}$$

Using the fit [Eq. (13)] and the π^0 data plotted in Fig. 28 we have obtained the $R_{\eta/\pi^0}(x_p)$ ratio shown in Fig. 29. As seen for the corresponding η/π^0 ratios in hadronic and nuclear collisions, at low values of (scaled) momentum the π^0 production overwhelms that of η (a significant fraction of low-energy pions issues from decay contributions of heavier hadrons), but the ratio increases with x_p. From $x_p \approx 0.35$–0.7, the ratio is consistent with the asymptotic ratio of 0.5 found in hadron and nuclear collisions (dashed curve). This x_p range corresponds to the values of fractional momenta $\langle z \rangle \gtrsim 0.3$–$0.7$ typically carried by the leading high-p_T hadrons produced in high-energy h+p, h+A, and A+A collisions [129,130]. New results on inclusive η and π^0 production above $x_p = 0.6$ in e^+e^- collisions at the B-factories (BELLE and BaBar) would be useful to determine whether the value of the ratio indeed saturates at $R_{\eta/\pi^0} = 0.5$ or keeps increasing with x_p as suggested by Fig. 29.

F. Summary of experimental results

The studies presented here on high-p_T π^0 and η production in the three colliding systems (p+p, d+Au, Au+Au) provide interesting insights on initial- and final-state QCD effects in

cold nuclear matter (d+Au) and on the properties of the hot and dense medium produced in central Au+Au collisions. The absence of any strong deviation from the pointlike scaling expectations for the p_T-differential π^0 and η yields measured in d+Au relative to $p+p$ (Fig. 18) indicates that the amount of nuclear shadowing and initial-state p_T broadening is a small effect (at the 10% level) at midrapidity at RHIC energies. This is in contrast with results at lower energies that showed a larger Cronin enhancement for high-p_T mesons than observed here. One reason for the difference is likely due to the fact that hadron spectra at lower $\sqrt{s_{NN}}$ have steeper slopes and thus initial-state k_T "kicks" produce a relatively larger net effect than on the harder spectra at RHIC energies. The unsuppressed d+Au yields combined with the observation of strongly depleted yields of η and π^0 in central Au+Au compared to binary-scaled $p+p$ collisions (Fig. 19) indicate that the suppression is a final-state effect in the hot and dense matter produced in the central Au+Au reactions. The consistent values of the η/π^0 ratios measured at high p_T in nuclear (Figs. 25 and 26) as well as in more elementary $p+p$ (Fig. 24) and e^+e^- (Fig. 29) collisions clearly supports the idea that the suppression occurs at the parton level before the fragmentation of the parent quarks and gluons into a given leading meson. In particular, the overall agreement of the η/π^0 ratio measured in Au+Au and e^+e^- collisions suggests that although the fast parent partons lose energy while traversing the system produced in central Au+Au collisions, their relative probability to fragment into a given meson, given by universal fragmentation functions, is preserved as expected for final hadron formation in the vacuum.

V. SUMMARY

In summary, the transverse momentum spectra of η mesons in the range $p_T = 2$–12 GeV/c have been measured at midrapidity by the PHENIX experiment at RHIC in $p+p$, d+Au, and Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The η mesons are reconstructed through their $\eta \to \gamma\gamma$ channel in the three colliding systems, as well as through the $\eta \to \pi^0\pi^+\pi^-$ decay mode in $p+p$ and d+Au collisions. These data provide additional characterization of high-p_T hadroproduction in hadronic and nuclear collisions at RHIC energies. The d+Au yields are largely consistent with the $p+p$ differential cross sections scaled by the number of incoherent nucleon-nucleon collisions ($R_{dA} \approx 1$). No p_T or centrality dependence is observed in the nuclear modification factor within uncertainties. Such an observation indicates a null or very weak p_T

TABLE XVII. Nuclear modification factor $R_{AA}(p_T)$ for η in Au+Au collisions for different centrality classes from most central (0–20%) to most peripheral (60–92%). Note that there is an additional 9.7% normalization uncertainty (Run-3 $p+p$ BBC error, gray box in Fig. 19) not quoted.

broadening and, in general, a very modest influence of cold nuclear matter effects, such as shadowing of parton distribution functions, Cronin broadening, and/or hadronization by parton recombination, on high-p_T meson production at midrapidity at top RHIC energies. In contrast, the invariant yields measured in Au+Au are increasingly depleted with centrality compared to expectations from binary-scaled $p+p$ collisions, up to a maximum factor of $\sim$5 suppression in central collisions. The magnitude, p_T and centrality dependence of the Au+Au suppression is the same for η mesons and neutral pions. The measured η/π^0 ratio in $p+p$, d+Au, and Au+Au is nearly flat over $p_T = 2$–12 GeV/c and is independent of the reaction centrality. A fit to a constant yields $R_{\eta/\pi^0}(p_T) = 0.4$–0.5, in agreement with the experimental world values at high p_T collected here for hadron-hadron, hadron-nucleus, and nucleus-nucleus collisions in a wide range of center-of-mass energies ($\sqrt{s} \approx 3$–1800 GeV), as well as at high x_p ($x_p \gtrsim 0.35$) in electron-positron annihilations measured at $\sqrt{s} = 91.2$ GeV at LEP. These results indicate that any initial- and/or final-state nuclear effects influence the production of light neutral mesons at large p_T in the same way. The similar suppression pattern of η and π^0 mesons is consistent with the expectations of final-state parton energy loss in the dense medium formed in Au+Au reactions. The approximately constant $\eta/\pi^0 = 0.40 \pm 0.04$ ratio measured in central Au+Au collisions indicates that the attenuated parent partons fragment into leading mesons (η, π^0) in the vacuum according to the same probabilities that govern high-p_T hadron production in more elementary (e^+e^-, $p+p$) collisions.

APPENDIX: DATA TABLES

A. Invariant η cross sections ($p+p$, d+Au) and yields (Au+Au)

This appendix collects the data tables of the p_T spectra of η mesons measured at midrapidity in $p+p$, d+Au, and Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The invariant cross sections for η production in MB $p+p$ and d+Au collisions are tabulated in Tables XII and XIII, respectively. The invariant d+Au yields measured in centralities 0–20, 20–40, 40–60, and 60–88% are tabulated in Table XIV. Finally, the invariant yields in Au+Au reactions (MB and centralities 0–20, 20–60, and 60–92%) are presented in Tables XV. The quoted errors are categorized by type:

(i) (**A**) is a point-to-point error uncorrelated between p_T bins,
(ii) (**B**) is p_T correlated, all points move in the same direction but not by the same factor,
(iii) (**C**) is a normalization error in which all points move by the same factor independent of p_T.

B. Nuclear modification factors (d+Au, Au+Au)

We report in Tables XVI and XVII the $R_{AA}(p_T)$ η data tables for various centralities in d+Au and Au+Au collisions. The errors quoted are the point-to-point and absolute normalization ones. Note that there is an additional 9.7% overall normalization uncertainty (Run-3 $p+p$ BBC error, gray box in Fig. 19) not tabulated.

C. η/π^0 ratios ($p+p$, d+Au, Au+Au)

The ratio of η to π^0 invariant yields in $p+p$, d+Au, and Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV at midrapidity are tabulated in Tables XVIII, XIX, and XX. The data presented here are for minimum bias events and various centrality bins in d+Au and Au+Au collisions.

(Received 23 October 2006; published 24 April 2007)

The dependence of transverse momentum spectra of neutral pions and η mesons with $p_T < 16$ GeV/c and $p_T < 12$ GeV/c, respectively, on the centrality of the collision has been measured at midrapidity by the PHENIX experiment at the BNL Relativistic Heavy Ion Collider (RHIC) in d + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The measured yields are compared to those in $p + p$ collisions at the same $\sqrt{s_{NN}}$ scaled by the number of underlying nucleon-nucleon collisions in d + Au. At all centralities, the yield ratios show no suppression, in contrast to the strong suppression seen for central Au + Au collisions at RHIC. Only a weak p_T and centrality dependence can be observed.

DOI: 10.1103/PhysRevLett.98.172302 PACS numbers: 25.75.Dw

High-energy nucleus-nucleus collisions provide the opportunity to study strongly interacting matter at very high energy densities where Quantum Chromodynamics (QCD) predicts a transition from normal nuclear matter to a deconfined system of quarks and gluons, the Quark-Gluon Plasma (QGP) [1]. At the Relativistic Heavy Ion Collider (RHIC), the energy density is well in excess of the critical energy density that is expected for this transition [2]. One of the most intriguing results observed at RHIC so far is the suppression of hadrons with high transverse momentum (p_T) in central (head-on) Au + Au collisions. The hadron yield at high p_T is a factor of 5 less than expected from $p + p$ collisions scaled by the number of corresponding nucleon-nucleon collisions [3]. Such suppression was predicted as an effect of parton energy loss in the medium generated in the collisions [4,5]. A control experiment of d + Au collisions, where no medium is produced in the final state of the collision, showed no indication of hadron suppression at midrapidity [6], ruling out strong initial-state effects (final-state energy loss in the cold nucleus is generally expected to be small) as the cause for the suppression in Au + Au. For a better understanding of the medium effects at work in Au + Au, however, it is crucial to explore the exact role initial-state effects play in the modification of high-p_T particle production at RHIC.

Initial-state nuclear effects include p_T broadening, shadowing, and gluon saturation. The p_T broadening, often called Cronin effect [7], is an enhancement of the particle yield at intermediate p_T, which is often attributed to multiple soft parton scatterings before a hard interaction of the parton [8,9]. Shadowing is an apparent depletion of the structure function in the nucleus at small Bjorken x ($x \leq 10^{-2}$) [10] with (in some models) a corresponding enhancement at intermediate x ($x \sim 5 \times 10^{-2}$) called antishadowing. This is not well understood, but usually attributed to coherence effects or to gluon saturation. Gluon saturation refers to the nonlinear dynamics of gluons at small x where, due to the large densities, they tend to fuse rather than split. The Color Glass Condensate (CGC) model is a classical description of this saturation effect. In this picture, particle production at moderate p_T originally was predicted to be suppressed in central d + Au collisions at RHIC [11]. In recent CGC models, a Cronin enhancement can also be reproduced with a suitable choice of initial-state parameters [12].

One established way to test the contribution of different initial- and final-state nuclear effects is the study of the centrality dependence of particle production at high p_T. Initial state and medium effects are strongest in central collisions. In Au + Au collisions, a strong dependence of the suppression of high-p_T hadrons on the centrality of the collision has been observed [13–15]; the suppression weakens going to peripheral collisions and finally disappears. This can be compared to the centrality dependence of (initial-state) hadron production in d + Au. The yield of nonidentified charged hadrons in d + Au collisions with $p_T < 6$ GeV/c was found to be increasingly enhanced going from peripheral to central collisions [16], mainly attributed to the influence of (anti)protons [17]. At high p_T, the baryon contribution to the yield of unidentified charged hadrons is expected to become small, and instead the yield is dominated by charged pions [2]. All this sparks paramount interest in the centrality dependence of neutral pion (π^0) production especially as it can be measured up to very high p_T where particle production is truly perturbative. Furthermore, the high-p_T measurement of an additional identified particle like the eta meson (η), with 4 times the mass of the pion, may shed light on the question to what extent the particle-species dependence of the suppression (enhancement) observed in Au + Au (d + Au) depends on the number of constituent quarks rather than on the mass of the particle [18,19].

In this Letter, we present measurements by the PHENIX experiment [20] on the production of π^0 and η in $p + p$ and d + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The data provide the first measurement of neutral mesons in d + Au collisions at midrapidity as a function of the centrality of the collision. The π^0 measurements described in this Letter are similar to the analysis of minimum bias d + Au data in [6] but are based on an improved data set that allows the study of the particle production for different selections of the centrality of the collision. A more detailed description of the η analysis can be found in [21].

π^0 and η are measured by the PHENIX electromagnetic calorimeter (EMCal) via the $\pi^0 \rightarrow \gamma\gamma$ and $\eta \rightarrow \gamma\gamma$ decay. The EMCal consists of six lead scintillator (PbSc) and two lead glass (PbGl) sectors, each located at a radial distance of ~5 m from the beam axis. The detector covers a pseudorapidity range of $|\eta| \leq 0.35$ and an azimuthal angle of $\Delta\phi = \pi$. The EMCal granularity is $\Delta\eta \times \Delta\phi \approx 0.011 \times 0.011$ for the PbSc and 0.008×0.008 for the PbGl. The data sets from PbSc and PbGl are analyzed separately and combined for the final results. The energy calibration for the EMCal is obtained from beam tests, cosmic rays, and minimum ionizing energy peaks of charged hadrons. In a recent improvement of the calibration, the EMCal is calibrated by the invariant mass distribution of neutral pions for each of the 24768 readout channels separately. The uncertainty on the energy scale is 1.2%.

The data used in this analysis were recorded in 2002-2003 (RHIC Run-3) under two different trigger conditions. 25.2×10^6 and 58.3×10^6 minimum bias events were analyzed for $p + p$ and d + Au collisions, respectively. Minimum bias (MB) events are triggered by the Beam-Beam Counters (BBC) [20] ($|\eta| = 3.0$–3.9) and require a vertex position along the beam axis within $|z| < 30$ cm.

The minimum bias trigger accepts $(88 \pm 4)\%$ of all inelastic $d + \mathrm{Au}$ collisions that satisfy the vertex condition. This corresponds to 1.99 b $\pm 5.2\%$, the measured fraction of the total $d + \mathrm{Au}$ inelastic cross section, determined using photo-dissociation of the deuteron [22]. In $p + p$, this trigger measures 23.0 mb $\pm 9.7\%$ of the $p + p$ inelastic cross section. The measured particle yields are corrected for the $p + p$ MB trigger bias [23]: the MB trigger measures only $(79 \pm 2)\%$ of high-p_T particles. In $d + \mathrm{Au}$ collisions, this fraction varies from 85% to 100% from peripheral to central collisions; here the uncertainty is $\sim 3\%$. The second data sample was collected with a high-p_T photon trigger in the EMCal in addition to the MB trigger requirement in order to extend the measurement to higher p_T. This trigger requires a photon of $p_T > 1.4(1.4)$ GeV and $p_T > 2.5(3.5)$ GeV for PbSc (PbGl) and for $p + p$ and $d + \mathrm{Au}$ collisions, respectively. We analyzed 45.1×10^6 (19.5×10^6) events in $p + p$ ($d + \mathrm{Au}$) under this trigger condition. The sampled integrated luminosity was 216 nb^{-1} for $p + p$ and 1.5 nb^{-1} for $d + \mathrm{Au}$. (In $d + \mathrm{Au}$, that corresponds to an integrated nucleon-nucleon luminosity of 590 nb^{-1}).

The division of $d + \mathrm{Au}$ collisions in different centrality classes is based on the charge deposited in the backward BBC ($-3.9 < \eta < -3.0$), i.e., in the Au beam direction. For each centrality class, the corresponding average nuclear overlap function $\langle T_{AB} \rangle$ (compare Eq. (1)) is calculated using a Glauber Monte Carlo model and simulations of the BBC, taking into account its limited efficiency for peripheral collisions. For the four centrality classes (0–20%, 20–40%, 40–60%, and 60–88%) used in this analysis, the $\langle T_{AB} \rangle$ values are (0.365 ± 0.024), (0.252 ± 0.017), (0.165 ± 0.014), and (0.073 ± 0.007) mb^{-1}. The corresponding number of collisions can be calculated as $\langle N_{\mathrm{coll}} \rangle = \sigma_{\mathrm{inel}}^{pp} \times \langle T_{AB} \rangle$ with $\sigma_{\mathrm{inel}}^{\mathrm{pp}} = 42.2$ mb.

Photon candidates in the EMCal are selected by applying particle identification (PID) cuts based on the shower profile in the detector. To determine the yields of π^0 and η, the invariant mass of all photon pairs with an energy asymmetry $|E_1 - E_2|/(E_1 + E_2) < 0.7$ in a given p_T bin is calculated. After subtraction of the combinatorial background, the invariant mass distribution is integrated around the particle mass peak [13]; the integration window reflects thereby the p_T dependence of the mass peak position and width. The combinatorial background is determined by pairing photons from different events with similar centrality (for $d + \mathrm{Au}$) and vertex. In this analysis, the signal-to-background ratio for high-p_T π^0 is about 25 and 13 at $p_T = 4$ GeV/c in $p + p$ and central $d + \mathrm{Au}$ collisions, respectively. It decreases to 7 and 2 at $p_T = 2$ GeV/c. For η, this ratio is about 2 at $p_T = 8$ GeV/c, decreasing to 0.3 ($p + p$) and 0.2 (central $d + \mathrm{Au}$) at $p_T = 3$ GeV/c. The raw spectra are corrected for trigger efficiency, acceptance, and reconstruction efficiency. This includes dead areas, the influence of energy resolution, analysis cuts, the peak extraction window, and photon conversion. The corrections are determined using Monte Carlo simulations. Because of the fine granularity of the calorimeter, occupancy effects are negligible. Furthermore, the π^0 spectra are corrected at $p_T > 10$ GeV/c (15 GeV/c) for two-photon merging effects in the PbSc (PbGl), studied in Monte Carlo simulations and confirmed with test beam data [24]. Finally, a correction in the π^0 and η yields to account for the true mean value of each p_T bin is applied to the steeply falling spectra. For $p_T < 3.5(3.0)$ GeV/c, the $p + p$ π^0 (η) spectrum is calculated from the minimum bias data sample; above this threshold, the high-p_T triggered sample is used. In $d + \mathrm{Au}$, this transition is made at $p_T = 4.5$ and 3.5 GeV/c for π^0 and η, respectively.

The main contributions to the systematic uncertainty on the $p + p$ and $d + \mathrm{Au}$ spectra are given in Table I for π^0 and η. Most uncertainties are identical for $p + p$ and $d + \mathrm{Au}$; only the uncertainty on the peak extraction is slightly larger in $d + \mathrm{Au}$. Category (d) includes uncertainties on the EMCal global energy scale and nonlinearity. The uncertainties in (d) and (e) are partially correlated. All others are uncorrelated and added in quadrature to get the total uncertainty.

The fully corrected p_T distributions of π^0 and η are shown in Fig. 1. The top panels show the invariant yield in $d + \mathrm{Au}$ collisions for four centrality bins scaled for clarity by the factors indicated. The bottom panels show the

TABLE I. Main systematic uncertainties in % on π^0 and η spectra. The uncertainties are given for PbSc (PbGl). The normalization uncertainties of 9.7% for the $p + p$ and 5.2% for the $d + \mathrm{Au}$ cross section as well as the MB-trigger-bias uncertainty of $\sim 3\%$ for the centrality-selected yields are not listed.

invariant cross section in $p + p$ and $d + \mathrm{Au}$ collisions. The improved data set allows the study of π^0 (η) production up to 18(12) GeV/c, the highest p_T values measured for identified particles in $p + A$ ($d + A$) collisions. For the first time, the invariant cross section for π^0 and η in $d + \mathrm{Au}$ collisions has been measured at this energy. The π^0 result in $p + p$ agrees with the previous measurement at $\sqrt{s_{NN}} = 200$ GeV [23] within statistical uncertainties, and confirms the agreement with pQCD within the uncertainty of the calculation. Therefore, the $p + p$ cross section can be used as a well-understood reference for the production in $d + A$ and Au + Au collisions.

To quantify nuclear medium effects at high p_T, it is customary to use the *nuclear modification factor* which is given by the ratio of the invariant $d + \mathrm{Au}$ yield to the invariant $p + p$ cross section [13] scaled by $\langle T_{AB} \rangle$:

$$R_{AB}(p_T) = \frac{d^2 N_{AB}^{\pi^0}/dy dp_T}{\langle T_{AB} \rangle d^2 \sigma_{pp}^{\pi^0}/dy dp_T}. \quad (1)$$

The average nuclear overlap function $\langle T_{AB} \rangle$, averaged over the respective impact parameter range, is determined solely by the density distribution of the nucleons in the nuclei A and B and the impact parameter.

Figure 2 shows the nuclear modification factor $R_{dA}(p_T)$ for π^0 and η in $d + \mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV for four different centrality selections and for minimum bias events. As the $p + p$ and $d + \mathrm{Au}$ measurements are both made in the same year, many of the systematic errors associated with detector performance are nearly identical, and the corresponding systematic errors in the comparison are negligible. Within systematic errors, $R_{dA}(p_T)$ for π^0 and η is ≈ 1 in all centrality bins, and only a weak p_T dependence can be seen. In order to check the absolute normalization systematics, we can also calculate $R_{dA}(p_T)$ using the inelastic cross section measured through photodissociation of the deuteron. This constitutes an important cross check. It replaces the systematic uncertainties of the BBC efficiency and $\langle T_{AB} \rangle$, which are determined by model calculations, by the uncertainty of the cross section measurement of similar size. The resulting $R_{dA}(p_T)$ is 9.8% larger than that obtained from the minimum bias yield, consistent within 1.5 σ.

Though very different in mass, η and π^0 show a similar, weak centrality dependence of $R_{dA}(p_T)$ over the measured p_T range. These results do not show the significant enhancement seen for protons where the proton R_{AA} is substantially larger than that of pions in the intermediate p_T (2 GeV/c $< p_T <$ 4 GeV/c) region [17]. The π^0 data exhibit small shape variations with centrality that may be due to initial-state effects including shadowing and multiple scattering. Possible Cronin enhancements in the intermediate p_T region due to initial-state multiple scattering or antishadowing are not more than 10% around 4 GeV/c. At low p_T ($p_T < 3$ GeV/c), the drop towards smaller R_{dA} is consistent with analogous measurements for charged pions [17] and is usually attributed to a change to a regime of soft physics (N_{part} scaling) at the smallest p_T values. At the largest p_T values measured ($p_T > 9$ GeV/c), the most central π^0 result hints at a small suppression, though this is only a ~1.7 sigma effect.

In conclusion, we have presented the first study of the centrality dependence of π^0 and η production at midrapidity in $d + \mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV. Transverse momentum spectra up to $p_T = 18$ and 12 GeV/c have been measured for π^0 and η, respectively. The invariant yield per nucleon-nucleon collision is compared to that in $p + p$ collisions measured at the same $\sqrt{s_{NN}}$. The strong suppression observed for π^0 production at high p_T in central Au-Au collisions is not seen for $d + \mathrm{Au}$ in any centrality: Within systematic errors, $R_{dA}(p_T)$ is ≈ 1 in all centrality bins. A weak centrality dependence of the shape of R_{dA} versus p_T is seen, presumably due to initial-state effects. A possible Cronin enhancement is substantially smaller than the $R_{dA} \gtrsim 1.9$ that corresponds to results from lower energy measurements [7,25]. Within systematic errors, R_{dA} for π^0 and η agree well, giving no indication for cold nuclear matter effects having a mass dependence. Since nuclear modifications in $d + \mathrm{Au}$ are

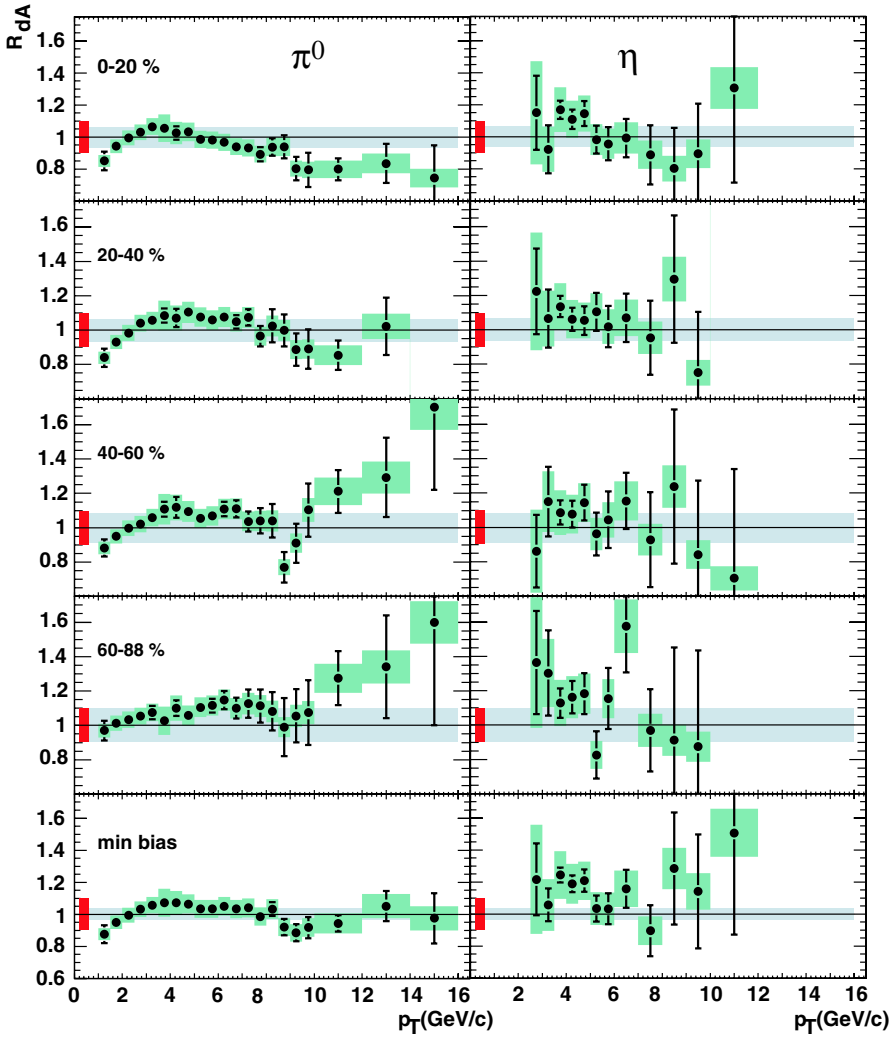

FIG. 2 (color online). Nuclear modification factor R_{dA} for π^0 and η in different centrality selections and min. bias data at midrapidity. The bands around the data points show systematic errors which can vary with p_T. The shaded bands around unity indicate the $\langle T_{AB} \rangle$ uncertainty, and the small bands on the left side of the data points indicate the normalization uncertainty due to the $p + p$ reference.

small even in the most central collisions where initial-state effects are expected to be largest, we conclude that initial-state effects in Au + Au must be small as well, and therefore the large suppression seen in Au + Au must be mostly due to medium effects.

Abstract. Results from the PHENIX experiment at RHIC on direct photon production in $p+p$, $d+\mathrm{Au}$, and $\mathrm{Au}+\mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200\,\mathrm{GeV}$ are presented. In $p+p$ collisions, direct photon production at high p_T behaves as expected from perturbative QCD calculations. The $p+p$ measurement serves as a baseline for direct photon production in $\mathrm{Au}+\mathrm{Au}$ collisions. In $d+\mathrm{Au}$ collisions, no effects of cold nuclear matter are found within the large uncertainty of the measurement. In $\mathrm{Au}+\mathrm{Au}$ collisions, the production of high p_T direct photons scales as expected for particle production in hard scatterings. This supports jet quenching models, which attribute the suppression of high p_T hadrons to the energy loss of fast partons in the medium produced in the collision. Low p_T direct photons, measured via e^+e^- pairs with small invariant mass, are possibly related to the production of thermal direct photons.

1 Introduction

Depending on their transverse momentum, direct photons convey information about different aspects of ultra-relativistic nucleus–nucleus ($A+A$) collisions. High transverse momentum (p_T) direct photons are produced in early, hard parton–parton scatterings by processes like quark–gluon Compton scattering ($q+g \longrightarrow q+\gamma$). Unlike scattered quarks or gluons, direct photons do not interact strongly with the medium subsequently produced in the collision. High p_T direct photons ($p_\mathrm{T} \gtrsim 6\,\mathrm{GeV}/c$) therefore provide a baseline for measuring medium modifications of high p_T hadron production.

A significant fraction of low p_T direct photons ($1 \leq p_\mathrm{T} \leq 3\,\mathrm{GeV}/c$ in central $\mathrm{Au}+\mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200\,\mathrm{GeV}$) is expected to come from a thermalized medium of deconfined quarks and gluons, the quark–gluon plasma (QGP), possibly created in $A+A$ collisions [1]. These thermal photons carry information about the initial temperature of the QGP. Thermal photons are produced in the QGP as well as in the hadronic gas over the entire life time of the collision. The initial temperature can be extracted comparing measurements to models which convolute the production rate with the space-time evolution of the collision.

At low and intermediate p_T ($p_\mathrm{T} \leq 6\,\mathrm{GeV}/c$ in central $\mathrm{Au}+\mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200\,\mathrm{GeV}$) another significant source of direct photons might be the interaction of fast partons from jets with thermal partons in the QGP [2] like $q_\mathrm{hard} + g_\mathrm{QGP} \longrightarrow q+\gamma$.

Possible modifications of direct photon production from cold nuclear matter effects can be measured in $d+\mathrm{Au}$ collisions where no medium is created. Direct photon measurements in $p+p$ collisions are a superb test of QCD. They constrain the gluon distribution function since the gluon is a direct participant of the partonic scattering. Furthermore, they provide a baseline for understanding direct photon production in $A+A$ collisions.

2 High p_T direct photons

2.1 Measurement

Experimentally, the measurement of direct photons is challenging due to a large background from hadron decays like $\pi^0 \longrightarrow \gamma\gamma$ and $\eta \longrightarrow \gamma\gamma$. PHENIX measures all those photon sources. Photons are measured with the electromagnetic calorimeter (EMCal). Neutral pions and η mesons are measured through their two-photon decay branch [3, 4]. The EMCal [5] consists of six sectors of a lead scintillator and two sectors of a lead glass calorimeter centered at midrapidity ($\eta < 0.35$) and covering 1/4 of the azimuthal angle.

The direct photon spectrum is obtained by subtracting the decay photon spectrum from the inclusive photon spectrum. This is gained from photon-like showers in the EMCal corrected for contaminations from charged hadrons and neutrons. The decay photon spectrum is calculated from the measured π^0 and η spectrum, taking into account minor contributions from other hadrons that decay into photons.

If the detector occupancy is low as in $p+p$ or $d+\mathrm{Au}$ collisions, the signal-to-background ratio can be improved

by event by event tagging of photons that have a matching partner as decay photons.

2.2 Results

2.2.1 $p+p$ collisions

The preliminary direct photon cross section for $p+p$ collisions at $\sqrt{s} = 200\,\mathrm{GeV}$ is shown in Fig. 1 [6]. It is based on an integrated luminosity of $266\,\mathrm{nb}^{-1}$ collected in RHIC Run-3. For the whole p_T range of 5 to 16 GeV/c the observed cross section is consistent with a next-to-leading-order perturbative-QCD (NLO pQCD) calculation [7]. This measurement establishes a reference for direct photon production in $A+A$. In RHIC Run-5, PHENIX took a $p+p$ data set with ten times the Run-3 statistics.

2.2.2 Au + Au collisions

The high p_T direct photon yield in $A+A$ collisions relative to $p+p$ is expected to scale with the parton luminosity in the overlap region of the two nuclei. The parton luminosity is quantified by the nuclear overlap function, T_{AA}. In the absence of nuclear effects the nuclear modification factor

$$R_{AA}(p_\mathrm{T}) = \frac{\mathrm{d}N/\mathrm{d}p_\mathrm{T}|_{A+A}}{\langle T_{AA}\rangle_f \, \mathrm{d}\sigma/\mathrm{d}p_\mathrm{T}|_{p+p}} \qquad (1)$$

is unity for particle production from hard scattering.

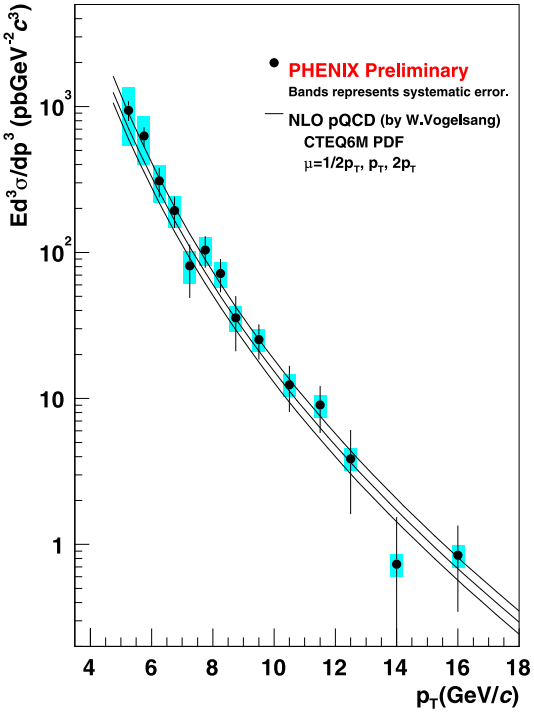

Fig. 1. Preliminary direct photon cross section as a function of p_T for $p+p$ collisions at $\sqrt{s} = 200$ GeV [6]. The *solid curves* are pQCD predictions [7] for three different scales, which represent the uncertainty on the calculation

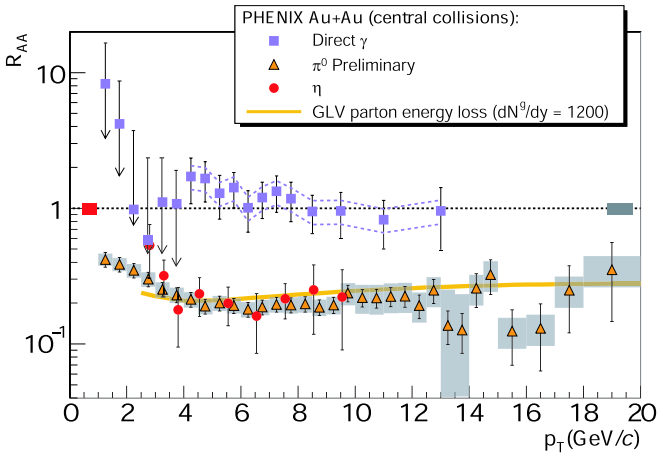

Fig. 2. Nuclear modification factor for direct photon, π^0, and η production in central Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. For direct photons, a pQCD calculation is used as the reference

As shown by PHENIX in RHIC Run-2 [8], at high p_T direct photon production is consistent with the T_{AA}-scaled pQCD expectation also in Au + Au collisions. Figure 2 compares the nuclear modification factor for direct photon, π^0, and η production in central Au + Au collisions at $\sqrt{s_{NN}} = 200\,\mathrm{GeV}$. For direct photons, the pQCD calculation is used as a reference. The suppression for π^0 and η, supported by the non-suppression of photons, can be described with energy loss of partons in the produced medium.

While high p_T direct photon production is consistent with the pQCD expectation, one should keep in mind that there are a number of medium effects that might alter direct photon production. On the one hand, a significant fraction of direct photons is expected to stem from the fragmentation of hard-scattered partons into jets. As those partons lose energy in the medium, also the fragmentation photons should be suppressed. On the other hand, as partons lose energy through gluon bremsstrahlung, they should also generate photon bremsstrahlung, enhancing the direct photon yield. It would be a coincidence if these counterbalancing effects exactly canceled.

Experimentally, contributions from these effects can be quantified by studying the azimuthal distribution of direct photon production with respect to the reaction plane. If fragmentation photons are suppressed, less direct photons are expected to be emitted outside of the reaction plane. If bremsstrahlung is enhanced, more direct photons will be found outside of the reaction plane.

2.2.3 d + Au collisions

The preliminary direct photon yield for minimum-bias d + Au collisions at $\sqrt{s_{NN}} = 200\,\mathrm{GeV}$ is shown in the upper panel of Fig. 3 along with the yield in $p+p$ collisions. The d + Au analysis is based on ≈ 3 billion events sampled in RHIC Run-3. The lower panel shows the ratio to the

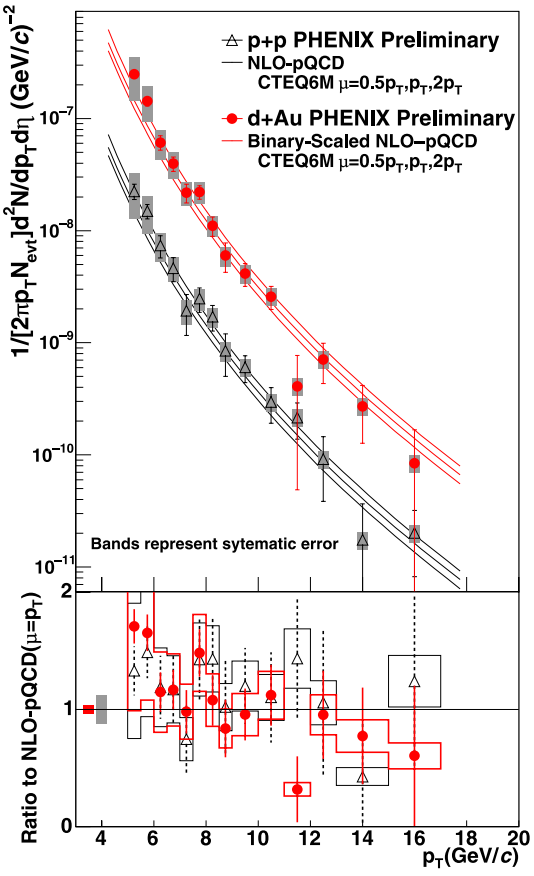

Fig. 3. Preliminary direct photon invariant yield as a function of p_{T} for $p+p$ [6] and minimum-bias $d+\mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV. The *solid curves* are pQCD predictions [7] for three different scales, which represent the uncertainty on the calculation

T_{AA}-scaled NLO pQCD calculation. The ratio is consistent with unity over the entire p_{T} range, showing no indication of cold nuclear matter effects. However, the uncertainty of the measurement is large. A high statistics $d+\mathrm{Au}$ run is planned.

3 Low p_{T} direct photons

3.1 Measurement

The EMCal measurement at low p_{T} suffers from a large background from decay photons. Also, the relative energy resolution of the EMCal becomes worse at low energy. Therefore, a new method [9, 10] to measure direct photons at low p_{T} has been employed. It has been carried out in heavy ion experiments for the first time. The method is based on the measurement of pairs of e^+e^-, which are identified with the PHENIX Ring Imaging Cherenkov Detector (RICH). The basic idea is that any source of real photons also produces virtual photons that decay into e^+e^- with small invariant mass. An example is the π^0 Dalitz decay ($\pi^0 \longrightarrow \gamma e^+e^-$). This internal conversion method is

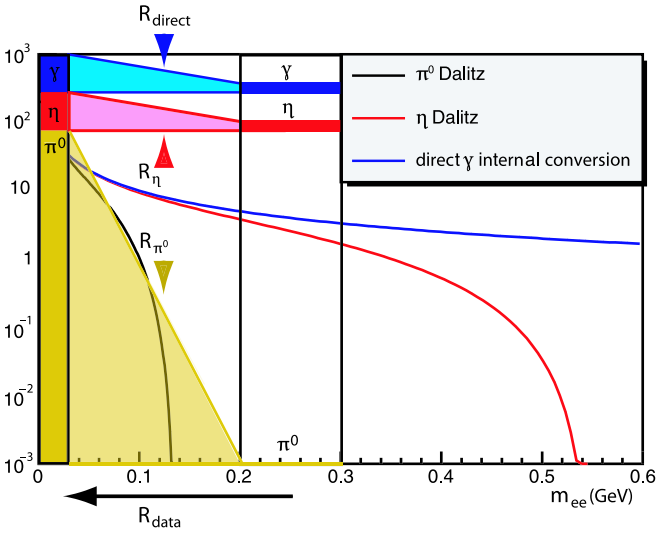

Fig. 4. Invariant-mass distribution of virtual photons from the π^0 and η Dalitz decay as well as from direct photons according to (2). It is illustrated how the various contributions decrease to a fraction R when going to higher invariant mass with the π^0 contribution exhausting

based on two assumptions: first, the ratio of direct-to-all photons is the same for real and virtual photons at small invariant mass close to zero ($m_\gamma < 30$ MeV): $\gamma^\star_{\mathrm{direct}}/\gamma^\star_{\mathrm{incl.}} = \gamma_{\mathrm{direct}}/\gamma_{\mathrm{incl.}}$. Second, the mass distribution can be described by the Kroll–Wada formula [11], which has been established to describe the Dalitz decay[1]:

$$\frac{1}{N_\gamma}\frac{\mathrm{d}N_{ee}}{\mathrm{d}m_{ee}} = \frac{2\alpha}{3\pi}\sqrt{1-\frac{4m_e^2}{m_{ee}^2}}\left(1+\frac{2m_e^2}{m_{ee}^2}\right) \times \frac{1}{m_{ee}}\left|F\left(m_{ee}^2\right)\right|^2\left(1-\frac{m_{ee}^2}{M^2}\right)^3, \qquad (2)$$

The mass distribution according to (2) is depicted in Fig. 4. For e^+e^- pairs from π^0 and η Dalitz decays the yield is suppressed towards higher m_{ee} due to the mass, M, of the parent meson in the phase space factor $(1-m_{ee}^2/M^2)^3$ whereas no suppression takes place for e^+e^- pairs from virtual direct photons as long as $m_{ee} \ll p_{\mathrm{T}}^{ee}$. For the small invariant masses considered here the form factor $\left|F\left(m_{ee}^2\right)\right|$ is assumed to be unity in all cases.

The key advantage of this method is the greatly improved signal-to-background ratio, which is achieved by eliminating the contribution from π^0 Dalitz decays when the invariant mass is increased. In addition, the electron measurement through charged particle tracking provides a better energy resolution at low p_{T} than the EMCal photon measurement. This excellent energy resolution at low p_{T} combined with little material upstream of the detector,

[1] Since the virtual photons decay in the medium, this relation might be slightly modified. This would not affect the significance of the observed excess of direct photons, only its translation into an absolute yield of real direct photons.

where photons could convert generating background e^+e^- pairs, makes this measurement feasible in PHENIX.

The experimentally observed quantity is the ratio of e^+e^- pairs in an invariant mass bin where the π^0 Dalitz decay is largely suppressed to the yield at an invariant mass close to zero: $R_{\rm data} = N_{ee}^{90-300\ {\rm MeV}}/N_{ee}^{<30\ {\rm MeV}}$. If there is no direct photon signal, $R_{\rm data} = R_{\rm hadron}^{\rm calc}$, *i.e.* $R_{\rm data}$ can be calculated[2] from (2) based on the known ratio $\eta/\pi^0 = 0.45 \pm 0.1$. An excess $R_{\rm data} > R_{\rm hadron}^{\rm calc}$ translates into the fraction of virtual direct photons at close to zero invariant mass according to:

$$\frac{\gamma^\star_{\rm direct}}{\gamma^\star_{\rm incl.}} = \frac{R_{\rm data} - R_{\rm hadron}^{\rm calc}}{R_{{\rm direct}\ \gamma}^{\rm calc} - R_{\rm hadron}^{\rm calc}}\,. \tag{3}$$

This can be derived starting from

$$R_{\rm data} = N_{ee}^{90-300\ {\rm MeV}}/N_{ee}^{<30\ {\rm MeV}} \tag{4}$$

with

$$N_{ee} = N_{\rm hadron} + N_{{\rm direct}\ \gamma}: \tag{5}$$

$$R_{\rm data} = \frac{R_{\rm hadron}^{\rm calc} N_{\rm hadron}^{<30\ {\rm MeV}} + R_{{\rm direct}\ \gamma}^{\rm calc} N_{{\rm direct}\ \gamma}^{<30\ {\rm MeV}}}{N_{\rm hadron}^{<30\ {\rm MeV}} + N_{{\rm direct}\ \gamma}^{<30\ {\rm MeV}}} \tag{6}$$

$$= R_{\rm hadron}^{\rm calc} + (R_{{\rm direct}\ \gamma}^{\rm calc} - R_{\rm hadron}^{\rm calc}) \frac{N_{{\rm direct}\ \gamma}^{<30\ {\rm MeV}}}{N_{ee}^{<30\ {\rm MeV}}}\,. \tag{7}$$

The direct photon spectrum is then obtained by multiplying $\gamma^\star_{\rm direct}/\gamma^\star_{\rm incl.}$ by the inclusive photon spectrum measured with the EMCal.

The full 2004 data set of about 900 million minimum bias events is analyzed. Events and centrality are selected as described in [12]. Electrons in the central arms are identified by matching charged particle tracks to clusters in the EMCal and to rings in the RICH detector. To obtain a clean invariant-mass distribution of e^+e^- pairs, pairs originating from photon conversions in the beam pipe or detector material are rejected based on their orientation with respect to the magnetic field. The combinatorial background is removed by an event-mixing technique. The uncertainty of the η-to-π^0 ratio of about 20% [13] is the main source of uncertainty, translating into an uncertainty of 20% of the measured direct photon yield. Other sources are the EMCal-measured inclusive photon yield (10%) and the e^+e^--pair acceptance (5%). The total systematic uncertainty is 25%.

3.2 Results

Figure 5a shows the direct photon signal for central Au + Au collisions at $\sqrt{s_{NN}} = 200\,{\rm GeV}$ in terms of the double ratio $\left(\gamma/\pi^0|_{\rm meas.}\right) / \left(\gamma/\pi^0|_{\rm bckgrd.}\right)$. This ratio indicates a direct photon excess above the decay photon contribution as an enhancement above 1. In this figure, two measurements are compared: the result from the internal conversion method as described above [14] and a preliminary analysis of the conventional EMCal measurement based on a subset of the RHIC Run-4 data set [14]. [3] While the internal conversion measurement results in a significant direct photon signal of about 10% above the decay photon background for $1 < p_{\rm T} < 5\,{\rm GeV}/c$, the EMCal measurement does not yield a significant direct photon signal below $p_{\rm T} = 3\,{\rm GeV}/c$, but agrees with the internal conversion measurement within the uncertainties over the entire range.

Figure 5b shows the direct photon invariant yield from the internal conversion measurement [14] and compares it to theoretical calculations. With large significance, a direct photon spectrum is obtained for $1 < p_{\rm T} < 5\,{\rm GeV}/c$. The spectrum lies significantly above a T_{AA}-scaled NLO pQCD calculation [7] for $p_{\rm T} \lesssim 3\,{\rm GeV}/c$. The pQCD calculation indicates the contribution from hard scatterings. The lines show the scale uncertainty of the calculation. However, it is not clear how meaningful the comparison is down to this low $p_{\rm T}$ where the pQCD calculation reaches its limit of applicability. It is planned to replace the pQCD calculation by a reference measurement of direct photon production in $p+p$ collisions with the same method as in Au + Au.

The excess of the measured direct photon spectrum above the pQCD calculation can be described by models that allow for a significant contribution of thermal photons. In order to describe thermal photon production in $A+A$ collisions, the entire space-time evolution has to be accounted for including the hadronic phase. This is done in hydrodynamical models, which assume local thermal equilibrium. An important free parameter in such models is the initial temperature of the fireball. Figure 5b compares the measured direct photon spectrum to a $2+1$ hydrodynamical model [15] for thermal-photon emission with an average initial temperature of $T_0^{\rm ave} = 360\,{\rm MeV}$ ($T_0^{\rm max} = 570\,{\rm MeV}$) and a formation time of $\tau_0 = 0.15\,{\rm fm}/c$. The model underpredicts the data for $p_{\rm T} \gtrsim 3\,{\rm GeV}/c$. The data can be described when both sources, thermal and pQCD, are combined. Various other calculations come to similar descriptions with initial temperatures in the range $370 < T_{\rm i} < 570\,{\rm MeV}$ [2, 16, 17]. The temperatures are significantly above the critical temperature for the QGP phase transition of $T_{\rm c} = 170\,{\rm MeV}$. However, the obtained temperature is only meaningful if the excess above pQCD is of thermal origin. Besides hard photons, also jet-plasma interactions may play a significant role [2].

4 Conclusions

The direct photon cross section in $p+p$ collisions at $\sqrt{s} = 200\,{\rm GeV}$ is found to be consistent with a NLO pQCD cal-

[2] Besides π^0 and η, decay photons from a cocktail of hadrons are considered here.

[3] The preliminary result from the measurement of virtual photons is presented in the same figure in terms of $\gamma_{\rm direct}/\gamma_{\rm incl.} + 1$, which also indicates a direct photon excess as an enhancement above 1. Note that the two quantities are not exactly equivalent.

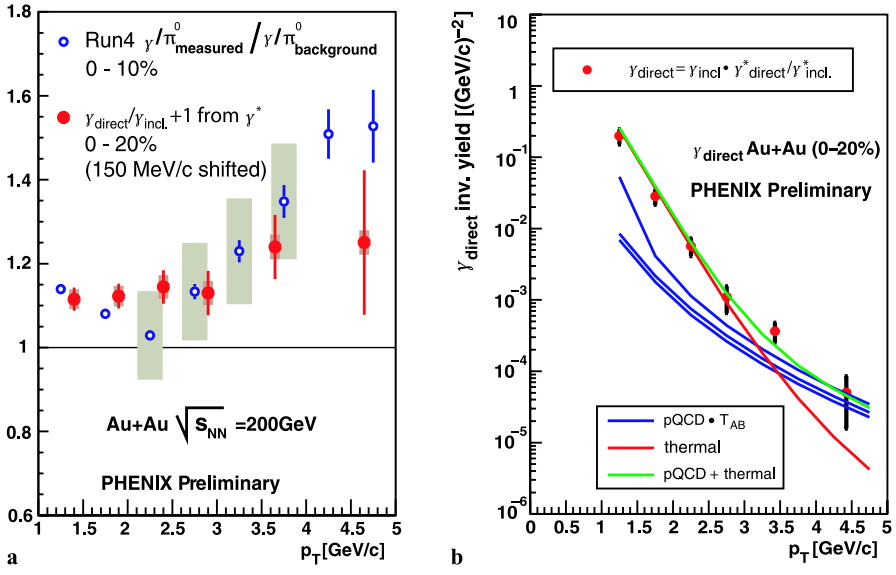

Fig. 5. **a** Direct photon excess for the conventional and the internal-conversion measurement in central Au + Au collisions [14]; **b** direct photon spectrum from the latter [14] compared to pQCD [7], thermal-photon [15], and the sum of both calculations

culation over the entire range of the measurement from 5 GeV $\leq p_{\mathrm{T}} \leq$ 16 GeV/c. In d + Au collisions, no indications for cold nuclear matter effects are found within the large uncertainties of the measurement. A high statistics d + Au run is planned. High p_{T} direct photon production in Au + Au collisions is found to scale with the nuclear overlap function T_{AA}, establishing medium effects as the cause for the hadron suppression observed in central Au + Au collisions.

At low p_{T} ($1 \leq p_{\mathrm{T}} \leq 5$ GeV/c) a significant direct photon excess above the decay photon background is observed employing a new method in heavy ion collisions, which measures low invariant mass e^+e^- pairs from direct photon internal conversions. The signal appears to be above pQCD calculations for $p_{\mathrm{T}} \leq 3$ GeV/c, whose applicability is questionable, however, at this low p_{T}. If a thermal photon source modeled by hydrodynamical calculations is added to the pQCD calculation, the data can be described over the entire p_{T} range. Other direct photon sources like jet-plasma interactions might play a significant role as well.

(Received 18 September 2006; revised manuscript received 21 May 2007; published 13 November 2007)

Muon production at forward rapidity ($1.5 \leq |\eta| \leq 1.8$) has been measured by the PHENIX experiment over the transverse momentum range $1 \leq p_T \leq 3$ GeV/c in $\sqrt{s} = 200$ GeV $p + p$ collisions at the Relativistic Heavy Ion Collider. After statistically subtracting contributions from light hadron decays an excess remains which is attributed to the semileptonic decays of hadrons carrying heavy flavor, i.e. charm quarks or, at high p_T, bottom quarks. The resulting muon spectrum from heavy flavor decays is compared to PYTHIA and a next-to-leading-order perturbative QCD calculation. PYTHIA is used to determine the

[*]Deceased.
[†]PHENIX Spokesperson; zajc@nevis.columbia.edu

charm quark spectrum that would produce the observed muon excess. The corresponding differential cross section for charm quark production at forward rapidity is determined to be $d\sigma_{c\bar{c}}/dy|_{y=1.6} = 0.243 \pm 0.013(\text{stat.}) \pm 0.105(\text{data syst.}) \,^{+0.049}_{-0.087}\,(\text{PYTHIA syst.})$ mb.

I. INTRODUCTION

Measurements of heavy quark production in proton-proton ($p + p$) interactions at collider energies serve as important tests for perturbative quantum chromodynamics (pQCD). Bottom production at the Tevatron collider ($\sqrt{s} =$ 1.8 and 1.96 TeV) [1,2] is reasonably well described by a recent fixed order next-to-leading logarithm (FONLL) calculation [3–5]. Charm production at FNAL, which has only been measured at relatively high p_T (> 5 GeV/c), is $\approx 50\%$ higher than the FONLL prediction [6]. However, theoretical and experimental uncertainties are large, such that significant disagreement between theory and data cannot be claimed.

Measurements at Brookhaven National Laboratory's Relativistic Heavy Ion Collider (RHIC), by both the PHENIX and STAR experiments, have provided a wealth of information on midrapidity open charm production in collisions at $\sqrt{s_{NN}} = 130$ GeV ($p + p$) and $\sqrt{s_{NN}} =$ 200 GeV ($p + p$, $d + Au$, and $Au + Au$) down to $p_T \approx$ 0.5 GeV/c. Semileptonic decay of produced charm quarks is the primary source of high p_T leptons after contributions from known (light hadron) sources are subtracted. Both PHENIX [7–16] and STAR [17,18] have made statistical measurements of charm production via single-electron spectra. STAR has also made a direct measurement of charm production through reconstruction of hadronic decay modes of D mesons [17]. In $p + p$ collisions at $\sqrt{s_{NN}} = 200$ GeV PHENIX finds $d\sigma_{c\bar{c}}/dy|_{y=0} = 0.123 \pm 0.012(\text{stat.}) \pm 0.045(\text{syst.})$ mb [13]. STAR finds a somewhat higher central value, $d\sigma_{c\bar{c}}/dy|_{y=0} = 0.30 \pm 0.04(\text{stat.}) \pm 0.09(\text{syst.})$ mb [17], but the two measurements are consistent within the stated uncertainties. Both measurements are noticeably (2–4 $\times$) higher than PYTHIA (a leading order pQCD event generator) [19] [see experimental references for specific parameter sets] and FONLL [20]. Again, quantitative disagreement cannot be established with current experimental and theoretical uncertainties. However, we note that there is some debate about whether charm quarks are heavy enough to be reliably treated by pQCD [21].

Such measurements also serve as an important baseline for charm production in proton-nucleus or deuteron-nucleus ($p + A$ or $d + A$), and nucleus-nucleus ($A + B$) collisions [22–25]. In the absence of any nuclear effects, charm production (since it is a pointlike process) is expected to scale with the number of binary nucleon-nucleon collisions (N_{coll}), which depends on the impact parameter of the nuclear collision and can be obtained from a Glauber calculation [26]. The degree of scaling for any given centrality bin is quantified by the nuclear modification factor:

$$R_{AB} = \frac{1}{N^{AB}_{\text{coll}}} \times \frac{dN^{AB}/dy}{dN^{pp}/dy}. \quad (1)$$

Deviations from this scaling ($R_{AB} \neq 1$) in $p + A$ or $d + A$ collisions quantify cold nuclear matter effects (such as initial state energy loss [27–32], and shadowing [33–37]). Any such deviation must be understood so that in $A + B$ collisions contributions to $R_{AB} \neq 1$ from hot nuclear matter effects (such as in-medium energy loss [[38] and references therein] and cold nuclear matter effects can be disentangled. In $d + Au$ collisions both PHENIX and STAR find little or no effect of cold nuclear matter on charm production ($R_{dAu} \approx 1$ over the measured lepton p_T [10,17]). This contrasts with measurements of open charm in $Au + Au$ collisions: although the *total* charm production appears to scale with N_{coll} [8], there is a strong suppression of lepton spectra for $p_T > 2$ GeV/c that increases with centrality [11,12,18]. Furthermore the elliptical flow of nonphotonic single electrons, as measured by PHENIX in $Au + Au$ collisions [14–16], implies that the charm quarks interact strongly with the created medium.

Finally, since the initial formation of open and closed charm are both sensitive to initial gluon densities [39,40], open charm production serves as an appropriate normalization for J/ψ production. The production of J/ψ mesons is expected to be sensitive to the production of a quark gluon plasma (QGP), should one be formed in $A + B$ collisions [41–46]. In order to understand J/ψ production differences in $A + B$ collisions compared to $p + p$ and $p + A$ collisions it is important to take into account any differences in the charm quark production in each of the different systems.

Until now, open charm measurements at RHIC have been limited to midrapidity. Measurements at forward rapidity are interesting for a variety of reasons. First is the need to constrain theoretical calculations over a wide kinematic range. The importance of this is demonstrated by the D0 measurement of bottom production at large rapidity ($\sqrt{s} = 1.8$ TeV, $p_T > 5$ GeV/c, $2.4 < y_\mu < 3.2$), as deduced from the production of high p_T muons [1]. Significant theoretical improvements resulted from the effort to reduce what was, initially, a discrepancy between theory and experiment that increased with increasing rapidity [5]. Second, significant cold nuclear effects have been seen in RHIC collisions at forward rapidity. PHENIX [47], BRAHMS [48,49], and STAR [50] have all measured light hadron production in $d + Au$ collisions at forward

rapidity and have found significant deviations from $R_{dAu} = 1$. It will be interesting to see whether charm production follows a similar pattern. Finally, open charm production at forward rapidity needs to be understood to fully interpret PHENIX J/ψ measurements at forward rapidity [24,25,51–53].

In this paper we report on the measurement of muon production at forward rapidity ($1.5 \leq |\eta| \leq 1.8$), in the range $1 < p_T < 3$ GeV/c, in $\sqrt{s} = 200$ GeV $p + p$ collisions by the PHENIX experiment. The upper limit of the p_T range is determined by available statistics. The vertex-independent muon yield is statistically extracted by calculating and subtracting contributions from light mesons (π's and K's) which decay into a muon, and hadrons which penetrate through the muon arm absorber material. In the absence of new physics, and in the p_T range measured in this analysis, such muons come dominantly from the decay of hadrons containing a charm quark (with small contributions from decays of hadrons containing a bottom quark and decays of light-vector mesons). PYTHIA is used to determine the charm quark spectrum that would produce the observed vertex-independent muon spectrum, and from this we obtain the differential cross section of charm quark production at forward rapidity. Although the statistical and systematic errors in this analysis preclude strong conclusions about the details of charm production, this paper establishes a method to extract this information from future PHENIX data sets.

The remainder of this paper is organized as follows: In Sec. II we describe the PHENIX experimental apparatus, with special emphasis on the muon arm detectors. In Sec. III we describe the methodology used to extract the vertex-independent muon signal. This section includes details on the run, event, and track selection criteria; values obtained for contributions to the muon yield from abundant light hadrons, which are subtracted to obtain the vertex-independent muon yield; and details on the systematic error analysis. In Sec. IV we extract the differential cross section for charm production at $y = 1.6$, integrated over p_T. Finally, in Sec. V we compare to other measurements, draw conclusions, and discuss the prospects for such measurements with improved data sets currently under analysis.

II. THE PHENIX EXPERIMENT

The PHENIX experiment [54], shown in Fig. 1, is a large multipurpose set of detectors optimized for measuring relatively rare electromagnetic probes (photons, muons, and electrons) of the spin structure of the proton and of the hot dense matter created in ultrarelativistic heavy ion collisions. The data acquisition system and multilevel triggers are designed to handle the very different challenges presented by $p + p$ collisions (relatively small events at very high rates) and $Au + Au$ collisions (very large events at relatively low rates) with little or no dead time [55,56].

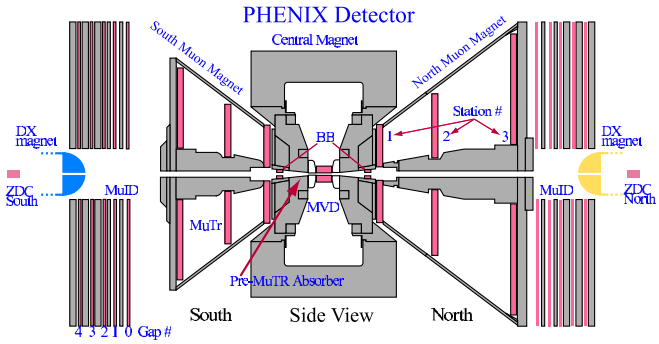

FIG. 1 (color online). Elevation view of the PHENIX experimental layout during the 2001/2 run period.

Event characterization devices, such as the beam-beam counters (BBCs) [57] used in this analysis, provide information on the vertex position, start time, and centrality of the collision. The two muon arms cover $1.2 < |\eta| < 2.4$ in pseudorapidity and $\delta\phi = 2\pi$ in azimuth. The two central arms, which each cover $|\eta| < 0.35$ and $\delta\phi = \pi/2$, are not used in this analysis.

The BBCs [57] each consist of 64 quartz radiators instrumented with mesh dynode photomultiplier tubes (PMTs) and arranged in a cylinder coaxial with the beam. The BBCs are placed on either side of the collision vertex and cover $3.0 < |\eta| < 3.9$. Each channel has a dynamic range extending to 30 times the average energy deposit of a minimum ionizing particle. The BBCs measure the arrival times of particles on both sides of the collision vertex, t_S and t_N. From the average of these times we determine the event start time. From their difference we obtain the position of the vertex along the beam direction, z_{vtx}. The BBCs also provide the minimum bias interaction trigger, which requires that there be at least one hit in each BBC and that $|z_{vtx}| < 38$ cm.

The muon arms [58] are coaxial with the beam on opposite sides of the collision vertex. By convention the arm on the south (north) end of the interaction region is assigned negative (positive) z coordinates and rapidity. For the 2001/2 run period, in which the data for this paper were collected, only the south muon arm was operational. Each muon arm is comprised of a muon tracker (MuTR) and a muon identifier (MuID). The MuTR makes an accurate measurement of particle momenta. The MuID allows coarse resolution track reconstruction through a significant amount of steel absorber. Together the muon arm detectors provide significant pion rejection (> 250:1, increasing with decreasing momentum) through a momentum/penetration-depth match.

Before ever reaching the MuTR detectors a particle must pass through the pre-MuTR absorber: 20 cm of copper (the nosecone) plus 60 cm of iron (part of the MuTR magnet). The nominal nuclear interaction lengths of iron and copper are $\lambda_I^{\mathrm{Fe}} = 16.7$ cm and $\lambda_I^{\mathrm{Cu}} = 15.3$ cm (although this varies with particle species and energy, see Sec. III F).

Therefore the pre-MuTR absorber presents a total thickness of $4.9\lambda_I/\cos\theta$, where θ is the polar angle of a particle's trajectory. This absorber greatly reduces the MuTR occupancy and provides the first level of pion rejection.

Each MuTR arm consists of three stations of cathode strip chambers installed in an eight-sided conical magnet [59]. The radial magnetic field ($\int \mathbf{B} \cdot \mathbf{dl} = 0.72$ T $\cdot$ m at 15 degrees, $B(\theta) \approx B(15°)\tan(\theta)/\tan(15°)$) bends particles in the azimuthal direction. Each station occupies a plane perpendicular to the beam axis and consists of multiple ionization gaps (3 gaps for the two stations closest to the collision vertex, 2 gaps for the last station) which have their charge imaged on two cathode strip planes oriented with a small stereo angle to provide two-dimensional information. An ionizing particle typically fires three adjacent strips in each orientation. A fit to the charge distribution on adjacent strips provides a position measurement with a resolution of $\sigma \approx 100$ μm in the bend direction. The MuTR achieves a momentum resolution of $\sigma_p/p \approx 5\%$, nearly independent of momentum over the analyzed kinematic range. The momentum independence is due to the significant contribution from energy-loss fluctuations in the pre-MuTR absorber, which falls as $1/p$, and which counters the more familiar linear momentum dependence seen for particles tracked through a ''thin'' detector.

Each MuID arm consists of five steel absorber plates interleaved with Iarocci tubes (operated in proportional mode) and specialized shielding to reduce backgrounds not originating from the collision vertex. Gaps are labeled 0–4 proceeding downstream from the collision point.

The Iarocci tubes, which are between 2.5 and 5 m in length, have eight 1 cm^2 square cells, each consisting of a three-sided ground electrode and an anode wire, mounted inside a polyvinyl chloride (PVC) gas enclosure. A readout channel (''two-pack'') is formed by wire-ORing the 16 anode wires of two tubes which are mounted in planes perpendicular to the beam axis and staggered by half of a cell width (0.5 cm). This provides redundancy, eliminates geometric inefficiency due to the cell walls, and reduces the maximum drift time for charge collection. Discriminator outputs from the two-pack signals provide a coarse one-dimensional hit position ($\sigma = 9$ cm$/\sqrt{12} = 2.6$ cm). The tubes in each gap are mounted in six individual panels, each of which contains two layers of two-packs (horizontally and vertically oriented), thus providing two-dimensional information.

The first MuID absorber plate (thickness = 20 cm—south; 30 cm—north) also serves as the return yoke of the MuTR magnet. Successive plates (identical for the two arms) are 10, 10, 20, and 20 cm thick, thus totaling $4.8\lambda_I/\cos\theta$ ($5.4\lambda_I/\cos\theta$) for the south (north) arm. Because of ionization energy loss a particle must have a momentum at the vertex which exceeds $2.31\cos\theta$ GeV$/c$ ($2.45\cos\theta$ GeV$/c$) to penetrate to the most downstream MuID gap of the south (north) arm.

Steel plates surrounding the beam pipe guard against backgrounds caused by low-angle beam-beam collision products which scrape the beam pipe near the MuID z-location (7–9 m) or shine off the RHIC dipole steering magnets immediately downstream of each MuID arm. Steel blocks in the RHIC tunnels guard against penetrating radiation generated by the incoming beams scraping against beamline components, primarily the final focusing quadrupole magnets.

The MuID also contributes information to the first-level trigger decision. For the 2001/2 run, during which the data for this analysis were collected, a relatively coarse trigger was implemented using memory lookup units (MLUs). Each gap was divided into quadrants with a horizontal and vertical split going through the beam axis. Signals from tubes in an individual gap/orientation (layer) and quadrant were logically combined. Only gaps 0, 2, 3, and 4 were used in the trigger due to the 16-bit input limitation of the MLUs. The penetration depth required for the trigger to fire was programmable. The *M1D* trigger fired if more than 6 out of 8 layers in a particular quadrant were hit (indicating the possibility that the event contained a particle penetrating to MuID gap 4). The *M1S* trigger fired if 3 of the 4 most shallow layers (horizontal and vertical layers in gaps 0 and 2) were hit for a particular quadrant. Both triggers required a coincidence with the BBC minimum bias trigger.

III. METHOD FOR EXTRACTION OF MUONS FROM CHARM DECAY

Inclusive muon candidates, N_I, are those particles which are successfully reconstructed to the last MuID gap (gap 4). These consist of four components:

(1) ''free-decay muons,'' N_D, which result from the decay of light hadrons (π and K mesons) before reaching the pre-MuTR absorber.
(2) ''punchthrough hadrons,'' N_P, which penetrate the entire detector and are thus misidentified as muons.
(3) ''background tracks,'' N_B, which in $p + p$ collisions are dominated by hadrons which decay into a muon after reaching the MuTR.
(4) ''vertex-independent muons,'' N_μ, which are primarily due to the decay of heavy flavor mesons.

Figure 2 shows a schematic depiction of the relative yield per event of these different contributions as a function of flightpath into the muon arms, as described below.

The number of hadrons is large and essentially independent of flightpath until the first absorber layer is reached. In each absorber layer these hadrons undergo strong interactions with a probability $\mathcal{P} \approx 1 - \exp(-L/\lambda)$, where L is the length of absorber material traversed, and λ is the species and p_T-dependent nuclear interaction length determined in Sec. III F. The punchthrough hadrons are that small fraction of hadrons ($< 0.4\%$) which penetrate to the last MuID gap and are indistinguishable from muons.

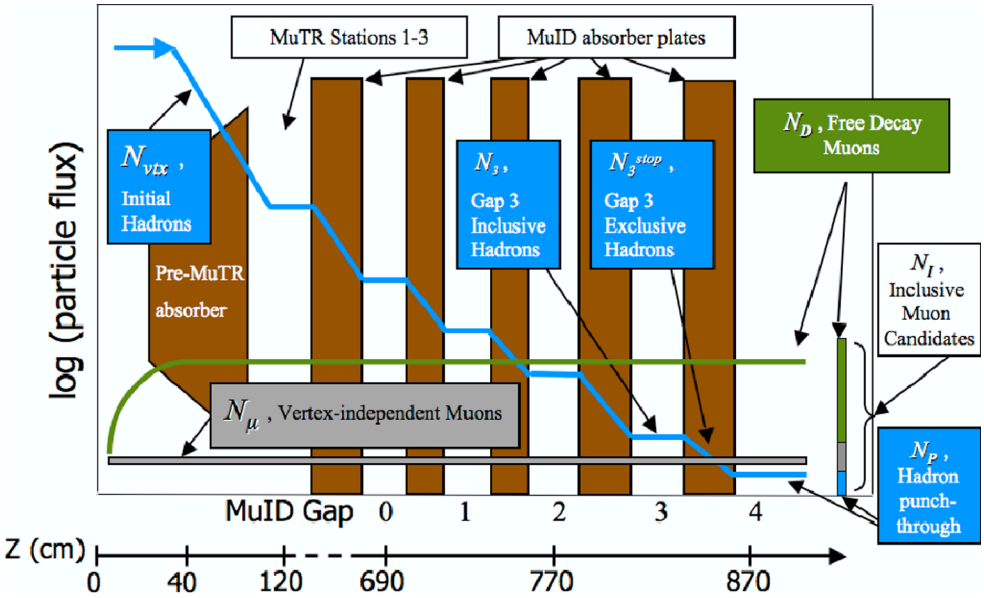

FIG. 2 (color online). Schematic depiction of the relative flux of different components of the inclusive muon candidate yield as a function of flightpath into the muon arm absorber (the nominal event vertex is at $z = 0$). See text for details.

The decay lengths for π's ($c\tau = 780$ cm) and K's ($c\tau = 371$ cm) are long compared to the flightpath from the vertex to the absorber. Therefore, the fraction of decay muons from these sources is relatively small, but increases linearly with the flightpath until the first absorber layer is reached. A hadron which decays prior to the pre-MuTR absorber into a muon that is inside the detector acceptance is indistinguishable from a muon originating at the vertex. After the first absorber layer the number of these free-decay muons remains constant by definition.

Hadrons which decay in the MuTR volume are a relatively small contribution for several reasons: most are absorbed prior to reaching the MuTR; the Lorentz-dilated decay lengths are long compared to the length of the MuTR volume (south ≈ 280 cm, north ≈ 420 cm); and a particle which decays in the MuTR is less likely to be reconstructed. Such tracks are partially accounted for in the calculation of punchthrough hadrons (see Sec. III F) and the remaining fraction falls under the category of background tracks (Sec. III G). This small contribution is not shown in Fig. 2.

Without a high-resolution vertex detector muons from various sources (the decay of open heavy flavor hadrons, the decay of quarkonia, the decay of light-vector mesons, and Drell-Yan production) originate indistinguishably close to the collision vertex. Thus their yield is independent of the flightpath and independent of the vertex position. Since inclusive muon candidates, by definition, penetrate to MuID gap 4, we measure the combined yield at $z \approx 870$ cm.

Figure 3 shows a sample distribution of the inclusive muon candidate yield as a function of collision vertex (z_{vtx}), and its decomposition into the four different contributions. The yield of free-decay muons is seen to have a linear dependence that is set to 0 at $z_{vtx} = z_{abs} - \lambda_D$. Here $z_{abs} = -40$ cm is the upstream face of the pre-MuTR absorber (indicated by the thick solid line), and λ_D is the effective absorption length, beyond which there are no free-decay muons. λ_D was found to be within a few mm of the species and p_T-dependent nuclear interaction lengths determined in Sec. III F. Muons originating from meson decays downstream of this location have no z_{vtx}

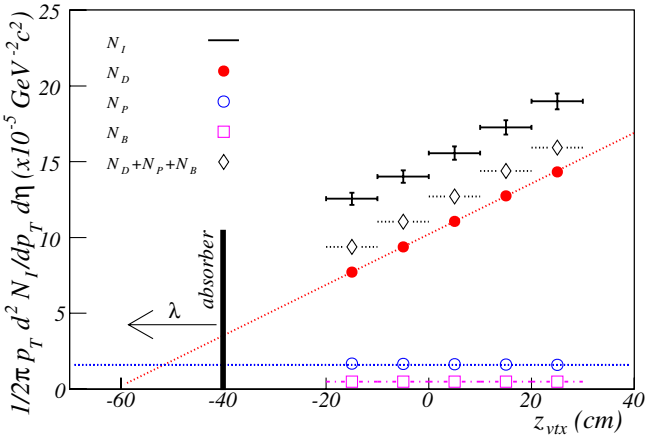

FIG. 3 (color online). Sample z_{vtx} distribution of different components of the inclusive muon candidate yield (measured data for both charge signs over the range $1.0 < p_T < 1.2$ GeV/c). Crosses show inclusive muon candidates, filled circles show free-decay muons, open circles show punchthrough hadrons, open squares show background tracks, and open diamonds show the sum of these three hadronic sources. The vertex-independent muon yield is obtained from the difference between the yield of inclusive muon candidates and the yield of light-hadronic sources.

dependence. The fraction not accounted for in the calculation of the punchthrough hadron yield forms the small contribution from background tracks. The yield of punchthrough hadrons and vertex-independent muons also have no z_{vtx} dependence. Note that the ratio of different contributions to the inclusive muon candidate spectrum is p_T dependent.

In order to extract the cross section for charm production we first need to determine the yield of vertex-independent muons, $N_\mu(p_T)$, the amount beyond that which is due to light hadrons and fake backgrounds. As described in Sec. III A, we select good runs, events, and tracks, and restrict our acceptance to regions where the detector was fully active, and the acceptance variation versus z_{vtx} was negligible. Next, as described in Secs. III B and III C, we obtain the yield of inclusive muon candidates vs p_T and z_{vtx}, corrected for acceptance and efficiency: $N_I(p_T, z_{vtx})$. In Sec. III D we describe a data-driven hadron generator. This generator is used in Sec. III E, in which we describe how the vertex dependence of the inclusive muon candidate yield allows us to obtain the yield of muons from light-meson decay before the pre-MuTR absorber, similarly corrected and binned: $N_D(p_T, z_{vtx})$. This generator is also used in Sec. III F, in which we describe how we use hadrons which stop in MuID gap 3 (the penultimate gap), together with simulations of hadron penetration in the MuID absorber, to obtain the yield of punchthrough hadrons in MuID gap 4: $N_P(p_T, z_{vtx})$. The yield of fake tracks, $N_B(p_T, z_{vtx})$, determined from simulations described in Sec. III G, is found to be small.

The yield of vertex-independent muons is determined by subtracting the contributions from light hadrons and fake backgrounds and averaging over z_{vtx} bins:

$$N_\mu(p_T) = \frac{1}{N_{z_{vtx}}} \sum_{j=1}^{N_{z_{vtx}}} N_I(p_T, z^j_{vtx}) - N_D(p_T, z^j_{vtx}) - N_P(p_T, z^j_{vtx}) - N_B(p_T, z^j_{vtx}), \quad (2)$$

where $d^2/2\pi p_T dp_T d\eta$ is implicit in all terms of the equation.

We convert this into a cross section via

$$\frac{d^2\sigma_\mu(p_T)}{2\pi p_T dp_T dy} = \frac{\sigma^{pp}_{BBC}}{\varepsilon^{c,\bar{c}\to\mu}_{BBC}} \frac{d^2N_\mu(p_T)}{2\pi p_T dp_T d\eta}. \quad (3)$$

Here σ^{pp}_{BBC} is the cross section of the BBC trigger for $p + p$ interactions and $\varepsilon^{c,\bar{c}\to\mu}_{BBC}$ is the efficiency of the BBC trigger for events in which a charm quark is created and decays into a muon. Substituting $\eta \to y$ introduces negligible error due to the small mass of the muon, the only component left after the subtraction. As described in Sec. III I, systematic errors are determined for each component and combined into a term that applies to the overall normalization and a term that applies to the p_T dependence of the spectrum.

We use PYTHIA to derive the p_T-dependent differential cross section for the production of charm quarks responsible for the vertex-independent muon yield. This procedure is very similar to that in Refs. [7–13], and is described in detail, along with the associated systematic error analysis, in Sec. IV.

A. Data reduction

1. Data sets and triggering

Runs were selected for this analysis based on stable detector operation using the same criteria as an earlier analysis of J/ψ production [51]. Further runs were eliminated due to the presence of large beam-related backgrounds entering the *back* of the detector.

We select only those events in the vertex range $-20 < z_{vtx} < 30$ cm. This minimizes the z_{vtx} dependence of the detector acceptance ($< 1\%$ over the entire z_{vtx} range, see Table II) and allows us to treat the amount of absorber material as a simple function of polar angle, ignoring complications in the pre-MuTR absorber near the beam pipe.

The decision to collect an event was made by the Local Level-1 Trigger [55] within 4μs of the collision. Input to the trigger decision was given by the BBC (collision with a valid event vertex) and the MuID (reconstructed penetrating track). Each trigger could be independently scaled down, so that it occupied a predetermined fraction of the available bandwidth, by selecting every N_i^{th} instance, where N_i is the scaledown factor for the i^{th} trigger. Three different data sets were selected from the good runs for different aspects of the data analysis:

(i) *BBC*: To extract N_D the z_{vtx} dependence of N_I is needed. The unbiased collision vertex distribution is obtained from a set of events collected with this trigger, which required at least one hit in each BBC counter and a vertex position, $|z_{vtx}| < 38$ cm. σ^{pp}_{BBC} was found to be 21.8 ± 2.1 mb using a van der Meer scan [60]. This uncertainty is included in the systematic error on the derived cross section, see Table VIII. There were 1.72×10^7 *BBC* triggered events passing offline vertex selection criteria in this data set ($-20 < z_{vtx} < 30$ cm), corresponding to a sampled luminosity of $\int Ldt = 0.79$ nb^{-1}.

(ii) *M1D*: In order to extract N_I, N_D, and N_B we used events selected with this trigger, which enriched the sample of events with tracks penetrating to MuID gap 4. For the *M1D* and *BBC* data sets we used identical run selection criteria. The total number of sampled *BBC* triggers for this data set was 5.77×10^8, corresponding to a sampled luminosity of $\int Ldt = 26.5$ nb^{-1}.

(iii) *M1S*: In order to extract N_P a data set which provides an unbiased measurement of the number of particles which penetrate to MuID gap 3 is needed. Since the *M1D* trigger required tracks to

penetrate to MuID gap 4 it could not be used. This trigger, which only used information from MuID gaps 0–2, is suitable. We used a subset of runs for which the scaledown factor for this trigger was only 10, corresponding to a sampled luminosity of $\int Ldt = 1.72\ \mathrm{nb}^{-1}$.

2. Track selection

The muon arm reconstruction algorithm starts by finding "roads" (collections of hits in the MuID which form straight, two-dimensional lines) and then combining them with hits in the MuTR to form "tracks." We apply strict cuts on both road and track parameters in order to reduce backgrounds, (see Table I).

The resulting purity of the selected tracks is demonstrated in Fig. 4. This figure shows $p\delta\theta$, the angular deviation through the pre-MuTR absorber, scaled by the particle momentum to give a quantity which should be momentum independent, for different p_T bins. As shown in Fig. 5, $\delta\theta$ is the angular difference between the reconstructed particle trajectory at the collision vertex ($x = 0$, $y = 0$, $z = z_{vtx}$) and at MuTR station 1. A GEANT [61] simulation of the PHENIX detector showed that tracks which do not suffer a strong interaction in the pre-MuTR absorber undergo angular deviations consistent with expectations based on standard multiple scattering: $\sigma_{\delta\theta} \propto \sqrt{x/X_0}/p$. The curves in each panel are fits to $Cp\delta\theta \exp(-(p\delta\theta)^2/2(p\sigma_{\delta\theta})^2)$, in which the normalization constant is allowed to float, and $p\sigma_{\delta\theta} = 130\ \mathrm{rad}\cdot\mathrm{MeV}/c$ is given by GEANT and is consistent with a simple estimate based on the radiation length of the pre-MuTR absorber and the standard multiple scattering formula [62–64] ($x/X_0 \approx 48 \rightarrow p\theta^{rms}_{\mathrm{space}} \approx (\sqrt{2}) \times (13.6\ \mathrm{MeV}/c)(\sqrt{48})\ \mathrm{rad} = 133\ \mathrm{rad}\cdot\mathrm{MeV}/c$). The integral beyond $3p\sigma_{\delta\theta}$ is $\approx 5\%$ and is largely due to hadrons which have a strong interaction in the pre-MuTR absorber and are still reconstructed as a muon candidate. Such tracks are accounted for in the calculation of the punchthrough hadron yield, as described below.

TABLE I. Road and track cuts. Here D_p is the penetration depth, defined to be the most downstream MuID gap with at least one hit (from the horizontal or vertical layer) associated with the track; z is the coordinate along the beam; x and y are transverse to each other and to the beam axis; the vertex cut refers to the transverse position of the MuID road projected to the xy plane at $z = 0$; and the slope cut refers to the direction cosine of the road in each transverse direction.

Road cuts:
· # Associated MuID hits >6 (out of a possible $2 \times D_p$)
· Vertex cut, $\sqrt{x^2 + y^2} < 100$ cm at $z = 0$
· Slope cut, $\sqrt{(\frac{dx}{dz})^2 + (\frac{dy}{dz})^2} > 0.25$
· ≥ 1 associated hit in MuID gap 4
Track cuts:
· Track fit quality, $\chi^2/\mathrm{dof} \leq 10$
· # Associated MuTR hits >12 (out of a possible 16)

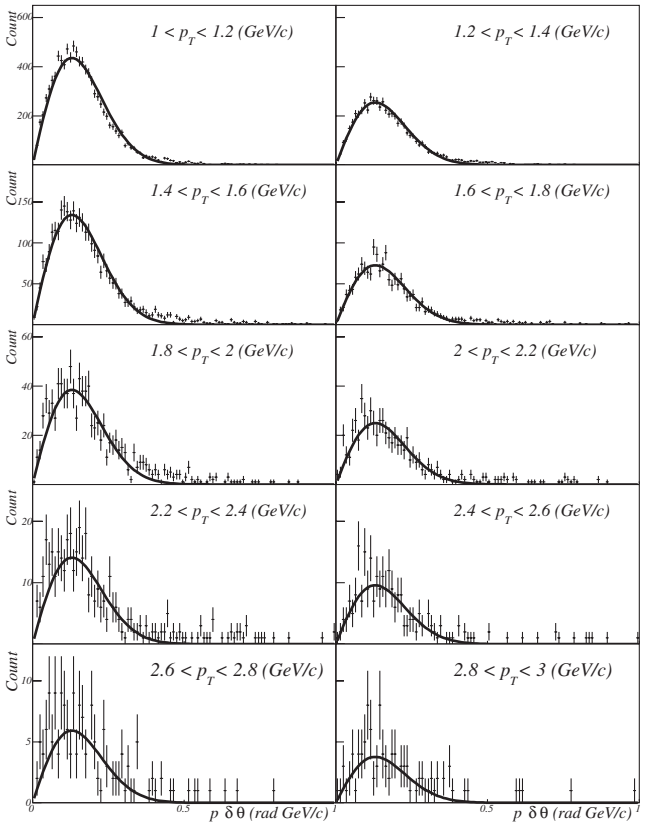

FIG. 4. The scaled angular deflection is the difference in a particle's polar angle caused by passage through the pre-MuTR absorber scaled by the particle's momentum, $p\delta\theta$. For muons (and hadrons not undergoing a strong interaction in the pre-MuTR absorber) one expects the distribution of this quantity to be well described by the standard multiple scattering formula. The different panels show $p\delta\theta$ for different p_T bins with fits (normalization only) to the expected distribution.

3. Acceptance restriction

We further restricted the acceptance of muon candidates for this analysis in two ways:

(1) Tracks were required to pass through regions of the detector that were fully active.
(2) Tracks were required to lie within a pseudorapidity range, $1.5 < |\eta| < 1.8$, in which the acceptance depends negligibly on the collision z_{vtx} location. As shown in Table II the variation is <1% over the entire z_{vtx} range.

B. Acceptance and efficiency

We evaluated four ratios to obtain the acceptance and efficiency for reconstructing tracks penetrating to a particular MuID gap, i:

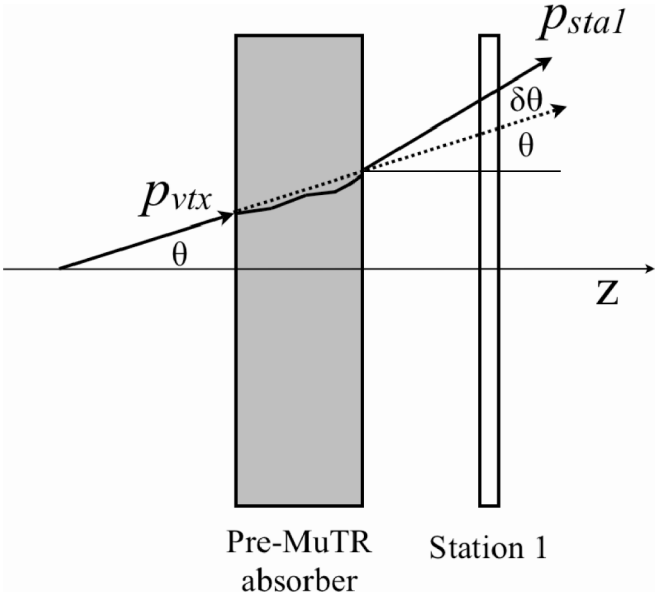

FIG. 5. The angular deflection $\delta\theta$ is the angular difference between the reconstructed particle trajectory at the collision vertex and at MuTR station 1. The momentum used to scale $\delta\theta$ is the average of the momentum reconstructed inside the MuTR magnet ($p_{\rm sta1}$) and the momentum extrapolated to the vertex (p_{vtx}).

(1) $\varepsilon^i_{\rm acc}$: the fraction of particles thrown in $2\pi\delta\eta$ ($\delta\eta = 0.3$) which penetrate to MuID gap 4, pass through active areas in every detector plane, and which pass the acceptance restrictions described above. This quantity ($\approx 50\%$) accounts for nonsensitive structural members in between the cathode strip chambers and chamber regions removed from consideration for the entirety of this analysis.

(2) $\varepsilon^i_{\rm rec}$: the fraction of particles within the accepted region, defined in the previous step, that are reconstructed. This quantity is somewhat low (64%) due to detector problems in this first physics run that have been subsequently resolved.

(3) $\varepsilon^i_{\rm user}$: the fraction of reconstructed tracks that pass the cuts listed in Table I.

(4) $\varepsilon^i_{\rm trig}$: the fraction of selected tracks that fire the MuID trigger.

The overall acceptance and efficiency is the product of these ratios. Note that by construction these ratios factorize since the denominator of each successive ratio is the numerator of the previous ratio.

$\varepsilon^i_{\rm acc}$, $\varepsilon^i_{\rm rec}$, and $\varepsilon^i_{\rm user}$ were evaluated with a GEANT simulation using single muons thrown with a realistic p_T spectrum into the muon arms. The applied detector response incorporated measured detector performance. Reductions in efficiency due to occupancy are negligible in $p + p$ collisions. Run-to-run variations were ignored since we selected runs in which the detector performance was similar and stable. For cuts used in this analysis the acceptance and efficiency are the same for different components of the inclusive muon candidate yield. Efficiency values for tracks penetrating to MuID gap 4 were parametrized in terms of z_{vtx} and p_T and are listed in Table II. There are minor differences in these parametrizations for particles with different charge sign. Fit errors on these parametrizations are included in the systematic uncertainty, as shown in Table V.

We also determined the efficiencies for tracks which only penetrate to MuID gap 3, since these are needed to obtain the yield of punchthrough hadrons. These were found to scale from the efficiencies for tracks penetrating to MuID gap 4: $\varepsilon^3_{\rm acc}\varepsilon^3_{\rm rec}\varepsilon^3_{\rm user} = \varepsilon^3_{\rm scale} \times \varepsilon^4_{\rm acc}\varepsilon^4_{\rm rec}\varepsilon^4_{\rm user}$, where $\varepsilon^3_{\rm scale} = 0.66$. $\varepsilon^3_{\rm scale}$ is less than one because the MuID and the road reconstruction algorithm are optimized for deeply penetrating particles. Particles which do not penetrate to the last gap have poorer resolution matching to MuTR tracks (due to reduced lever arm and smaller number of hits) and are also more susceptible to MuID inefficiencies. There is considerable ambiguity in determining which particles *should* have been reconstructed. Different definitions, together with statistical uncertainties, combined to give a systematic error of 23%, as shown in Table VII.

Trigger efficiencies, $\varepsilon^3_{\rm trig}$ and $\varepsilon^4_{\rm trig}$, are also listed in Table II. These were evaluated using the *BBC* data set, which did not require the MuID trigger to fire.

$$\varepsilon^4_{\rm trig} = \frac{(N_4|M1D) \times S_{M1D}}{(N_4|BBC) \times S_{BBC}}, \tag{4}$$

where $N_4|M1D$ is the number of selected tracks penetrating to MuID gap 4 for events in which the *M1D* trigger fired, S_{M1D} is the scaledown factor applied to the *M1D* trigger, and similarly for $M1D \rightarrow BBC$. $\varepsilon^3_{\rm trig}$ was also evaluated according to Eq. (4), but with $N_4 \rightarrow N_3$, and $M1D \rightarrow M1S$. Different procedures for calculating $\varepsilon^3_{\rm trig}$ gave slightly different answers, resulting in the assignment of a 4.7% systematic error, as shown in Table V.

TABLE II. Trigger, acceptance, track reconstruction, and track selection efficiencies. In the formulae below, the units for p_T are GeV/c and the units for z_{vtx} are cm. Systematic errors for these quantities are given in Tables V and VII.

Quantity	Value
$\varepsilon^{4,+}_{\rm acc}$	$0.51 \times (1 - 114\exp(-5.9p_T)) \times (1 + 0.0015z_{vtx})$
$\varepsilon^{4,-}_{\rm acc}$	$0.50 \times (1 - 531\exp(-7.5p_T)) \times (1 + 0.0013z_{vtx})$
$\varepsilon^{4}_{\rm rec}$	0.64
$\varepsilon^{4,+}_{\rm user}$	$0.74 \times (1 - 0.0019z_{vtx})$
$\varepsilon^{4,-}_{\rm user}$	$0.74 \times (1 - 0.0009z_{vtx})$
$\varepsilon^{3}_{\rm scale}$	0.66
$\varepsilon^{4}_{\rm trig}$	0.86
$\varepsilon^{3}_{\rm trig}$	0.97
$\varepsilon^{c,\bar{c}\rightarrow\mu}_{\rm BBC}$	0.75

Since both the *M1D* and *M1S* triggers required a coincidence with the *BBC* trigger we must also account for the *BBC* trigger efficiency for events in which a reconstructed muon is created via charm quark decay: $\varepsilon_{BBC}^{c,\bar{c}\to\mu}$. The BBC efficiency was evaluated for events in which a J/ψ was produced in the muon arm acceptance using PYTHIA + GEANT simulations [51]. The BBC efficiency was also evaluated for events in which π^0's were produced in the central arm acceptance [60] using data triggered without a BBC requirement. The BBC efficiency under both conditions was found to have a similar value that we therefore adopt: $\varepsilon_{BBC}^{c,\bar{c}\to\mu} = 0.75 \pm 0.04$. This uncertainty is included in the systematic error on the derived cross section (Table VIII).

C. Inclusive muon candidates

We first form two sets of collision vertex (z_{vtx}) histograms with 10 cm bins: one histogram for all interactions selected with the *BBC* trigger, and a series of histograms for interactions selected with the *M1D* trigger and having a good muon candidate within a p_T bin ($1 < p_T < 3$ GeV/c, 200 MeV/c bins). The muon candidate histograms are formed separately for each charge sign. Entries into each histogram are scaled by the appropriate trigger scaledown factor. The muon candidate histograms are divided by the minimum bias histogram to give $N_I(p_T, z_{vtx})$, as shown in Fig. 6. Systematic errors shown in this figure are discussed in Sec. III I and listed in Table V.

In Fig. 6 one can clearly see the linear dependence in the yield of inclusive muon candidates vs z_{vtx} at low transverse momentum ($p_T < 2$ GeV/c). This dependence is due to muons from the decay of abundant light hadrons (π's and K's) prior to the pre-MuTR absorber material at $z_{abs} = -40$ cm. One also observes a charge asymmetry, with the yield of positives significantly exceeding that of negatives. This is due to the substantial charge asymmetry in the kaon nuclear interaction length—positive kaons are much more likely to punch through the muon arm absorber than any other species. This effect is discussed in Sec. III F.

D. Hadron generator

The background components of the inclusive muon candidate yield (free-decay muons (Sec. III E), and punch-through hadrons (Sec. III F)) arise from charged hadrons,

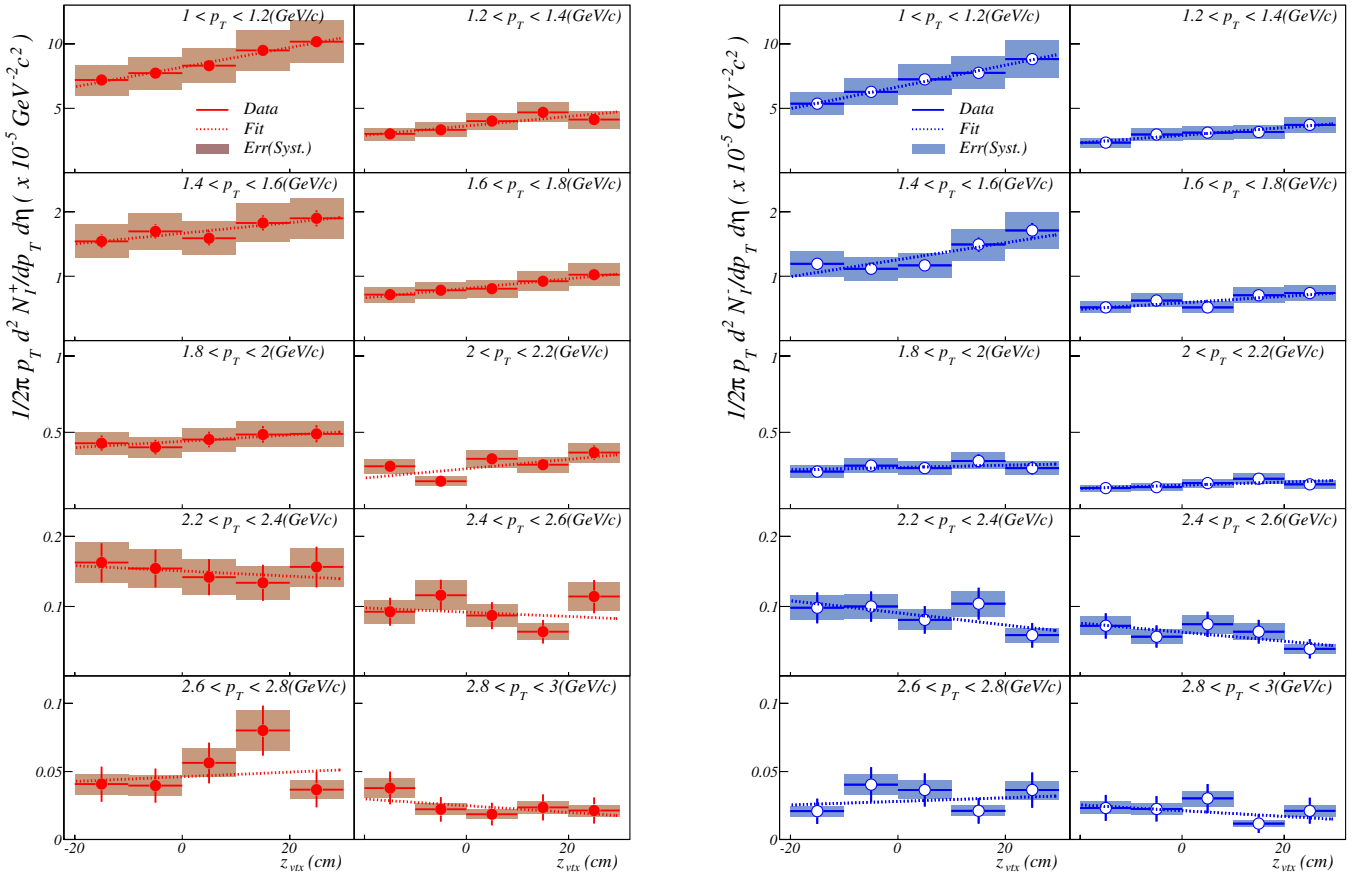

FIG. 6 (color online). Yield of (left) positively and (right) negatively charged inclusive muon candidates vs z_{vtx} for different p_T bins. Fits shown use the functional form $a + bz_{vtx}$ to extract the contribution from hadron decay, as discussed in Sec. III E. Error bars show statistical errors. Shaded bands show systematic errors, as discussed in Sec. III I and listed in Table V. The substantial charge asymmetry is due to the relatively long nuclear interaction length for positive kaons, as discussed in Sec. III F.

primarily pions and kaons, produced in the kinematic range of our measurement. There are no measurements of hadron production in this kinematic range and model predictions have substantial disagreement. This disagreement would lead to unacceptable systematic uncertainty in the extraction of the heavy flavor muon component. In order to reduce this uncertainty we developed a data-driven hadron generator that is based on PHENIX midrapidity measurements and then constrained by the z_{vtx} dependence of the inclusive muon candidate yield presented in this analysis.

The input for this generator is obtained from PHENIX measurements in $\sqrt{s} = 200$ GeV $p + p$ collisions at $y = 0$ [65,66] using the following procedure:

(1) π^+ and π^- spectra at $y = 0$ ($0 < p_T < 3.5$ GeV/c) are fit to a power law and then scaled assuming a Gaussian rapidity dependence ($\sigma_y = 2.5$) and $y - p_T$ factorization:

$$N^{\pi^\pm}_{y=1.65}(p_T) = N^{\pi^\pm}_{y=0}(p_T)\exp(-(1.65^2/2\sigma_y^2)).$$

This rapidity dependence and factorization is observed both in PYTHIA and in BRAHMS [49] data measured at $y = 1$ and $y = 2.2$.

(2) A similar procedure is used to obtain the charged kaon yield at $y = 1.65$.
First the charged kaon yield at $y = 0$ is extrapolated beyond the current measurement limit ($p_T < 2$ GeV/c). To do this we form the isospin averaged K/π ratio vs p_T at $y = 0$. We use charged particles, $(K^+ + K^-)/(\pi^+ + \pi^-)$, for $p_T < 2$ GeV/c [65] and neutral particles, K^0/π^0, for $2 < p_T < 6.5$ GeV/c [66]. This combined ratio is then fit to $f(p_T) = A(1 - B\exp(-Cp_T))$. This function is then normalized separately to the K^+/π^+ and K^-/π^- ratios for $p_T < 2$ GeV/c and multiplied by the corresponding charged pion spectrum to obtain $N^{K^\pm}_{y=0}(p_T)$, our parametrization of the midrapidity charged kaon p_T spectra extending out to 3.5 GeV/c.
As with pions, we need to extrapolate this parametrization of the yield at $y = 0$ to obtain the yield at $y = 1.65$. One possibility is to assume boost invariance of the K/π ratio. However, PYTHIA gives a slightly narrower rapidity distribution for kaons than for pions, resulting in a kaon yield at $y = 1.65$ that is only 85% of that predicted with the boost invariance assumption. We split the difference between these two assumptions:

$$N^{K^\pm}_{y=1.65}(p_T) = 92.5\% N^{K^\pm}_{y=0}(p_T) \times \exp(-(1.65^2/2\sigma_y^2)),$$

where, again, $\sigma_y = 2.5$.

(3) The p and $\bar{p}$ spectra are assumed to have the same shape as the pion spectra with normalization factors set to the measured values at $y = 0$, $p_T = 3$ GeV/c (0.4 for p/π^+, 0.24 for $\bar{p}/\pi^-$) [65]. The exact form used for the p, $\bar{p}$ spectra is unimportant. They obviously do not contribute to the yield of decay muons and their contribution to the yield of punchthrough hadrons is greatly suppressed due to their relatively short nuclear interaction length.

E. Free-decay muons

We fit the histograms shown in Fig. 6 with the function $a + bz_{vtx}$. After multiplying by $dz/dl_{fp} = \cos(\langle\theta\rangle) = 0.947$ the slope, b, and its fit error give, respectively, the yield *per unit length of decay flightpath* of muons from hadron decay, $dN_D(p_T)/dl_{fp}$, and the statistical error on this quantity. We do not allow a to vary in the fit, but we perform the fits for different values of a to account for uncertainty in that quantity. We also allow the z_{vtx} fit range to vary from $|z_{vtx}| < 20$ cm to $|z_{vtx}| < 40$ cm. The resulting variations in N_D (5% and 3.3%, respectively) are incorporated into the systematic error, as shown in Table VI. Results are shown in Fig. 7.

This procedure does not provide a quantitative measure of the decay muon spectrum above $p_T \sim 2$ GeV/c, even though a substantial fraction of the inclusive muons are decay muons up to significantly higher p_T. This is due to the fact that at high p_T the decay slopes decrease (Lorentz time dilation) as do the statistics, both of which make it more difficult to quantify the decay component directly.

In order to extend our estimate of decay muons to higher p_T we simulate charged hadron spectra using the hadron generator described in Sec. III D. These hadrons are allowed to decay into the muon arms, resulting in a predicted p_T spectra (per unit length) of muons from hadron decay separately for each charge sign. We then normalize these predicted spectra to the measured spectra. The normalized predicted spectra are shown as the dashed lines in Fig. 7. The predicted spectral shape agrees with the data where we have a statistically significant measurement. The absolute normalization of the prediction is within 7% of the measured value, easily consistent within errors. This difference, and the effects of reasonable variations on the input spectral shapes, are incorporated into the systematic uncertainty on N_D, as listed in Table VI.

We obtain $N_D(p_T, z_{vtx})$ from the product of $dN_D(p_T)/dl_{fp}$ and the average value of the decay flightpath, $l_{fp} = \lambda_D + |z_{vtx} - z_{abs}|/\cos(\theta)$, for each z_{vtx} bin.

F. Punchthrough hadrons

A reconstructed hadron that penetrates to MuID gap 4 is impossible to distinguish from a muon. The straightforward technique to calculate the contribution of this background component would be to use the PHENIX GEANT-based Monte Carlo program to simulate the response to hadrons sampled from the hadron generator spectra. However, this approach suffers from unacceptable systematic uncertainty due to differences in the predictions for

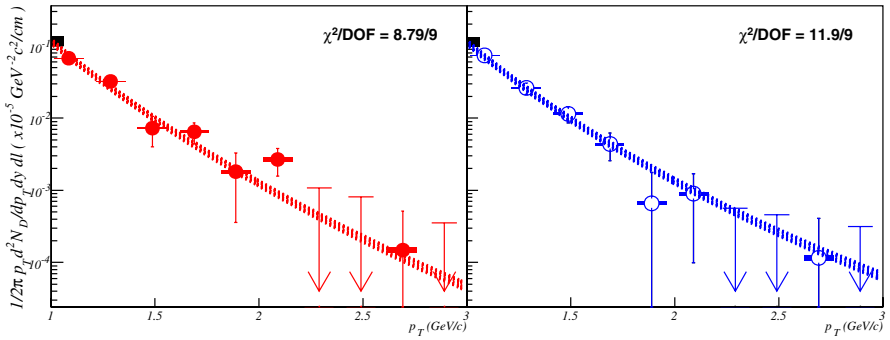

FIG. 7 (color online). Yield per unit length of (left) positively and (right) negatively charged free-decay muons. Points are the measured values determined by linear fits to the inclusive muon candidate yield (Fig. 6). Error bars indicate statistical errors for those fits. p_T bins with a negative (nonphysical) slope in those fits are shown with a line at the 90% C.L. upper limit (statistical errors only) and an arrow pointing down. See Sec. III E for details. Dashed lines are the predictions for each sign from the data-driven hadron generator with the normalization fit to the measured points. See Sec. III D for details. The χ^2/dof for these fits are indicated. The width of the lines corresponds to σ_{R_D} (Table VI), the error on the ratio of free-decay muons to inclusive muon candidates. Black bands at the left edge of each panel show the p_T-independent systematic error on the inclusive muon candidate yield. Shaded bands on each point show the systematic errors that affect the p_T shape of the inclusive muon candidate spectrum. These last two systematic errors (Table V) need to be included in the total error budget for the yield of free-decay muons, σ_{N_D}/N_D (Table VI), but are displayed separately since they are common to all components of the inclusive muon candidate yield. See Eqs. (12) and (13). Systematic errors are discussed in Sec. III I.

different hadronic interaction packages implemented in GEANT. To avoid this limitation we developed a procedure in which we cleanly identify hadrons in shallow gaps and then extrapolate their yield to obtain the yield of punchthrough hadrons in MuID gap 4.

Figure 8 shows the longitudinal momentum (p_z, the momentum projected onto the beam axis) distribution of particles that *stop* in MuID gap 3. The sharp peak at $p_z \approx 2.2$ GeV/c corresponds to charged particles which stopped because they ranged out in the absorber plate between gaps 3 and 4 (this includes both muons and also hadrons which only suffered ionization energy loss.) The width of this peak is due to the 20 cm (11.4 X_0) absorber thickness between MuID gaps 3 and 4, and energy-loss fluctuations in all the preceding absorber layers. Particles at momenta beyond the peak ($p_z > 3$ GeV/c) form a relatively pure sample of hadrons, with only a negligible contamination due to inefficiencies in MuID gap 4 and particles with misreconstructed momentum values. After correcting for acceptance and efficiency these particles are used to obtain the p_T spectrum for the "gap 3 exclusive yield," as shown in Fig. 9. We use data from the *M1S* trigger sample since the *M1D* sample required a hit in MuID gap 4, which would bias this measurement.

In order to extrapolate this measured spectrum for hadrons stopping in MuID gap 3 to the spectrum of punchthrough hadrons which penetrate to MuID gap 4, we start by assuming exponential absorption of hadrons entering the muon arm absorber material. With this assumption we obtain an expression for the "gap 3 inclusive yield," those hadrons that reach *at least* MuID gap 3:

$$N_3^i(p_T, \theta) = N_{vtx}^i(p_T, \theta) \exp(-L_3(\theta)/\lambda^i(p_T)), \quad (5)$$

where i indicates the contributing hadron species ($\pi^{\pm}$, $K^{\pm}$, p, $\bar{p}$), $N_{vtx}^i(p_T, \theta)$ is the yield at the vertex of the i^{th} species, $L_3(\theta)$ is the amount of absorber material traversed to reach MuID gap 3, and $\lambda^i(p_T, \theta)$ is the p_T-dependent nuclear interaction length of the i^{th} species. We can write a similar expression for the punchthrough hadron yield:

$$N_P^i(p_T, \theta) = N_{vtx}^i(p_T, \theta) \exp(-L_4(\theta)/\lambda^i(p_T)), \quad (6)$$

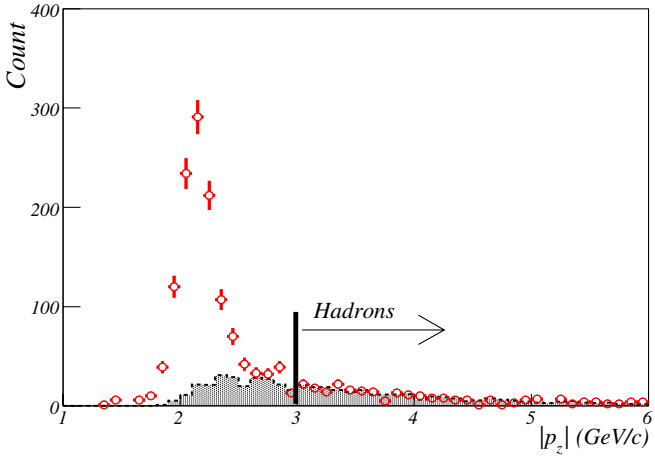

FIG. 8 (color online). Points (measured data) show the longitudinal momentum, measured at the vertex (p_z^{vtx}), of particles that stop in MuID gap 3. The sharp peak is due to muons which range out in the absorber plate between gaps 3 and 4. The histogram (Monte Carlo) shows the longitudinal momentum of all particles that stop in MuID gap 3 and do not decay before the pre-MuTR absorber. The Monte Carlo is normalized to the data for $p_z^{vtx} > 3$ GeV/c. Particles beyond the peak form a relatively pure sample of hadrons.

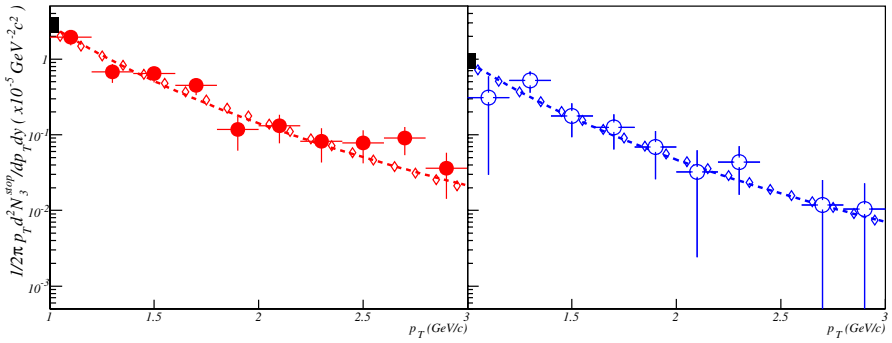

FIG. 9 (color online). Points show the p_T spectrum of (left) positively and (right) negatively charged hadrons stopping in MuID gap 3 (''gap 3 exclusive yield'') with statistical errors. Open diamonds show a power-law fit to the data, effectively a smoothed version of the data. Dashed lines are fits to the smoothed data using the hadron generator (normalized by the measured free-decay spectrum, as shown in Fig. 7) and Eqs. (8) and (9) to obtain values for the species-dependent nuclear interaction lengths, $\lambda^i(p_T)$.

where $L_4(\theta)$ is the amount of absorber material traversed to reach MuID gap 4.

By taking the difference between these two equations we obtain an expression for the gap 3 exclusive yield:

$$\begin{aligned} N_3^{i,\mathrm{stop}}(p_T,\theta) &= N_3^i(p_T,\theta) - N_P^i(p_T,\theta) \\ &= N_{vtx}^i(p_T,\theta)\exp(-L_3(\theta)/\lambda^i(p_T)) \\ &\quad\times(1-\exp((L_3(\theta)-L_4(\theta))/\lambda^i(p_T))). \end{aligned} \quad (7)$$

The species comprising the gap 3 exclusive yield are not determined, but their charge sign is. As a result, Eq. (7) can be rewritten as two equations with six unknowns for each p_T bin:

$$\begin{aligned} N_3^{+,\mathrm{stop}}(p_T,\theta) &= N_3^+(p_T,\theta) - N_P^+(p_T,\theta) \\ &= \sum_{i=\pi^+,K^+,p} N_{vtx}^i(p_T,\theta)\exp(-L_3(\theta)/\lambda^i(p_T)) \\ &\quad\times(1-\exp((L_3(\theta)-L_4(\theta))/\lambda^i(p_T))), \end{aligned} \quad (8)$$

$$\begin{aligned} N_3^{-,\mathrm{stop}}(p_T,\theta) &= N_3^-(p_T,\theta) - N_P^-(p_T,\theta) \\ &= \sum_{i=\pi^-,K^-,\bar{p}} N_{vtx}^i(p_T,\theta)\exp(-L_3(\theta)/\lambda^i(p_T)) \\ &\quad\times(1-\exp((L_3(\theta)-L_4(\theta))/\lambda^i(p_T))). \end{aligned} \quad (9)$$

Based on measured cross sections for various species [67], the number of unknowns is reduced with the following assumption:

$$\begin{aligned} \lambda^{K^+} &= \lambda^{\mathrm{long}}, \\ \lambda^p = \lambda^{\pi^+} = \lambda^{\pi^-} = \lambda^{K^-} &= \lambda^{\mathrm{short}}, \\ \lambda^{\bar{p}} &= 0. \end{aligned}$$

We further assume that λ^{short} and λ^{long} have the form $a + b(p_T[\mathrm{GeV}/c] - 1)$.

We effectively smoothed the gap 3 exclusive yield for each sign by fitting the measured values to a power law. Using $N_{vtx}^i(p_T,\theta)$ from the hadron generator (normalized to the free-decay muon spectrum, as described in Sec. III E) and known values for $L_{3,4}(\theta)$, we fit Eqs. (8) and (9) to the smoothed gap 3 exclusive yield for each sign to obtain:

$$\lambda^{\mathrm{short}} = 19.0 + 2.2(p_T[\mathrm{GeV}/c] - 1)\ \mathrm{cm}, \quad \text{and}$$
$$\lambda^{\mathrm{long}} = 25.9 + 4.4(p_T[\mathrm{GeV}/c] - 1)\ \mathrm{cm}.$$

Results of these fits are shown in Fig. 9. The fit error on the normalization (10%) is incorporated into the systematic error, as listed in Table VII.

With these values for $\lambda^i(p_T)$ and the hadron generator input spectra, we could directly apply Eq. (6) to obtain the final punchthrough spectra. However, we made one further correction, described below, after finding that our assumption of exponential absorption does not hold when applied to GEANT simulations of the punchthrough process.

Using our GEANT-based PHENIX simulation program, we generated data sets with both the FLUKA [68] and GHEISHA [69] hadronic interaction packages. Input spectra for these data sets were given by our decay hadron generator. We selected all particles which did not decay before the pre-MuTR absorber. ''Truth'' values for the punchthrough and gap 3 exclusive yields were obtained by splitting those particles based on the absence (gap 3 exclusive) or presence (punchthrough) of associated charged particles with $E_4 > 100$ MeV in MuID gap 4. We varied E_4 from 50–300 MeV and saw no significant change in the results.

Using the known input spectra, known values for $L_{3,4}(\theta)$, and truth values for the gap 3 exclusive yield, we applied Eq. (7) to the Monte Carlo data sets to obtain $\lambda^i(p_T)$. Because of statistical limitations we integrated our results over θ and into two p_T bins: $1 < p_T < 2$ GeV/c and $p_T > 2$ GeV/c. Values extracted for $\lambda^i(p_T)$ for the different hadronic interaction packages are listed in Table III.

TABLE III. Nuclear interaction lengths, $\lambda^i(p_T)$, for different particle species and p_T bins (in GeV/c) for FLUKA and GHEISHA. Statistical errors on these values are ≈ 2 mm.

	FLUKA $\lambda^i(p_T)$ [cm]		GHEISHA $\lambda^i(p_T)$ [cm]	
Species	$1 < p_T < 2$	$p_T > 2$	$1 < p_T < 2$	$p_T > 2$
π^+	19.6	24.5	16.0	21.1
π^-	19.4	24.8	15.0	19.3
K^+	24.4	29.6	24.9	30.8
K^-	20.5	24.2	17.2	21.2

These values are consistent with those found for our measured data, listed above.

Inserting these values for $\lambda^i(p_T)$ into Eq. (6) we obtained a prediction for $N_P^i(p_T, \theta)$. Ratios of the truth values and predicted values for the punchthrough yield ($R_{N_P^i(p_T)}$) for the different hadronic interaction packages are listed in Table IV. The limitation of the simple exponential absorption model is illustrated by the fact that these ratios deviate significantly from unity. Furthermore, the two hadronic interaction packages disagree on the direction of the deviation: the exponential absorption model tends to overpredict the punchthrough yield for FLUKA and underpredict it for GHEISHA.

TABLE IV. Ratios, $R_{N_P^i(p_T)}$, of truth values for the punchthrough hadron yield to those predicted assuming exponential hadron absorption for different particle species and p_T bins (in GeV/c), for FLUKA and GHEISHA. Average values of the ratios for the two different hadronic interaction packages, $\langle R\rangle^i \times (p_T)$, are smoothed across the p_T bin at 2 GeV/c to obtain correction factors for the exponential absorption model. Statistical errors on these quantities are $\approx 10\%$. The maximum fractional difference in the ratios for the two different packages (32%) is incorporated into the systematic error estimate, as shown in Table VII.

Species	$1 < p_T < 2$	$p_T > 2$	Description
π^+	0.76	0.86	$R^{\mathrm{FLUKA}}_{N_P^i(p_T)}$
π^-	0.91	0.75	
K^+	0.91	1.00	
K^-	1.17	1.06	
π^+	1.48	1.04	$R^{\mathrm{GHEISHA}}_{N_P^i(p_T)}$
π^-	1.47	1.09	
K^+	1.31	1.07	
K^-	2.21	1.69	
π^+	1.12	0.95	$\langle R\rangle^i(p_T)$
π^-	1.19	0.92	
K^+	1.11	1.04	
K^-	1.67	1.38	
π^+	32%	10%	$\delta R_{N_P^i(p_T)}/C^i(p_T)$
π^-	24%	18%	
K^+	18%	3%	
K^-	32%	22%	

Relatively little data exist in the relevant momentum range that would allow us to conclude which, if either, hadronic interaction package is correct. Measurements by RD10 and RD45 [70] of the penetration depth of identified hadrons found that GHEISHA did well for protons and FLUKA did not. But neither did well for pions and no data exist for kaons. Furthermore, the results are sensitive to the definition of a penetrating particle. For RD10/45 an incoming particle with any associated charged particles in the 120×120 cm^2 detector area at a particular depth was defined to have penetrated to that depth. In our measurement we reconstruct particle trajectories, and MuID hits are not associated with a road unless they are within a narrow search window surrounding the projected trajectory. Thus we are relatively insensitive to the leakage of a showering hadron.

As a result of these uncertainties on the applicability of our exponential absorption model we incorporate a species and p_T-dependent correction factor to Eq. (6):

$$N_P^i(p_T, \theta) = C^i(p_T) N_{vtx}^i(p_T, \theta) \exp(-L_4(\theta)/\lambda^i(p_T)). \tag{10}$$

The correction factors for pions and kaons are obtained from the average of the values of $R_{N_P^i(p_T)}$ for the two packages, $\langle R\rangle^i(p_T) = (R^{\mathrm{FLUKA}}_{N_P^i(p_T)} + R^{\mathrm{GHEISHA}}_{N_P^i(p_T)})/2$, which are listed in Table IV. We incorporate the maximum fractional difference in the ratios for the two packages (32%) into our systematic error estimate, as listed in Table VII. The values of $\langle R\rangle^i(p_T)$ for a given species are not the same for the different p_T bins. Therefore we assume the values are valid at the average p_T of each bin ($p_T = 1.25$ GeV/c and 2.31 GeV/c, respectively) and use a linear extrapolation in p_T to obtain the final correction factors:

$$C^i(p_T) = \langle R\rangle^i_{\mathrm{low}\ p_t} + (\langle R\rangle^i_{\mathrm{high}\ p_t} - \langle R\rangle^i_{\mathrm{low}\ p_t}) \times \frac{p_T[\mathrm{GeV}/c] - 1.25}{2.31 - 1.25}. \tag{11}$$

We assume that p's and $\bar{p}$'s have the same correction factors as the corresponding sign pions. Since p's and $\bar{p}$'s make only small contributions to the punchthrough hadrons this simplifying assumption has little consequence. We incorporate a conservative 10% systematic error on N_P to cover extreme possibilities for the p and $\bar{p}$ nuclear interaction lengths, as shown in Table VII.

We use Eq. (10), with the tabulated correction factors, particle yields at the vertex given by our normalized hadron generator, the known value of $L_4(\theta)$, and the values for $\lambda^i(p_T)$ determined from the measured gap 3 exclusive yield, to obtain the p_T spectrum of punchthrough hadrons, $N_P(p_T)$, as shown in Fig. 10. Systematic errors shown in this figure are discussed in Sec. III I and listed in Table VII. We multiply $N_P(p_T)$ by the fraction of the accepted z_{vtx}

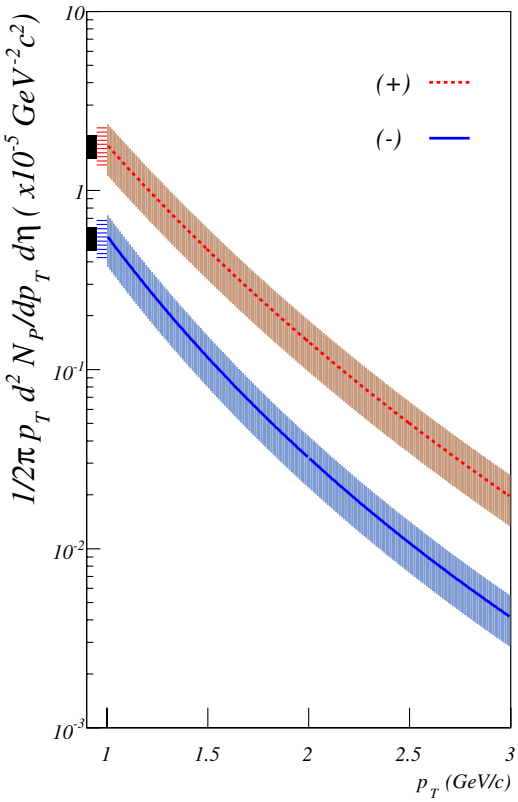

FIG. 10 (color online). Yield of positively (dotted line) and negatively (solid line) charged hadrons which penetrate to MuID gap 4. The curves are obtained from Eq. (10), as described above. Solid bands on the y-axis show the relative normalization uncertainty on the inclusive muon candidate yield, $\sigma^{\mathrm{norm}}_{N_I}/N_I$ (Table V). This needs to be included in the total error budget for the yield of punchthrough hadrons, σ_{N_P}/N_P (Table VII), but is displayed separately since it is common to all components of the inclusive muon candidate yield (see Eqs. (12) and (13)). Hatched bands on the y-axis show $\sigma^{\mathrm{norm}}_{R_P}$ (Table VII), the normalization uncertainty on the ratio of punchthrough hadrons to inclusive muon candidates. The relative fraction of positive and negative punch through hadrons can move up and down together by this amount. Shaded bands around the extracted punchthrough hadron yield show the systematic errors on $\sigma^{p_T}_{R_P}$ which can affect the p_T shape of the relative fraction of positive and negative punch through hadrons (positives and negatives can move independently). These are dominated by differences in the applicability of the simple exponential absorption model observed for FLUKA and GHEISHA. Systematic errors are listed in Tables V and VII and discussed in Sec. III I.

range represented by each z_{vtx} bin to finally obtain $N_P(p_T, z_{vtx})$.

The charge asymmetry in Fig. 10 is substantial, a result of the relatively long nuclear absorption length for positive kaons. As a result of the difference (λ^{K^+} is 19%–66% less than λ^{K^-}, λ^{π^+}, or λ^{π^-} based on GHEISHA and FLUKA values shown in Table III) the PHENIX muon arm steel presents 1.1–4.5 fewer interaction lengths to positive kaons than other hadron species.

G. Background tracks

The main source of tracks which are not accounted for in the yield of punchthrough hadrons and free-decay muons, and which are not due to vertex-independent muons, are light hadrons which penetrate through the pre-MuTR absorber, decay into a muon, and are still reconstructed as a valid track.

A simulation of single pions thrown into the muon arm acceptance shows that the number of hadrons which decay after the pre-MuTR absorber and penetrate to MuID gap 4 is only 5%–10% (increasing with increasing p_T) of the z_{vtx}-averaged number of free-decay muons, $N_D(p_T, z_{vtx} = 0)$. This ratio will be suppressed by the fact that tracks which decay are less likely to be reconstructed successfully. It is further suppressed by our punchthrough calculation procedure: the number of such tracks which stop in MuID gap 3 is roughly half the number that penetrate to gap 4; these will be counted in our calculation of the punchthrough hadron yield.

We express our estimate for the yield of background tracks not otherwise accounted for as $N_B(p_T) = 5\% \times N_D(p_T, z_{vtx} = 0)$. The systematic uncertainty assigned to this quantity, $\sigma_{R_B} = 5\% \times N_D(p_T, z_{vtx} = 0)$, covers the extreme possibilities that the N_B/N_D is unsuppressed or fully suppressed by reconstruction and punchthrough procedures, as described above (see Table VIII).

This estimate was verified in a simulation of π^-'s and K^-'s which were thrown into the muon arm acceptance and fully reconstructed. The reconstructed track information, together with the Monte Carlo truth information, allows us to eliminate uncertainties due to misreconstruction of the track p_T and due to determination of whether a track which penetrated to the last gap did so in a reconstructible fashion.

H. Vertex-independent muons

Figure 11 shows the yield of inclusive muon candidates, $N_I(p_T, z_{vtx})$, with contributions from individual components (free-decay muons, punchthrough hadrons, and background tracks) shown as well as their sum. The vertex-independent muons can be seen as the clear excess above the calculated background sources. The systematic error bands shown on the component sums are discussed in Sec. III I and listed in Tables VI and VII.

We obtain the yield of vertex-independent muons by applying Eq. (2) in each p_T bin, subtracting the hadronic contributions from the inclusive muon candidate yield, and averaging over z_{vtx} bins. This yield is shown, before averaging over z_{vtx} to demonstrate the expected vertex independence, in Fig. 12.

We make one final correction for momentum scale. The observed mass of the J/ψ, reconstructed with the same code and in the same data set, is higher than the nominal value by ≈ 100 MeV(3%) [51]. However, in a higher

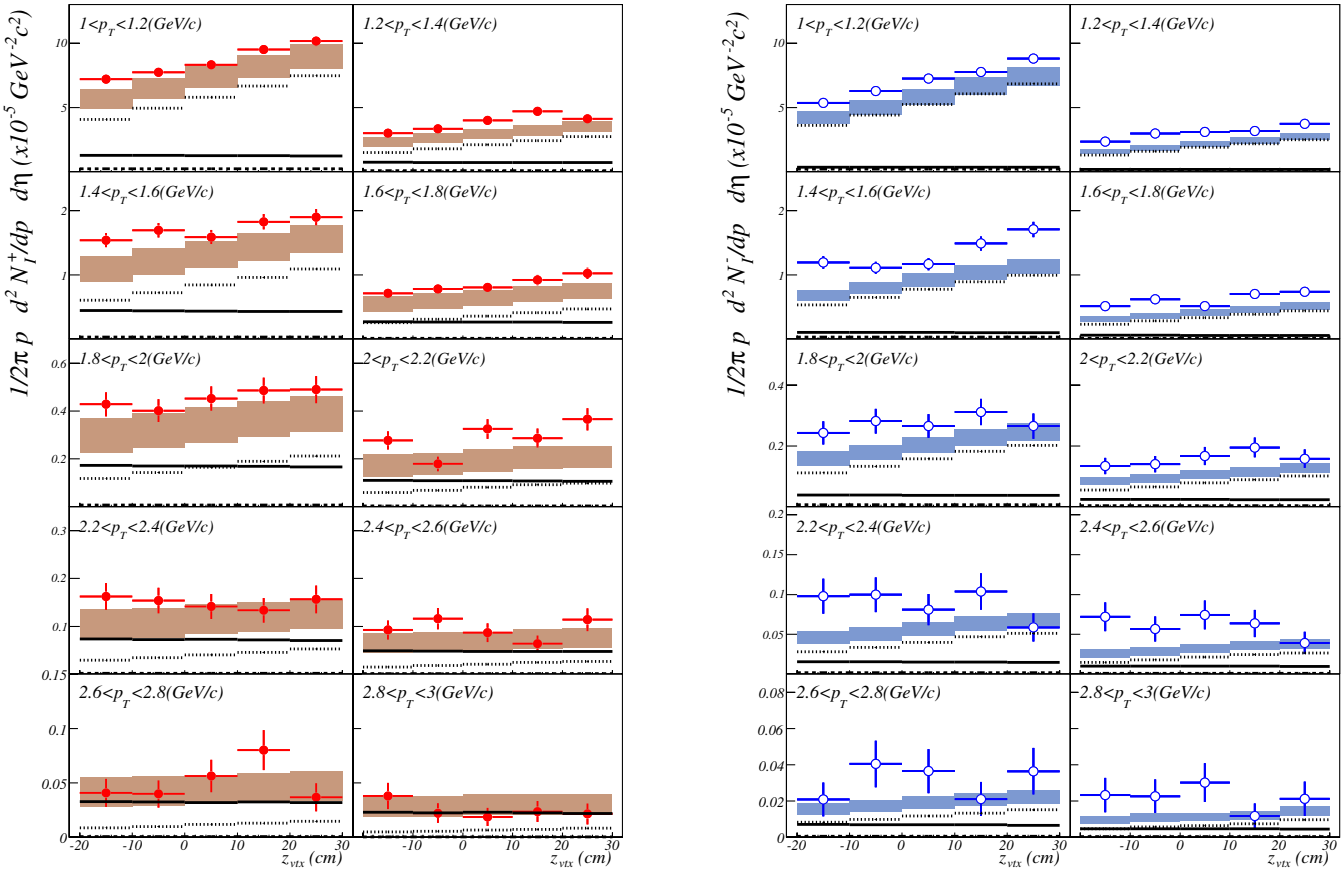

FIG. 11 (color online). Points show the yield of (left) positively and (right) negatively charged inclusive muon candidates vs z_{vtx} for different p_T bins with statistical errors. Dotted, solid, and dashed lines show contributions from decay muons, punchthrough hadrons, and background tracks, respectively. Shaded bands show the systematic error around the sum of these components, as listed in Tables V, VI, and VII and discussed in Sec. III I. The larger systematic uncertainties for positive particles are due to the larger fractional contribution of punchthrough background, which in turn is due to the relatively long nuclear interaction cross section for positive kaons.

statistics data set the momentum scale accuracy is verified to within 1% by our observation of the accepted value for the mass of the J/ψ [52]. Also, the peak observed in the longitudinal momentum distribution of particles stopping in MuID gap 3 (see Fig. 8) is within 0.5% of the predicted value. We therefore assume that the momentum scale is high by 1.5% (splitting the difference between 0 and 3%). This results in a momentum scale correction factor to the prompt muon yield of $0.94 + 0.987 \times (p_T[\mathrm{GeV}/c] - 1)$. We assume a 100% systematic error on this correction factor, as shown in Table V.

Finite momentum resolution can cause a similar effect. Contributions from energy-loss fluctuations, multiple scattering, and chamber resolution combine to give $\delta p/p \approx 5\%$ for the momentum range used in this analysis. Finite resolution, combined with an exponentially falling spectrum, artificially hardens the measured spectrum. For $1 < p_T < 3$ GeV/c this hardening increases the normalization of the yield by 3.7%. However, this is accounted for in our efficiency determination since we use a realistic p_T spectrum as input. Therefore, we apply no explicit correction and no additional systematic uncertainty for this effect.

The final values for the vertex-independent muon cross section, obtained from Eq. (3), are shown in Fig. 13. Points in this figure have been placed at the average p_T value of the bin contents to account for bin shifting in the steeply falling distributions. Systematic errors shown in this figure are discussed in Sec. III I and listed in Tables V, VI, and VII.

I. Systematic errors

Many sources of systematic error on the yield of vertex-independent muons, N_μ, are common to the different components of the inclusive muon candidate yield. In order to account for this we rewrite Eq. (2) (making the p_T and z_{vtx} dependencies implicit) as:

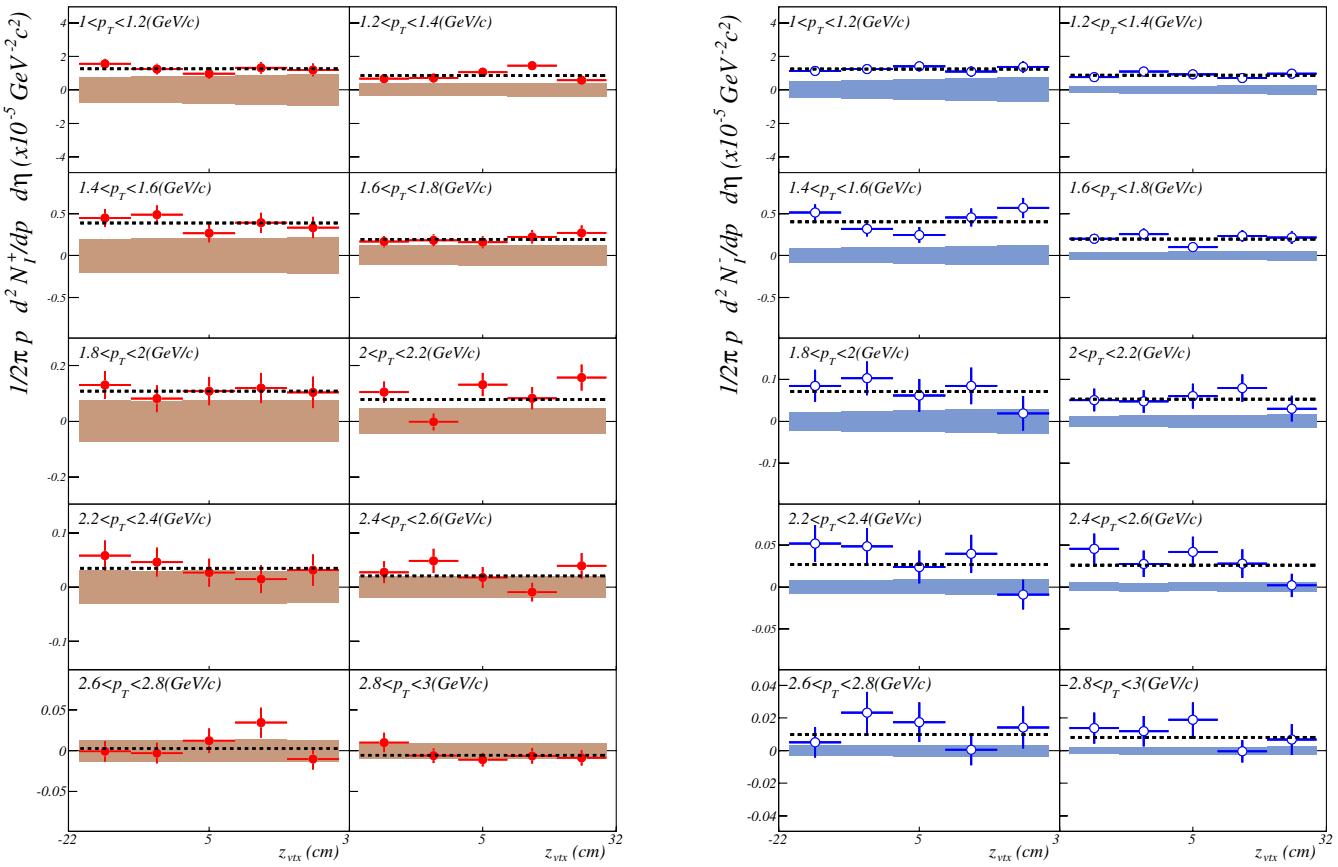

FIG. 12 (color online). Points show the yield of (left) positively and (right) negatively charged vertex-independent muons vs z_{vtx} for different p_T bins with statistical errors. The dashed lines show the yield for each p_T bin, averaged over z_{vtx}. The shaded bands around 0 show the systematic error on the sum of the contributions to the inclusive muon candidate yield from light-hadronic sources, as listed in Tables V, VI, and VII and discussed in Sec. III I. The larger systematic uncertainties for positive particles are due to the larger fractional contribution of punchthrough background, which in turn is due to the relatively long nuclear interaction cross section for positive kaons.

$$\begin{aligned} N_\mu &= N_I \times (N_\mu/N_I) \\ &= N_I \times ((N_I - N_D - N_P - N_B)/N_I) \\ &= N_I \times (1 - R_D - R_P - R_B), \end{aligned} \tag{12}$$

where $R_j = N_j/N_I$ is the fraction of the inclusive muon candidate yield attributed to the j^{th} component. We can now write the systematic error on N_μ as:

$$\sigma_{N_\mu} = \sqrt{(\sigma_{N_I}/N_I)^2 N_\mu^2 + (\sigma_{R_D}^2 + \sigma_{R_P}^2 + \sigma_{R_B}^2) N_I^2} \tag{13}$$

σ_{N_μ}, as determined below, is displayed in Figs. 11 and 12.

Note that the uncertainties for positive particles are significantly larger than for negative particles. This is due to the fact that the fraction of the inclusive muon candidate yield from punchthrough background is significantly larger for positive particles than for negative particles, as shown in Fig. 10. As discussed above, this is due to the relatively long nuclear interaction cross section for positive kaons.

Uncertainties contributing to σ_{N_I} are listed in Table V. Uncertainties contributing to σ_{N_D} and σ_{R_D} are listed in Table VI. Uncertainties contributing to σ_{N_P} and σ_{R_P} are listed in Table VII. Note that in these tables we separately list uncertainties that affect the overall normalization (σ/N^{norm}) and the shape of the p_T spectrum (σ/N^{p_T}).

TABLE V. Sources of systematic error on the calculation of N_I, the yield of inclusive muon candidates. σ_{N_I}/N_I is obtained by adding the different contributions in quadrature.

Error source	σ/N^{norm}	σ/N^{p_T}
Momentum scale	6.0%	$(p_T[\text{GeV}/c] - 1) \times 1.3\%$
ε_{acc}	10%	$(p_T[\text{GeV}/c] - 1) \times 1.5\%$
ε_{rec}	9.0%	0
$\varepsilon_{\text{user}}$	5.0%	$(p_T[\text{GeV}/c] - 1) \times 5.0\%$
$\varepsilon_{\text{trig}}$	4.7%	0
σ_{N_I}/N_I	16.3%	$(p_T[\text{GeV}/c] - 1) \times 5.4\%$

TABLE VI. Sources of systematic error on R_D, the ratio of free-decay muons to inclusive muon candidates, and N_D, the absolute yield of free-decay muons. σ_{R_D} is obtained by adding the different contributions in quadrature. σ_{N_D}/N_D is obtained by adding σ_{R_D} and σ_{N_I}/N_I in quadrature.

Error source	σ/N^{norm}	σ/N^{p_T}
Decay flight path	5%	0
z_{vtx} fit range	3.3%	0
Input hadron spectrum	0	$(p_T[\text{GeV}/c]-1)\times 5.0\%$
Decay normalization	7%	0
σ_{R_D}	9.2%	$(p_T[\text{GeV}/c]-1)\times 5.0\%$
σ_{N_D}/N_D	18.7%	$(p_T[\text{GeV}/c]-1)\times 7.4\%$

TABLE VII. Sources of systematic error on R_P, the ratio of punchthrough hadrons to inclusive muon candidates, and N_P, the absolute yield of punchthrough hadrons. σ_{R_P} is obtained by adding the different contributions in quadrature. σ_{N_P}/N_P is obtained by adding σ_{R_P} and σ_{N_I}/N_I in quadrature.

Error source	σ/N^{norm}	σ/N^{p_T}
$\varepsilon^3_{\text{scale}}$	23%	0
Exponential absorption model	0	32%
p and $\bar{p}$ contributions	10%	0
N_3^{stop} normalization	10%	0
σ_{R_P}	27%	32%
σ_{N_P}/N_P	31.5%	$\approx 32\%$

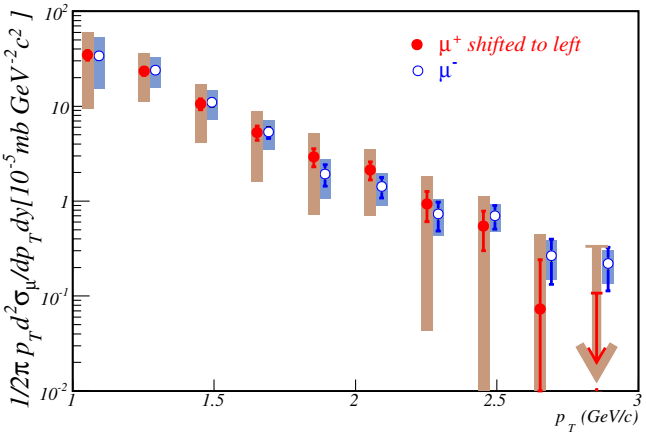

FIG. 13 (color online). p_T spectrum of vertex-independent muons. Error bars indicate statistical errors. One point with unphysical (less than zero) extracted yield is shown as an arrow pointing down from the 90% C.L. upper limit Shaded bands indicate systematic errors, as listed in Tables V, VI, and VII and discussed in Sec. III I. The larger systematic uncertainties for positive particles is due to the larger fractional contribution of punchthrough background, which in turn is due to the relatively long nuclear interaction cross section for positive kaons.

TABLE VIII. Other sources of systematic uncertainty. σ_{R_B} is incorporated into the systematic uncertainty on the vertex-independent muon yield, as shown in Eq. (13). Errors on σ^{pp}_{BBC} and $\varepsilon^{c,\bar{c}\to\mu}_{\text{BBC}}$ are added in quadrature along with the total uncertainty on the vertex-independent muon yield, σ_{N_μ}/N_μ to get the uncertainty on the vertex-independent muon cross section.

Error source	σ/N^{norm}	σ/N^{p_T}
σ_{R_B}	0	$5\%\times N_D(p_T, z_{vtx}=0)$
$\sigma_{\sigma^{pp}_{\text{BBC}}}$	9.6%	0
$\sigma_{\varepsilon^{c,\bar{c}\to\mu}_{\text{BBC}}}$	5%	0

Values for σ_{N_I}/N_I are displayed in Fig. 6. Values for σ_{R_D} and σ_{R_P} are displayed in Figs. 7 and 10 respectively. We insert σ_{N_I}/N_I, σ_{R_D}, σ_{R_P}, and σ_{R_B} into Eq. (13) as part of the final systematic error on N_μ.

To get the vertex-independent muon cross section, as defined in Eq. (3) and displayed in Figs. 13 and 16, we need to add in quadrature the errors on N_μ, σ^{pp}_{BBC}, $\varepsilon^{c,\bar{c}\to\mu}_{BBC}$. The error on N_μ is obtained from the components above according to Eq. (13). Errors on σ^{pp}_{BBC} and $\varepsilon^{c,\bar{c}\to\mu}_{BBC}$ are listed in Table VIII.

IV. CHARM CROSS SECTION

The charm production cross section obtained from the yield of vertex-independent muons (or from the yield of nonphotonic electrons, or D mesons) is necessarily model dependent since we do not measure the charm quarks directly. We use PYTHIA to convert our measurement of the vertex-independent muon yield into an estimate of the differential charm production cross section at forward rapidity, $d\sigma_{c\bar{c}}/dy|_{y=1.6}$, in a procedure very similar to that used in PHENIX measurements of charm production at $y=0$ [7–13]. We use PYTHIA version 6.205 with parameters tuned to reproduce charm production data at SPS and FNAL [71] and single-electron data at the ISR [72–74]. Tuned parameters are listed in Table VIII. The meaning of each parameter is more thoroughly defined in the PYTHIA manual [75].

Vertex-independent muon sources, predicted by a PYTHIA simulation using the same parameters (except that MSEL is set to 2 to generate unbiased collisions), are listed in Table X. These sources include decays of hadrons containing a heavy quark, and light-vector mesons with a decay length too short to be measured with the existing experimental apparatus (ρ, ω, ϕ). Their p_T spectra are shown in Fig. 14. Contributions from quarkonium decays, Drell-Yan, and τ lepton decays are negligible. This shows that vertex-independent muon production in our acceptance is dominated by muons from decay of charm hadrons, although for $p_T > 2.5$ GeV/c the contribution from decays of hadrons containing a bottom quark is starting to become significant.

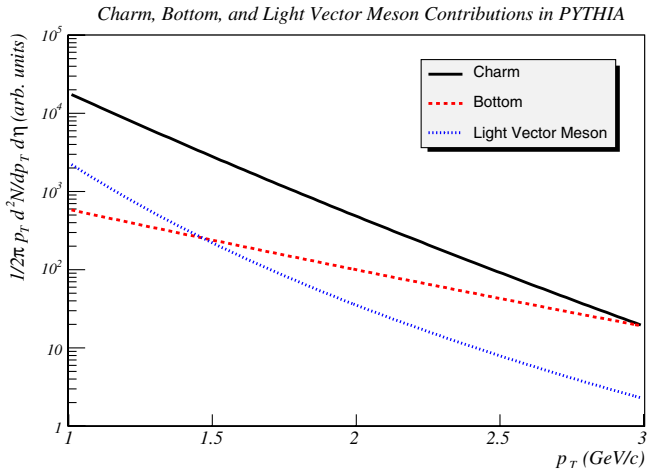

FIG. 14 (color online). PYTHIA calculation showing the major contributions to the vertex-independent muon p_T spectrum. Solid, dashed, and dotted lines show the yield from charm, bottom, and light vector mesons (ρ, ω, ϕ), respectively.

This simulation also gives the distribution of charm quarks (p_T vs y) that produce a muon in our acceptance, as shown in Fig. 15. This demonstrates that the vertex-independent muons we measure sample charm quarks down to $p_T \approx 1$ GeV/c, over a narrow rapidity slice centered at $y = 1.6$.

Figure 16 shows a comparison of the measured vertex-independent negative muon spectrum (from Fig. 13) to the prediction of this default PYTHIA simulation and to a FONLL calculation [20,77]. Note, larger systematic errors for the positive muon spectrum preclude a significant measurement for that charge sign. One can see that the measured values significantly exceed both predictions. The spectrum also appears to be somewhat harder than the PYTHIA spectrum with the parameters listed in Table IX.

We scale the charm (only) contribution to the PYTHIA vertex-independent muon p_T spectrum such that the total

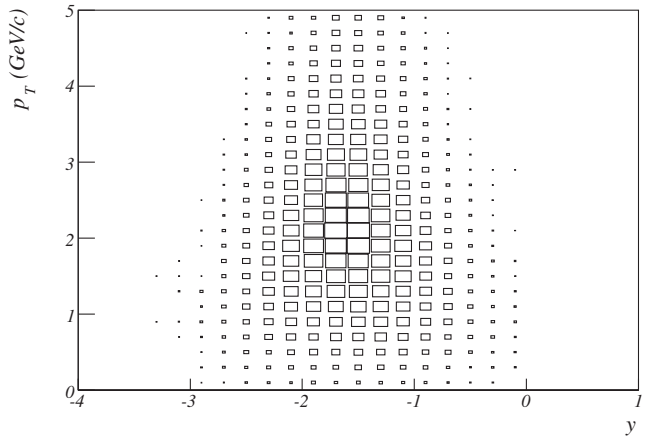

FIG. 15. PYTHIA results for the p_T vs y distribution (linear z-scale) of charm quarks that produce a muon in the PHENIX acceptance.

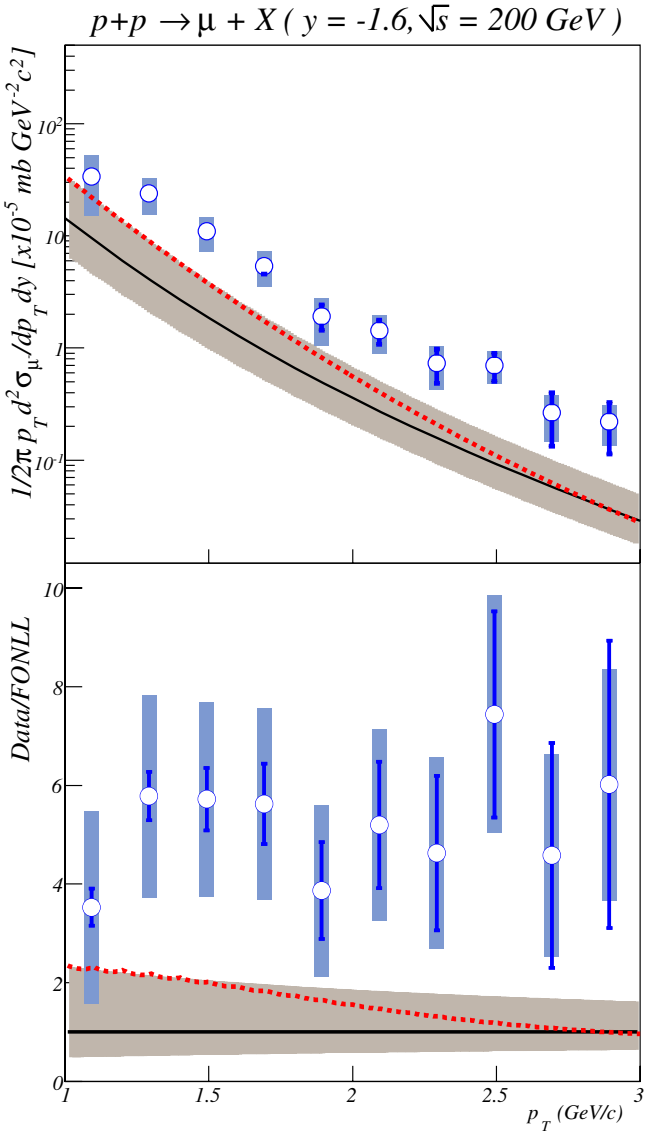

FIG. 16 (color online). The top panel shows the measured p_T spectrum of vertex-independent negative muons from Fig. 13, the PYTHIA prediction using settings listed in Table IX without scaling the charm contribution (dotted line), and a FONLL calculation (solid line with systematic error band) [20,77]. The bottom panel shows the ratio of the measured spectrum to the FONLL calculation with statistical (error bars) and systematic (bands) uncertainties on the data, as well as the theoretical uncertainty (shaded band around 1). The dashed line shows the PYTHIA/FONLL ratio.

spectrum (including the small contributions from open bottom and vector mesons) matches the central values of the measured vertex-independent negative muon spectrum. Only statistical errors are used in the fit. We multiply the scale factor from the fit (2.27) by the PYTHIA value for the charm production cross section, $d\sigma_{c\bar{c}}/dy|^{\mathrm{PYTHIA}}_{y=1.6}$ (0.107 mb), to obtain $d\sigma_{c\bar{c}}/dy|^{\mathrm{PHENIX}}_{y=1.6} = 0.243 \pm 0.013(\mathrm{stat.})$ mb.

TABLE IX. Tuned PYTHIA parameters (default settings for this analysis) for determination of charm production cross section central value.

Parameter	Value	Meaning
MSEL	4	Heavy quark production every event (gluon fusion + $q/\bar{q}$ annihilation).
MSTP (32)	4	Hard scattering scale, $Q^2 = \hat{s}$.
MSTP (33)	1	Use K-factor.
MSTP (52)	2	Use PDF libraries.
MSTP (51)	4046	Select CTEQ5L PDF libraries [76].
MSTP (91)	1	Use Gaussian distribution for intrinsic k_T.
PARP (31)	3.5	K-factor.
PARP (91)	1.5	$\langle k_T \rangle$ (GeV/c).
PARP (93)	5.0	Maximum k_T (GeV/c).
PMAS (4, 1)	1.25	m_c (GeV/c).
D^+/D^0	0.32	Default charm chemistry ratio.

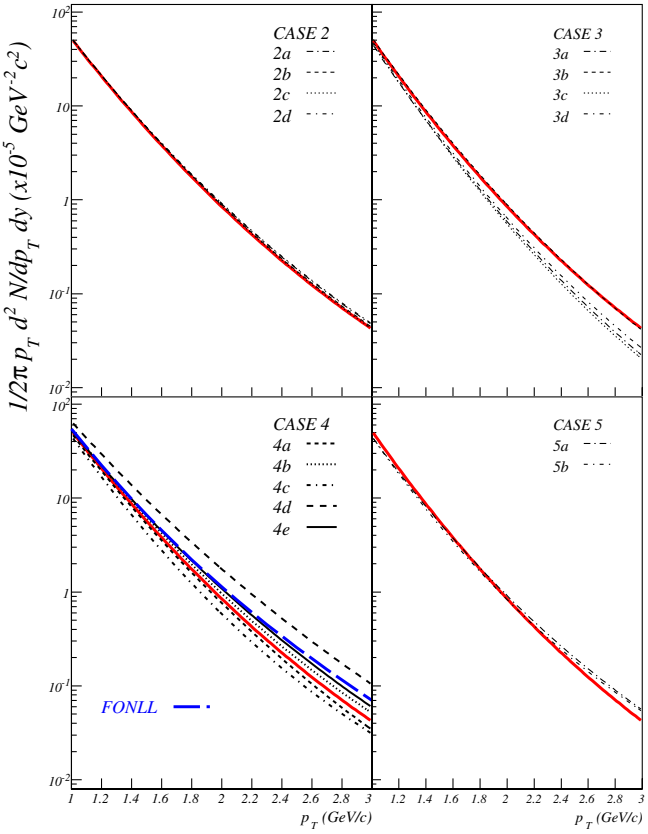

FIG. 17 (color online). PYTHIA results with different parameter sets for the negative vertex-independent muon p_T spectrum per event in which a $c\bar{c}$ pair is created. The solid line in each panel shows the result when using default settings listed in Table IX. Legends indicate the correspondence between line style and the simulation case label. Parameter sets for each case label are given in Table XI.

TABLE X. Percentage contribution of different sources of vertex-independent muons within our acceptance ($1 < p_T < 3$ GeV/c and $1.5 < |\eta| < 1.8$), from PYTHIA, with parameters listed in Table IX (except that MSEL = 2 to generate minimum bias collisions).

Source	Contribution
Open charm	84.6%
Open bottom	6.9%
ρ, ω, ϕ	8.1%
Quarkonia	<0.1%
Drell-Yan	<0.1%
τ leptons	0.4%

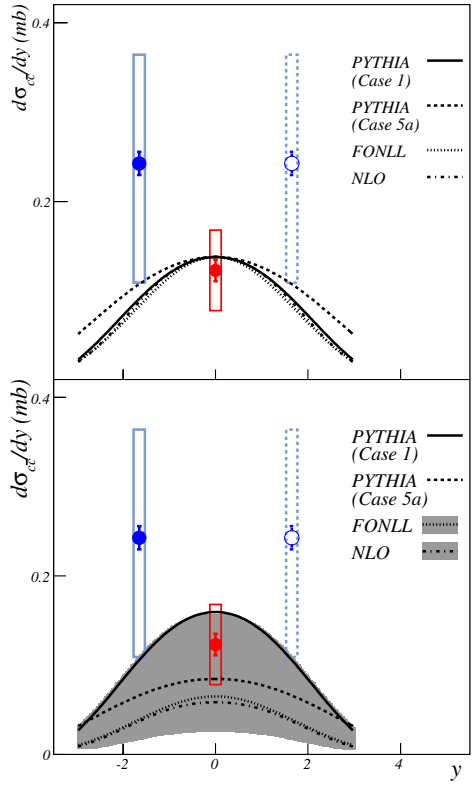

FIG. 18 (color online). Comparisons of measured charm rapidity distributions, $d\sigma_{c\bar{c}}/dy$ vs y, to theoretical predictions. Data points at $y = \pm 1.6$ are from this analysis (the point at $y = 1.6$ is reflected through $y = 0$). The point at $y = 0$ is the PHENIX measurement of charm through semileptonic decay to electrons [13]. Error bars on the data points indicate statistical uncertainties and boxes indicate systematic uncertainties. The top panel shows rapidity spectra from two PYTHIA parameter sets (see Table XI for details), FONLL [20,77], and a NLO calculation [83]. The PYTHIA curve with the default parameter set (case 1) was fit to the two PHENIX data points with statistical and systematic errors added in quadrature. All other theory curves were normalized so that they are equal at $y = 0$ to allow shape comparisons. The bottom panel shows the theory curves without normalization. Theoretical uncertainties associated with the FONLL and NLO calculations are indicated with shaded bands.

TABLE XI. Results for PYTHIA simulations with different parameter sets used to explore the systematic error on the charm cross section due to model uncertainties. The top of the table details the different parameter sets tested. Unless otherwise noted, parameters are the same as those listed in Table IX. The bottom of the table gives the results for different simulations: The first column identifies the simulation; the second column gives the total charm production cross section given the chosen PYTHIA parameter set; the third column gives the differential charm production cross section at $y = 1.6$; the fourth column gives the normalization factor needed to fit the PHENIX data; the fifth column gives the differential charm production cross section at $y = 1.6$ for PHENIX data (the product of the third and fourth columns); the sixth column gives the fractional difference between the results for each simulation compared to the simulation with the default PYTHIA parameter set; the last column gives the ratio $d\sigma_{c\bar{c}}/dy|^{\mathrm{PYTHIA}}_{y=1.6}/d\sigma_{c\bar{c}}/dy|^{\mathrm{PYTHIA}}_{y=0}$.

Case	PYTHIA Settings
1	Default settings, see Table IX.
2a	MSTP(51) = 4032, CTEQ4L PDF libraries [78].

We distinguish between two different sources of systematic uncertainty on the extraction of the charm cross section: (1) uncertainty in the PYTHIA calculation and (2) uncertainty in the data, which is largely independent of PYTHIA.

We determined the uncertainty in the data ($\pm$ 43%) by refitting PYTHIA to the data at the minimum and maximum of the 1σ systematic error band.

We determined the uncertainty in the PYTHIA calculation with a systematic study in which we varied simulation parameters, extracted the new simulated vertex-independent negative muon spectrum, normalized to the measured spectrum, and extracted $d\sigma_{c\bar{c}}/dy|_{y=1.6}^{\mathrm{PHENIX}}$ for the modified parameter sets. We varied PDF libraries, the hard scattering scale, the charm quark mass, the intrinsic k_T value, the D^+/D^0 ratio, charm production mechanism selections, and open bottom and vector meson scaling assumptions. The parameter sets used and the results of this study are summarized in Table XI.

The PYTHIA charm cross section varies substantially ($\Delta(d\sigma_{c\bar{c}}/dy)|_{y=1.6}^{\mathrm{PYTHIA}}) \approx 4$) for the chosen parameter sets. However, the extracted experimental charm cross section is relatively stable ($\Delta(d\sigma_{c\bar{c}}/dy)|_{y=1.6}^{\mathrm{PHENIX}} < 0.36$). This is due to the fact that the parameter set changes have relatively minor effects on the shape of the predicted vertex-independent muon p_T spectrum, and we obtain the experimental charm cross section by normalizing the PYTHIA charm cross section by the ratio of the measured and predicted muon p_T spectra.

One way to visualize this is to plot (see Fig. 17) the vertex-independent muon yield in our acceptance per event in which a $c\bar{c}$ pair is created for the different PYTHIA parameter sets. Because of our procedure, parameter sets which give similar vertex-independent muon yields per $c\bar{c}$ event in the low p_T region (which dominates the fit) will necessarily give similar values for $d\sigma_{c\bar{c}}/dy|_{y=1.6}^{\mathrm{PHENIX}}$, whatever the PYTHIA charm cross section is.

The largest variation in the predicted muon yield at $p_T = 1$ GeV/c per $c\bar{c}$ event is seen for simulations in which the intrinsic k_T is varied from its default value ($\langle k_T \rangle = 1.5$ GeV/c) to the value expected from arguments based on Fermi momentum (case 4c, $\langle k_T \rangle = 0.3$ GeV/c), or to a value which best reproduces the measured spectrum at higher p_T (case 4d, $\langle k_T \rangle = 3.0$ GeV/c). These parameter sets also result in the largest variation in $d\sigma_{c\bar{c}}/dy|_{y=1.6}^{\mathrm{PHENIX}}$, as shown in Table X. We use the cross section values obtained in this pair of simulations to define the systematic uncertainty in our measurement due to the uncertainty in our PYTHIA calculation. This gives us our final answer: $d\sigma_{c\bar{c}}/dy|_{y=1.6} = 0.243 \pm 0.013(\mathrm{stat.}) \pm 0.105(\mathrm{datasyst.})^{+0.049}_{-0.087}(\mathrm{PYTHIAsyst.})$ mb. As shown in the lower-left panel of Fig. 17, the FONLL prediction of the muon yield per $c\bar{c}$ collision lies well within the extreme cases defining the systematic error resulting from the necessary model dependence of our charm extraction. Therefore, using FONLL instead of PYTHIA for the charm extraction would yield consistent results.

Figure 18 shows the PHENIX charm rapidity spectrum. The result of this analysis (mirrored about $y = 0$ since this is a symmetric collision system) is plotted along with the result for $d\sigma_{c\bar{c}}/dy|_{y=0}$ [13]. In order to compare with the data at $y = 0$ the systematic uncertainty on the data from this analysis is shown as the quadrature sum of the two sources of systematic uncertainty described above (data and PYTHIA). Theoretical curves from PYTHIA (case 1 and case 5a), FONLL [20,77], and a NLO calculation from Vogt [83] are also displayed.

In the top panel of the figure PYTHIA with the default parameter set (case 1) is fit to the two PHENIX points with statistical and systematic errors added in quadrature. Other theory curves are normalized so that they are equal at $y = 0$ in order to allow shape comparisons. As shown in Table XI, different PYTHIA parameter sets differ in the predicted ratio $d\sigma_{c\bar{c}}/dy|_{y=1.6}^{\mathrm{PYTHIA}}/d\sigma_{c\bar{c}}/dy|_{y=0}^{\mathrm{PYTHIA}}$ by $>30\%$. Unfortunately, current systematic error bars preclude any conclusions about the charm production rapidity shape.

In the bottom panel of the figure the theory curves are without normalization to allow an absolute comparison. The quoted theoretical uncertainty bands for the FONLL and NLO calculations are also shown. We note that, although our data are above the FONLL prediction, the error bars touch. This is in contrast to the situation for the vertex-independent muon cross section, shown in Fig. 16, where the data are significantly above the prediction. The larger disagreement in the vertex-independent muon cross section is presumably due to different treatment of the fragmentation process in PYTHIA and FONLL [20,77,83].

V. CONCLUSION AND OUTLOOK

We have measured muon production at forward rapidity ($1.5 \leq |\eta| \leq 1.8$), in the range $1 < p_T < 3$ GeV/c, in $\sqrt{s} = 200$ GeV $p + p$ collisions at RHIC. We determined and subtracted the contribution from light hadron sources (π, K, p) to obtain the vertex-independent muon yield which, for the p_T range measured in this analysis, and in the absence of new physics, arises dominantly from the decay of D mesons. We normalized the PYTHIA muon spectrum resulting from the production of charm quarks to obtain the differential cross section for charm production at forward rapidity: $d\sigma_{c\bar{c}}/dy|_{y=1.6} = 0.243 \pm 0.013(\mathrm{stat.}) \pm 0.105(\mathrm{datasyst.})^{+0.049}_{-0.087}(\mathrm{PYTHIAsyst.})$ mb. This is compatible with PHENIX charm measurement at $y = 0$, although even further above predictions from PYTHIA and FONLL. Large systematic uncertainties in the current measurement preclude statements about the rapidity dependence of the charm cross section.

The systematic uncertainty in the data is dominated by uncertainty on the determination of the fractional contribution of decay muons. This will be improved with higher

statistics data sets (already collected) which will allow better measurements of the z_{vtx} dependence of particle production. Final results for identified particle p_T distributions in $p + p$ collisions by BRAHMS will also be invaluable for improving the input to our hadron generator. The systematic uncertainty in PYTHIA is dominated by differences observed when the intrinsic $\langle k_T \rangle$ is varied. In order to reduce this uncertainty we need to reduce the allowed parameter space by improving the measurement of the high p_T portion of the vertex-independent muon spectrum, where the error is dominated by the uncertainty in the yield of punchthrough hadrons. Data sets (already collected) with higher statistics, and with hadrons stopping in MuID gap 2, will allow a completely data-driven approach to the calculation of the punchthrough yield. This will eliminate the reliance on hadronic interaction simulation packages, differences in which are the largest source of systematic error at high p_T. Analogous measurements are also being carried out for $d + Au$, $Cu + Cu$, and $Au + Au$ [84] collisions at $\sqrt{s_{NN}} = 200$ GeV. These will allow determination of the magnitude of nuclear modification effects on charm production at forward rapidity.

Cross sections for midrapidity production of direct photons in $p + p$ collisions at the Relativistic Heavy Ion Collider (RHIC) are reported for transverse momenta of $3 < p_T < 16$ GeV/c. Next-to-leading order perturbative QCD (pQCD) describes the data well for $p_T > 5$ GeV/c, where the uncertainties of the measurement and theory are comparable. We also report on the effect of requiring the photons to be isolated from parton jet energy. The observed fraction of isolated photons is well described by pQCD for $p_T > 7$ GeV/c.

DOI: 10.1103/PhysRevLett.98.012002 PACS numbers: 13.85.Qk, 25.75.Dw

The production of direct photons, i.e., photons not from hadronic decays, in hadron-hadron collisions has been recognized as providing direct access to the gluon distributions in the hadron, both unpolarized and polarized [1,2]. The process of direct-photon production is described, at high energy and high momentum transfer, by perturbative quantum chromodynamics (pQCD). Three parton-parton subprocesses dominate at lowest order: Compton scattering $g + q \rightarrow \gamma + q$, annihilation $q + \bar{q} \rightarrow \gamma + g$, and parton-parton hard scattering with the scattered quark or gluon fragmenting to a photon, where g (q) represent gluon (quark) states. At next-to-leading order (NLO), bremsstrahlung emission of photons from the quarks undergoing hard scattering also contributes to the direct-photon signal. The annihilation process is suppressed for $p + p$ collisions, due to the lower probability density of $\bar{q}$ vs g in the proton. In general, the fragmentation and bremsstrahlung processes will produce photons in the vicinity of parton jets. Therefore, a requirement that the photon be isolated from parton jet activity can emphasize the Compton graph. Here, only the gluon distribution is unknown, particularly for the polarized case, and direct-photon production therefore provides direct access to this (polarized) gluon distribution.

Comparisons of data to theory test our understanding of direct-photon production in hadron-hadron collisions. Previous experiments have shown significant disagreement between data and theory at fixed target energy, $\sqrt{s} <$ 40 GeV, and good agreement at collider energy, $\sqrt{s} >$ 60 GeV [3,4]. Results from the Relativistic Heavy Ion Collider (RHIC) for $p + p$ collisions cover intermediate energy and momentum transfer, overlapping CERN Intersecting Storage Rings, and Super anti-Proton Proton Synchrotron collider kinematics, and address the robustness of the pQCD prediction for direct-photon production. In addition, the comparison of the direct-photon rate using no isolation requirement, to the rate of observed photons that are isolated from parton jets, tests our understanding of the processes of parton fragmentation to photons and of the bremsstrahlung emission of photons from quarks in hard scattering.

Furthermore, direct-photon production in $p + p$ collisions provides a valuable baseline for the interpretation of direct-photon data from heavy ion ($A + A$) collisions. Jet-quenching models attribute the strong suppression of high-p_T hadrons in central $A + A$ collisions to energy loss of scattered quarks and gluons in the hot and dense medium created in these collisions [5]. Since photons interact with the medium only electromagnetically, they provide a monitor of the initial parton flux and therefore test a crucial assumption of these models.

In this Letter, we present cross sections for direct-photon production in $p + p$ collisions at $\sqrt{s} = 200$ GeV, from the 2003 run of RHIC, at midrapidity for $3 < p_T < 16$ GeV/c. An earlier measurement [6] from the 2002 run of RHIC covered a much smaller region of p_T. Unpolarized cross sections are reported, obtained by averaging over the spin states of the beams, with $<1\%$ residual polarization.

The data were collected by the PHENIX detector [7]. The primary detector for this measurement is an electromagnetic calorimeter (EMCal), consisting of two subsystems, a six sector lead-scintillator (PbSc), and a two sector lead glass (PbGl) detector, each located 5 m radially from the beam line. Each sector covers a range of $|\eta| < 0.35$ in pseudorapidity and 22.5° in azimuth. The EMCal has fine granularity. Each calorimeter tower covers $\Delta\eta \times \Delta\phi \sim 0.01 \times 0.01$, and a tower contains $\sim$80% of the photon energy hitting the center of the tower. Two photons from $\pi^0 \rightarrow \gamma\gamma$ decays are clearly resolved up to a π^0 p_T of 12 GeV/c, and a shower profile analysis extends the γ/π^0 discrimination to beyond 20 GeV/c. The energy calibration of each tower is obtained from minimum-ionizing tracks and from the reconstructed π^0 mass. The uncertainty on the energy scale is less than 1.5%.

Beam-beam counters (BBC) positioned at pseudorapidities $3.1 < |\eta| < 3.9$ provide a minimum bias (MB) trigger. Events with high p_T photons are selected by a level-1 trigger that requires a minimum energy deposit of 1.4 GeV in an overlapping tile of 4×4 towers of the EMCal in coincidence with the MB trigger. The MB trigger cross section is $\sigma_{\mathrm{BBC}} = (23.0 \pm 2.2)$ mb, about 50% of $\sigma_{\mathrm{inel}}^{pp}$. The efficiency bias due to the MB trigger in the 2003 run, $\epsilon_{\mathrm{bias}} = 0.79 \pm 0.02$, is determined from the ratio of the yield of high $p_T \pi^0$ with and without the MB trigger. An integrated luminosity ($\mathcal{L}$) of 240 nb^{-1} after a vertex cut of ± 30 cm is used in this analysis.

The first step in the analysis is to cluster the hit towers. If there are two tower energy maxima and at least one lower-energy tower between them, the cluster is split into two, with the energy of each tower divided between the two clusters according to electromagnetic shower profiles associated with the clusters. Photons are identified by a shower profile cut that was calibrated using test beam data, identified electrons, and decay photons from identified π^0. The cut rejects $\sim$50% of hadrons depositing $E >$ 3 GeV in the EMCal and accepts $\sim$98% of real photons. The charged particle veto of the photon sample is based on tracks in drift chambers 2 m from the beam line, and hits in the pad chamber (PC3) immediately in front of the EMCal. Loss of photons from conversions in material before the EMCal is estimated using a GEANT [8] simulation and confirmed by the observed fraction of identified π^0 photons vetoed. The conversion correction is 3% for the drift chamber veto and $\sim$8% for the PC3 veto. Remaining nonphoton background, including converting neutral had-

rons and albedo from the magnet yokes, is also estimated from the GEANT simulation at ~1%.

The experimental challenge in direct-photon measurements is the large photon background from decays of hadrons, primarily from $\pi^0 \to \gamma\gamma$ (~ 80% of the decays) and $\eta \to \gamma\gamma$ (~15%). We use two techniques described below to subtract the decay background: a π^0-tagging method and a cocktail subtraction method.

In the π^0-tagging method, a candidate photon is tagged as a π^0 decay photon if it forms a pair with another photon in the mass range $105 < M_{\gamma\gamma} < 165$ MeV ($M_{\pi^0} \pm 3\sigma$), with $E_\gamma > 150$ MeV. A fiducial region for direct-photon candidates excludes 10 towers (0.1 rad) from the edges of the EMCal, while partner photons are accepted over the entire detector, to improve the probability of observing both decay photons from the π^0.

This method overestimates the yield of photons from π^0 decays, γ_{π^0}, due to combinatorial background. A p_T dependent correction (~10%) is estimated from a fit to the π^0 sidebands, with ±3% uncertainty. The yield of direct photons, $\gamma_{\rm dir}$, is obtained from the inclusive photon yield, $\gamma_{\rm incl}$, using the equation

$$\gamma_{\rm dir} = \gamma_{\rm incl} - (1 + \delta^{\gamma}_{h/\pi^0})(1 + R^{\rm miss}_{\pi^0})\gamma_{\pi^0}, \qquad (1)$$

where $R^{\rm miss}_{\pi^0}$ is the correction for missing photon partners to π^0; $(1 + R^{\rm miss}_{\pi^0})\gamma_{\pi^0}$ represents the total contribution of photons from π^0 decays in each p_T^γ bin, and $\delta^{\gamma}_{h/\pi^0}$ is the fraction of photons from hadrons other than π^0.

To estimate $R^{\rm miss}_{\pi^0}$, a Monte Carlo simulation is used that includes the acceptance, energy resolution, and our measured π^0 spectrum [9] as input. Figure 1 shows $R^{\rm miss}_{\pi^0}$ from the simulation. The largest uncertainty is from the calibration of the EMCal at low energy. $\delta^{\gamma}_{h/\pi^0}$ is estimated by a

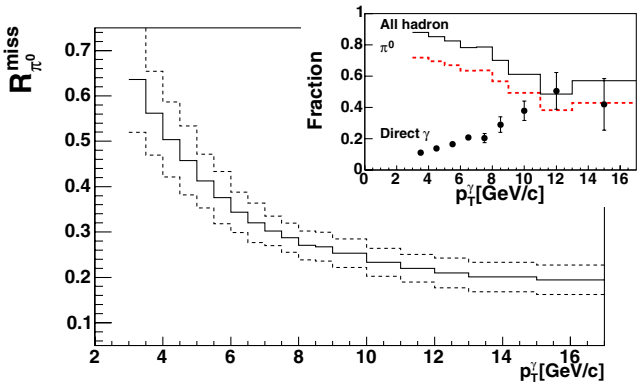

FIG. 1 (color online). Correction for missing photon partners to the π^0 ($R^{\rm miss}_{\pi^0}$) vs p_T^γ. Dashed lines show the systematic uncertainty. Inset: Different contributions to the inclusive photon spectrum. Solid (dashed) lines represent all hadronic (π^0) decay contributions. The data points show the remaining photon contributions.

simulation of hadron decays based on the η/π^0 [10] and ω/π^0 [11] ratios from our measurements: $\delta^{\gamma}_{h/\pi^0} \approx 0.24$, with $\delta^{\gamma}_{\eta/\pi^0} = 0.19$ and $\delta^{\gamma}_{\omega/\pi^0} = 0.05$. The contribution from other hadrons is less than 0.01. A small p_T dependence is assumed to follow m_T scaling [12]. The inset of Fig. 1 shows the fraction of photons from h, π^0, and $\gamma_{\rm dir}$ to $\gamma_{\rm incl}$. The direct-photon fraction ranges from 10% at low p_T^γ to 50% for $p_T^\gamma > 10$ GeV.

In the cocktail method [6,13], the spectrum of decay photons is simulated utilizing our measured π^0 spectrum and applying m_T scaling in order to account for other hadronic contributions. The effect of shower merging is also taken into account in the simulation. A double ratio $R_\gamma = (\gamma/\pi^0)^{\rm data}/(\gamma/\pi^0)^{\rm sim}$ is calculated for each p_T bin. $R_\gamma > 1$ indicates a direct-photon signal. The direct-photon yield is extracted as $\gamma_{\rm dir} = (1 - R_\gamma^{-1})\gamma_{\rm incl}$. Using the γ/π^0 ratio has the advantage that some systematic uncertainties cancel.

A summary of the systematic uncertainties is presented in Table I. Uncertainties of similar contributions are grouped together: global quantities (a), the inclusive photon yield (b), and the direct-photon background (c)–(e). The categories (a)–(d) apply to both analysis methods. Category (a) includes the uncertainties of the energy scale, luminosity, and geometrical acceptance. The main contribution to category (b) is the uncertainty of the nonphoton background estimation. The uncertainty of the charged particle veto is based on a study of the cluster vs track matching in the EMCal and the tracking detectors. The uncertainty in the neutral hadron contamination is estimated from identified charged hadrons. We assign the estimate of the albedo contribution as its uncertainty. Category (c) includes uncertainties of the correction for combinatorial background as estimated by different parametrizations of the background shape and the uncertainties of the π^0 reconstruction efficiency. Category (d) refers to the uncertainty of contributions from hadronic decays other than π^0's, derived from our measurement of the hadron production ratios. Finally, category (e) combines all remaining uncertainties separately for the two analysis

TABLE I. Relative systematic uncertainties of the direct-photon spectra.

p_T [GeV/c]	4.5–5	7.5–8	10–12
Signal fraction	9%	27%	49%
(a) Global	16.8%	14.9%	14.9%
(b) Inclusive photons	12.3%	4.7%	3.1%
(c) Photons from π^0	30.1%	10.7%	6.5%
(d) Other hadrons	21.4%	6.7%	3.8%
(e) Nonlinearity (+ remaining)			
(e_1) π^0 tagging	42.7%	6.8%	5.4%
(e_2) cocktail	69.5%	20.4%	13.4%
Total	71.6%	25.2%	19.8%

methods. Nonlinearity effects in the energy calibration affect the minimum energy cut in the π^0-tagging method (e_1) and distort the π^0 spectra in the cocktail method (e_2). After the individual calibration, a difference in the γ/π^0 ratio of PbGl and PbSc remains (5%–7%). This is used to assign a systematic uncertainty of the nonlinear part of the energy scale. Because of the small signal fraction at low p_T, this translates into the large relative uncertainty in the direct-photon spectra in Table I. In addition, the uncertainty of the shower profile analysis of the γ/π^0 discrimination at high p_T is included in this category. The two uncertainties (e_1, e_2) are combined by averaging the squared uncertainties, and then all uncertainties were added in quadrature.

The results from the π^0-tagging and cocktail method, obtained from independent analyses, agree within systematic uncertainties. We report an average of the results and uncertainties of the two methods giving equal weight to the two analysis methods.

The invariant cross section of direct-photon production is calculated by the following formula:

$$E\frac{d^3\sigma}{dp^3} = \frac{1}{\mathcal{L}}\frac{1}{2\pi p_T}\frac{\gamma_{\rm dir}}{\Delta p_T \Delta y}\frac{1}{\epsilon}\frac{1}{\epsilon_{\rm bias}}, \qquad (2)$$

where ϵ includes geometrical acceptance and the smearing effect from the energy resolution. The data points are plotted at the bin centers, with a correction to take into account the effect of finite bin sizes. The uncertainty of this correction is small compared to other systematic uncertainties.

Figure 2(a) shows the measured invariant cross section for midrapidity direct-photon production at $\sqrt{s} =$ 200 GeV. In addition, a NLO pQCD prediction [14–19], using CTEQ 6M parton distribution functions (PDF) [20] and the BFGII parton to photon fragmentation function (FF) [21], is shown with three theory scales (μ) as indicated. Figure 2(b) shows the fractional difference between the data and this calculation. The results are well described by pQCD.

The direct-photon sample includes photons from the Compton and annihilation subprocesses, which are expected to be isolated from parton jet activity. To measure the fraction of isolated photons, we apply an isolation requirement in the π^0-tagging method. Isolated photons are selected with less than 10% additional energy within a cone of radius $\Delta r = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} = 0.5$ around the candidate photon direction. The cone energy is the sum of track momenta in the drift chamber and EMCal energy. In most cases the cone is larger than the PHENIX acceptance, and this is corrected for with a 0.08 increase in the photon isolation fraction in the theory predictions below [22].

Figure 3 presents the results of the isolation cut for photons from the π^0-tagging method. Solid circles show the fraction of isolated direct photons to all direct photons.

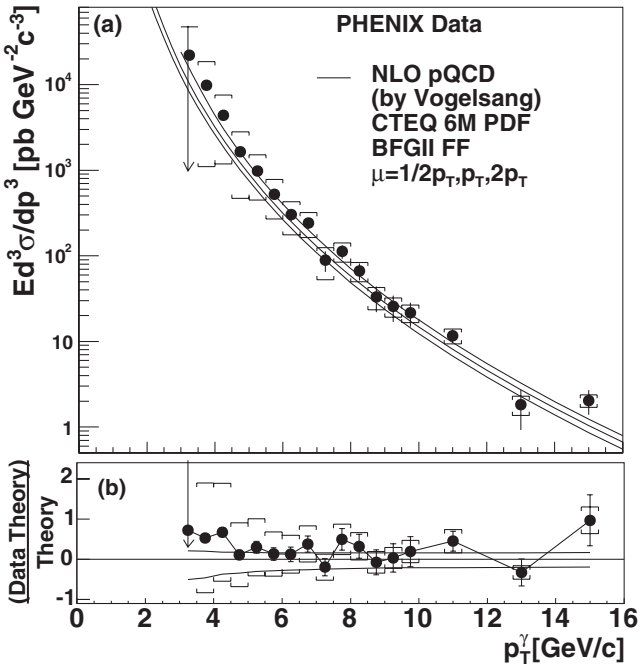

FIG. 2. (a) Direct-photon spectra with NLO pQCD calculations for three theory scales, μ. Brackets around data points show systematic errors. (b) Comparison to the NLO pQCD calculation for $\mu = p_T$, with upper and lower curves for $\mu = p_T/2$ and $2p_T$.

The curves are predictions from NLO pQCD, for the parton distribution and fragmentation functions as in Fig. 2, and for an additional parton to photon fragmentation function. The observed ratio is ~90% for $p_T^\gamma > 7$ GeV/c, and it is well described by pQCD. An additional loss of ~15%

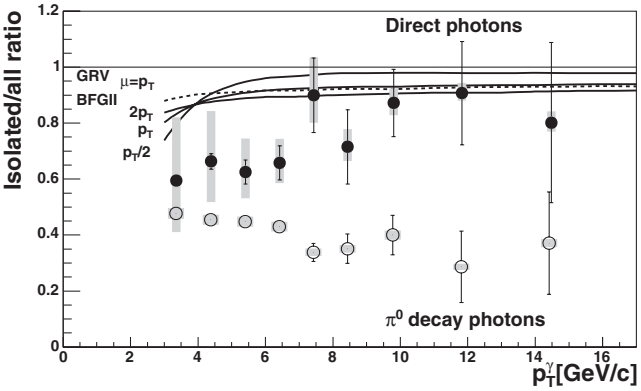

FIG. 3. Solid circles: Ratio of isolated direct photons to all direct photons from the π^0-tagging method. The statistical uncertainties are shown as black error bars and the systematic uncertainties are plotted as shaded bars. The solid and dashed curves are NLO pQCD calculations with three theory scales for BFGII [21] and one scale for GRV [25] parton to photon fragmentation functions. Open circles: Ratio of isolated photons from π^0 decays to all photons from π^0 decays.

($p_T^\gamma = 3$ GeV/c) to less than 5% (for $p_T^\gamma > 10$ GeV/c) due to the underlying event is estimated by a PYTHIA [23] simulation. Finally, for comparison, the open circles show the ratio of isolated photons from π^0 decays to all photons from π^0 decays. This indicates significantly less isolation than in the direct-photon sample.

In summary, invariant cross sections for direct-photon production at midrapidity have been measured up to $p_T = 16$ GeV/c in $\sqrt{s} = 200$ GeV $p + p$ collisions. The data are well described by NLO pQCD predictions for $p_T > 5$ GeV/c where the uncertainties of the measurement and theory are comparable. When these data are combined with fixed target and Tevatron collider data, these measurements demonstrate the robustness of the pQCD description of direct-photon production [24]. In addition, the ratio of isolated photons to all nonhadronic decay photons is well described by pQCD for $p_T > 7$ GeV/c.

Based on the comparison of high p_T direct-photon data from Au + Au collisions at RHIC with a $p + p$ reference from NLO pQCD, the origin of the observed suppression of high-p_T hadrons in central Au + Au collisions can be attributed to properties of the hot and dense matter created in the Au + Au collision [13]. The measurements presented here confirm this conclusion and put it on a firm experimental basis. Furthermore, the successful description of direct-photon production at RHIC is a necessary test for the extraction of the gluon polarization from direct-photon production in collisions of longitudinally polarized protons.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We thank Michel Fontannaz, Werner Vogelsang, and Monique Werlen for their interest and input. We acknowledge support from the Department of Energy and NSF (USA), MEXT and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), IN2P3/CNRS, CEA, and ARMINES (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE and DST (India), ISF (Israel), KRF and CHEP (Korea), RMIST, RAS, and RMAE (Russia), VR and KAW (Sweden), U.S. CRDF for the FSU, U.S.-Hungarian NSF-OTKA-MTA, and U.S.-Israel BSF.

(Received 6 September 2006; published 21 December 2006)

The momentum distribution of electrons from decays of heavy flavor (charm and bottom) for midrapidity $|y| < 0.35$ in $p + p$ collisions at $\sqrt{s} = 200$ GeV has been measured by the PHENIX experiment at the BNL Relativistic Heavy Ion Collider over the transverse momentum range $0.3 < p_T < 9$ GeV/c. Two independent methods have been used to determine the heavy-flavor yields, and the results are in good agreement with each other. A fixed-order-plus-next-to-leading-log perturbative QCD calculation agrees with the data within the theoretical and experimental uncertainties, with the data/theory ratio of $1.71 \pm 0.02^{\text{stat}} \pm 0.18^{\text{sys}}$ for $0.3 < p_T < 9$ GeV/c. The total charm production cross section at this energy has also been deduced to be $\sigma_{c\bar{c}} = 567 \pm 57^{\text{stat}} \pm 193^{\text{sys}}$ μb.

DOI: 10.1103/PhysRevLett.97.252002 PACS numbers: 13.85.Qk, 13.20.Fc, 13.20.He, 25.75.Dw

Heavy-flavor (charm and bottom) production serves as a testing ground of QCD. Because of the large quark mass, it is expected that next-to-leading order perturbative QCD (NLO pQCD) can describe the production cross section of charm and bottom at high energy, particularly at high p_T. At the Tevatron, bottom production is well described by NLO pQCD [1]. Charm production cross sections at high p_T are found to be higher than the theory by $\approx 50\%$, but are compatible within the theoretical uncertainties [2]. Since heavy-flavor production at Relativistic Heavy Ion Collider (RHIC) energies is dominated by gluon-gluon fusion, its production in polarized $p + p$ collisions probes the gluon distribution $G(x)$ and the gluon polarization $\Delta G(x)$. A good understanding of the reaction mechanism for heavy-flavor production is crucial for reliably extracting these distributions. Furthermore, in Au + Au collisions at RHIC strong suppression of single electrons from heavy-flavor decays has been observed [3]. Measurements of heavy-flavor production in $p + p$ collisions provide a baseline for studying hot and dense matter effects in heavy ion reactions. Earlier measurements at RHIC [4,5] have a limited p_T range with substantial experimental uncertainties, so an improved measurement is crucial.

We report the production cross section of electrons, $(e^+ + e^-)/2$, at midrapidity in $p + p$ collisions at $\sqrt{s} = 200$ GeV for $0.3 < p_T < 9$ GeV/c measured by the PHENIX experiment. Contributions from semileptonic decays of heavy flavor are determined using two independent methods. This measurement has over 2 orders of magnitude larger statistics with much reduced systematic uncertainties compared to our previous measurement [4].

The data were collected by the PHENIX detector [6] during the 2005 RHIC run using the two central arm spectrometers. Each spectrometer covers $|\eta| < 0.35$ in pseudorapidity and $\Delta\phi = \pi/2$ in azimuth. It includes a drift chamber (DC) and pad chambers (PC1) for charged particle tracking, a ring imaging Čerenkov detector (RICH) for electron identification, and an electromagnetic calorimeter (EMCal) for electron identification and trigger. Beam-beam counters (BBCs), positioned at pseudorapidities $3.1 < |\eta| < 3.9$, measure the position of the collision vertex along the beam (z_{vtx}) and provide the interaction trigger. In this run, helium bags, one for each arm, were placed in the space between the beam pipe and DC to reduce multiple scattering and photon conversion.

Two data sets are used for the analysis: (1) the minimum bias (MB) data set recorded by the BBC trigger, and (2) a "photon" trigger (PH) data set triggered at level-1 requiring a minimum energy deposit of 1.4 GeV in an overlapping tile of 4×4 EMCal towers in coincidence with the BBC trigger. The PH trigger has $\simeq 100\%$ efficiency for high p_T electrons above 2 GeV/c in the active trigger tiles. The BBC trigger cross section is 23.0 ± 2.2 mb. Since only $\simeq 50\%$ of inelastic $p + p$ collisions satisfy the BBC trigger condition, only a fraction of the inclusive electron production events is triggered. This p_T and process independent fraction is determined to be $\epsilon_{\text{bias}} = 0.79 \pm 0.02$ from the yield ratio of high p_T π^0's with and without the BBC trigger. After selection of good runs and a vertex cut of $|z_{\text{vtx}}| < 20$ cm, an integrated luminosity ($\mathcal{L}$) of 45 nb^{-1} in the MB data set and 1.57 pb^{-1} in the PH data set are used for the analysis.

Charged particle tracks are reconstructed using DC and PC1 and confirmed by a hit in the EMCal within 4σ in position. The momentum resolution is $\sigma_p/p \simeq 0.7\% \oplus 0.9\% p$ (GeV/c), and the momentum scale is calibrated within 1% using the reconstructed mass of $J/\psi \to e^+e^-$.

Electron identification (eID) requires at least two associated hits in the RICH, a shower shape cut in the EMCal, and a cut in the ratio E/p where E is energy measured in the EMCal. We require $0.7 < E/p < 1.3$ for $0.8 < p_T < 5$ GeV/c. For lower p_T, the minimum value of E/p decreases with decreasing p_T to 0.55 at $p_T = 0.3$ GeV/c. The E/p cut removes background electrons from photon conversions and semileptonic decay of kaons ($K \to e\nu\pi(K_{e3})$) that occur far from the vertex, and most of the remaining hadron background. The hadron contamination after the E/p cut is 3% at $p_T = 0.3$ GeV/c and less than 1% for $0.8 < p_T < 5$ GeV/c with eID efficiency of approximately 90%.

For $p_T > 5$ GeV/c, where pions also emit Čerenkov photons in the RICH, tighter electron identification cuts are applied. We require at least 5 associated hits in the RICH, a tighter shower shape cut in the EMCal, and $0.8 < E/p < 1.3$. With these cuts, the electron measurement is extended to 9 GeV/c in p_T. The eID efficiency of the

tighter cuts is p_T independent, and is determined to be 57% of that for $p_T < 5$ GeV/c by applying the same tighter cuts for $p_T < 5$ GeV/c. With the tighter cuts, hadron contamination is negligible for $p_T < 7$ GeV/c. For $7 < p_T < 8 (8 < p_T < 9)$ GeV/c, a 20% (40%) hadron contamination is determined and subtracted using a Gaussian plus exponential fit to E/p distribution.

The invariant cross section for electron production is calculated using the following formula,

$$E\frac{d^3\sigma}{dp^3} = \frac{1}{\mathcal{L}}\frac{1}{2\pi p_T}\frac{N_e}{\Delta p_T \Delta y}\frac{1}{\epsilon_{\rm rec}}\frac{1}{\epsilon_{\rm bias}}, \quad (1)$$

where N_e is the measured electron yield; $\epsilon_{\rm rec}$, calculated using a full GEANT [7] simulation, includes the geometrical acceptance, track reconstruction and eID efficiency, and the smearing effect due to finite momentum resolution. For the PH data set, $\epsilon_{\rm rec}$ also includes the PH trigger efficiency. The cross sections from the MB and the PH data sets are consistent with each other for the overlapped p_T region.

The inclusive electron yield consists of three components: (1) electrons from heavy-flavor decay, (2) "photonic" background electrons from Dalitz decays of light mesons and photon conversions primarily in the beam pipe, and (3) "nonphotonic" background electrons from the remaining K_{e3} decays and dielectron decays of vector mesons. The photonic background is much larger than the nonphotonic background. We determined the spectrum of electrons from heavy-flavor decay by subtracting the background components from the inclusive spectrum using the following two independent methods.

In the "cocktail subtraction" method [3,4,8] a cocktail of electron spectra from various background sources is calculated using a Monte Carlo event generator of hadron decays. The most important background is the π^0 Dalitz decay, so we use our measured π^0 and $\pi^\pm$ spectra as input to the generator. The spectral shapes of other light hadrons h are obtained from the pion spectra by m_T scaling ($p_T \rightarrow \sqrt{p_T^2 + M_h^2 - M_\pi^2}$). Within this approach the ratios h/π^0 are constant at high p_T. For the relative normalization, we use the following ratios: $\eta/\pi^0 = 0.48 \pm 0.03$ [9], $\rho^0/\pi^0 = 1.0 \pm 0.3$, $\omega/\pi^0 = 0.90 \pm 0.06$ [10], $\eta'/\pi^0 = 0.40 \pm 0.12$, $\phi/\pi^0 = 0.25 \pm 0.08$. For $p_T > 2$ GeV/c, contributions from η and all other hadrons combined are approximately 20% and 10% of π^0, respectively. Another major background electron source is conversions of photons in the beam pipe [0.29% of a radiation length (X_0)] as well as in the air and the helium bags (0.1% X_0). The conversion electron spectrum is very similar to that of Dalitz decays. Using a detailed GEANT simulation of the PHENIX detector, the ratio of electrons from conversions to Dalitz decays, $R_{\rm CD}$, is determined to be 0.40 ± 0.04 for π^0, essentially p_T independent. $R_{\rm CD}$ is approximately half of that in [4] since the helium bags eliminated most of the conversions outside of the beam pipe. The conversion spectra are calculated by scaling the Dalitz decay spectra by $R_{\rm CD}$, with small corrections to account for the species dependence of the relative branching ratio of Dalitz decay to photon decay [$(h \rightarrow ee\gamma)/(h \rightarrow \gamma\gamma)$]. The internal and external conversions of direct photons are also included in the cocktail, using our measured direct photon spectrum [11] as input. The direct photon contribution is comparable to or greater than that from the η for $p_T > 5$ GeV/c. Nonphotonic backgrounds are also included in the cocktail. Since the K_{e3} background depends on the analysis cuts, it is evaluated by a full GEANT simulation.

In the "converter subtraction" method [12], we introduce an additional photon converter (a thin brass sheet of 1.67% X_0) around the beam pipe for part of the run. The converter multiplies the photonic electron background by a fixed factor, $R_\gamma \simeq 2.3$, which is determined precisely via GEANT simulation. R_γ is larger than in [12] since we have less conversion material in the 2005 run. The photonic background N_e^γ is determined as $N_e^\gamma = [N_e^C - (1-\epsilon)N_e^{\rm NC}]/(R_\gamma - 1 + \epsilon)$, where N_e^C and $N_e^{\rm NC}$ are electron yield with and without the converter, respectively, and ϵ (2.1%) represents a small loss of electrons due to the converter. The nonphotonic component is then determined as $N_e^{\rm non\text{-}\gamma} = N_e^{\rm NC} - N_e^\gamma$. Small remaining nonphotonic backgrounds, such as K_{e3} and hadron contamination, are subtracted.

These two methods are complementary to each other. The converter method is more accurate, and it allows us to extract a heavy-flavor signal down to $p_T = 0.3$ GeV/c where the signal is only $\approx 10\%$ of inclusive electrons. In addition, the measured photonic background N_e^γ is used to confirm and to calibrate the normalization of the calculated cocktail yields. A drawback of the method is statistical precision: the converter run contains only a small fraction ($\simeq$7% in the 2005 run) of the data. The cocktail method can use the full statistics at high p_T, where the photonic background becomes a small fraction of inclusive electrons.

Systematic uncertainties are categorized into (a) inclusive electron spectra, (b) cocktail subtraction, and (c) converter subtraction. Category (a) is common to both analyses, and includes the uncertainties in luminosity (9.6%), geometrical acceptance (4%), eID efficiency (3%), and the PH trigger efficiency (3% at the plateau). Uncertainties in cocktail subtraction [category (b)] include the normalization (8%) and p_T dependent shape uncertainty (2% at $p_T \simeq 2$ GeV/c, increasing to 6% at 9 GeV/c). In the converter analysis [category (c)] the dominant uncertainties are in R_γ (2.7%) and in the relative acceptance in the converter and the normal runs (1.0%). These uncertainties are propagated into the uncertainties in the heavy-flavor electron yields and added in quadrature.

Figure 1 shows the ratio of the measured N_e^γ to the cocktail calculation as a function of p_T. The ratio is consistent with unity within the uncertainties of the cocktail. At high p_T (>1.8 GeV/c), the ratio is $0.94 \pm 0.02^{\rm stat}$ on average. Since this is within the uncertainty of the cocktail

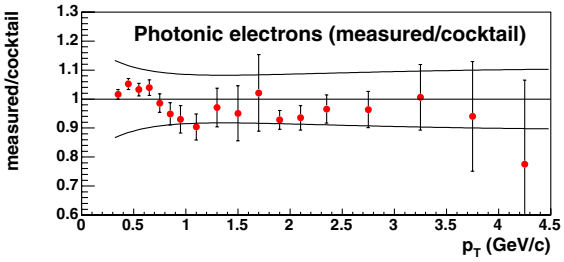

FIG. 1 (color online). Ratio of photonic electrons measured by the converter method to the cocktail calculation. Data from the MB (PH) data set are shown below (above) 1.8 GeV/c. The upper and lower curves show the systematic error of the cocktail. Error bars are statistical only.

normalization, we rescale the cocktail yields by this factor. This removes the 8% normalization uncertainty in the cocktail.

In Fig. 2, filled circles (squares) show the ratio of nonphotonic electrons relative to photonic background determined by the converter (cocktail) method. The nonphotonic electrons are dominantly heavy-flavor decay signals. The remaining nonphotonic background contributions have been calculated and are shown in Fig. 2. The two methods are consistent with each other. The ratio monotonically increases with increasing p_T, becoming greater than unity for $p_T > 2.4$ GeV/c, and saturates at $\simeq 3$ for $p_T > 5$ GeV/c. The large signal-to-background ratio is due to the small amount of conversion material in the spectrometer acceptance.

Figure 3(a) shows the invariant differential cross section of electrons from heavy-flavor decays. All background has been subtracted, including the nonphotonic components shown in Fig. 2. The data from the two analysis methods

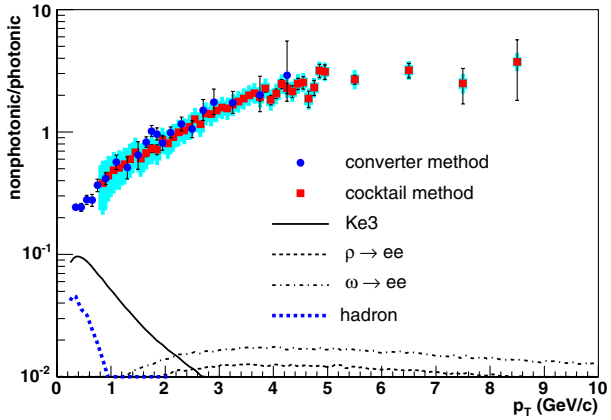

FIG. 2 (color online). Ratio of nonphotonic electrons to photonic background. Error bars are statistical errors and the error bands show the cocktail systematic errors. The solid, dashed, dot-dashed, and dot curve are the remaining nonphotonic backgrounds from K_{e3}, $\rho \rightarrow ee$, $\omega \rightarrow ee$, and hadron contamination, respectively.

are combined: at low p_T ($p_T < 1.6$ GeV/c) the converter subtraction method on the MB data set is used; at intermediate p_T ($1.6 < p_T < 2.6$ GeV/c) the converter method on the PH data set is used; and at high p_T ($p_T > 2.6$ GeV/c) the cocktail method on the PH data set is used.

The data are compared with a fixed-order-plus-next-to-leading-log (FONLL) pQCD calculation [13,14]. The top curve in Fig. 3 shows the central values of the FONLL calculation. The contributions of charm and bottom are also shown. For $p_T > 4$ GeV/c, the bottom contribution becomes dominant. In Fig. 3(b), the ratio of the data to the FONLL calculation is shown. The ratio is nearly p_T independent over the entire p_T range. Fitting to a constant for $0.3 < p_T < 9.0$ GeV/c yields a ratio of $1.71 \pm 0.02^{\text{stat}} \pm 0.18^{\text{sys}}$. Similar ratios are observed in charm production at high p_T at the Tevatron [2]. The upper limit of the FONLL calculation is compatible with the data. Recently STAR also reported nonphotonic electron production in $p + p$ at $\sqrt{s} = 200$ GeV [15].

The total charm cross section is derived by integrating the heavy-flavor electron cross section for $p_T > 0.4$ GeV/c: $d\sigma_e(p_T > 0.4)/dy = 5.95 \pm 0.59^{\text{stat}} \pm 2.0^{\text{sys}}$ μb. The systematic error is obtained by integrating the upper and lower systematic error limits of the differential cross sections, since the systematic errors are essentially coherent. The cross section is then extrapolated to

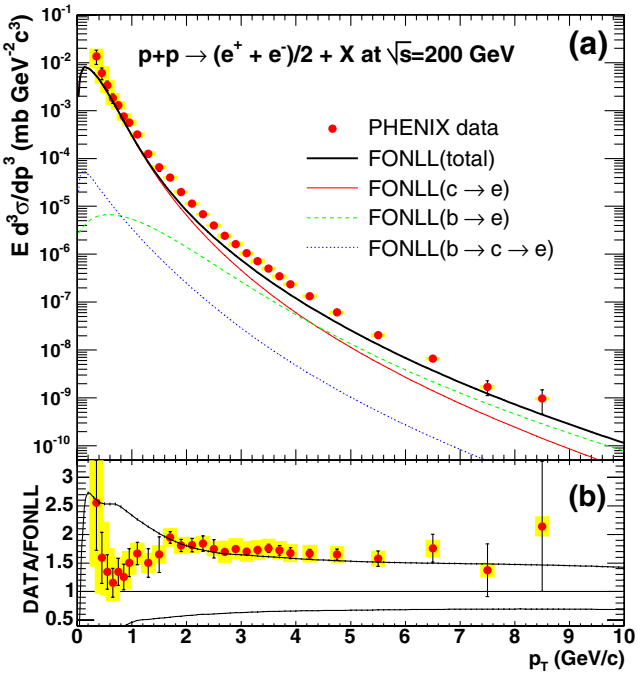

FIG. 3 (color online). (a) Invariant differential cross sections of electrons from heavy-flavor decays. The error bars (bands) represent the statistical (systematic) errors. The curves are the FONLL calculations (see text). (b) Ratio of the data and the FONLL calculation. The upper (lower) curve shows the theoretical upper (lower) limit of the FONLL calculation. In both panels a 10% normalization uncertainty is not shown.

$p_T = 0$ using the spectrum shape predicted by FONLL: $d\sigma_e(p_T > 0)/dy = 10.9 \pm 1.1^{\text{stat}} \pm 3.1^{\text{sys}}$ μb. We have assigned 10% to the systematic uncertainty of the extrapolation, and have subtracted contribution from bottom and bottom cascade decays (0.1 μb). We determine the charm production cross section, $d\sigma_{c\bar{c}}/dy = 123 \pm 12^{\text{stat}} \pm 37^{\text{sys}}$ μb, by using a $c \rightarrow e$ total branching ratio of $9.5 \pm 1.0\%$, calculated using the following charmed hadron ratios: $D^+/D^0 = 0.45 \pm 0.1$, $D_s/D^0 = 0.25 \pm 0.1$, and $\Lambda_c/D^0 = 0.1 \pm 0.05$. The rapidity distribution of electrons is broader than that of D mesons due to decay kinematics. A correction to this effect (7%) has been applied. Using the rapidity distribution from HVQMNR [16] with CTEQ5M [17] PDF, the total charm cross section is determined to be $\sigma_{c\bar{c}} = 567 \pm 57^{\text{stat}} \pm 193^{\text{sys}}$ μb. We have assigned 15% systematic error to the extrapolation. This result is compatible with our previous measurement [4] ($920 \pm 150^{\text{stat}} \pm 540^{\text{sys}}$ μb) and the value derived from Au + Au collisions [12] ($622 \pm 57^{\text{stat}} \pm 160^{\text{sys}}$ μb per NN collision). The FONLL cross section (256^{+400}_{-146} μb) is compatible with the data within its uncertainty. STAR has reported a somewhat larger value in d + Au [5] ($1.3 \pm 0.2^{\text{stat}} \pm 0.4^{\text{sys}}$ mb per NN collisions). Although the data extend to high p_T where the bottom contribution is expected to be dominant, the present analysis does not separate charm and bottom contributions. The bottom cross section predicted by FONLL is $1.87^{+0.99}_{-0.67}$ μb, and the upper FONLL curve is consistent with the data.

In conclusion, we have measured single electrons from heavy-flavor decays in $p + p$ collisions at $\sqrt{s} = 200$ GeV. The new data reported here provide a crucial baseline for the study of heavy quark production in hot and dense matter created in Au + Au collisions. The agreement between the data and the FONLL pQCD calculation within the theoretical and the experimental uncertainties suggests that a reliable extraction of gluon polarization from heavy-flavor production in polarized $p + p$ collisions is attainable.

(Received 16 August 2006; published 16 April 2007)

Differential measurements of elliptic flow (v_2) for Au + Au and Cu + Cu collisions at $\sqrt{s_{\mathrm{NN}}} = 200$ GeV are used to test and validate predictions from perfect fluid hydrodynamics for scaling of v_2 with eccentricity, system size, and transverse kinetic energy (KE_T). For $\mathrm{KE}_T \equiv m_T - m$ up to ~1 GeV the scaling is compatible with hydrodynamic expansion of a thermalized fluid. For large values of KE_T mesons and baryons scale separately. Quark number scaling reveals a universal scaling of v_2 for both mesons and baryons over the full KE_T range for Au + Au. For Au + Au and Cu + Cu the scaling is more pronounced in terms of KE_T, rather than transverse momentum.

DOI: 10.1103/PhysRevLett.98.162301 PACS numbers: 25.75.Dw

Quantum chromodynamics calculations performed on the lattice indicate a transition from a low-temperature phase of nuclear matter, dominated by hadrons, into a high-temperature plasma phase of quarks and gluons (QGP) [1]. For matter with zero net baryon density, this phase transition has been predicted to occur at an energy density of ~1 GeV/fm^3 or for a critical temperature $T_c \sim 170$ MeV [2]. Recent estimates from transverse energy (E_T) measurements at the relativistic heavy ion collider (RHIC) have indicated energy densities of at least 5.4 GeV/fm^3 in central Au + Au collisions [3]. Thus, an important prerequisite for QGP production is readily fulfilled at RHIC. Indeed, there is much evidence that thermalized nuclear matter has been created at unprecedented energy densities in collisions at RHIC [3–10].

Hydrodynamics provides a link between the fundamental properties of this matter (its equation of state (EOS) and transport coefficients) and the flow patterns evidenced in the measured hadron spectra and azimuthal anisotropy [11–15]. Experimentally, such a momentum anisotropy is commonly characterized at midrapidity, by the even order Fourier coefficients [16,17], $v_n = \langle e^{in(\phi_p - \Phi_{\mathrm{RP}})} \rangle$, $n = 2, 4, \ldots$, where ϕ_p is the azimuthal emission angle of a particle, Φ_{RP} is the azimuth of the reaction plane, and the brackets denote statistical averaging over particles and events.

At low transverse momentum ($p_T \lesssim 2.0$ GeV/c) the magnitude and trends of elliptic flow, measured by the second Fourier coefficient v_2, is found to be underpredicted by a hadronic cascade model [18]. By contrast, a broad selection of the data showed good quantitative agreement with perfect fluid (very low ratio of viscosity to entropy) hydrodynamics [9,10,12,15] and a transport model calculation which incorporates extremely large opacities [19]. For higher p_T, quark coalescence from a thermalized state of flowing partonic matter [20–22] has been found to be consistent with the data [23,24]. These results provide evidence for the production of a strongly interacting QGP whose subsequent evolution is similar to that of a "perfect" fluid [7–10].

Systematic theoretical and experimental studies of the influence of model parameters are now required to gain more quantitative insight on the transport coefficients and the EOS for this strongly interacting matter. The range of validity of perfect fluid hydrodynamics is affected by the degree of thermalization [25] and the onset of dissipative effects [25–27]. These questions can be addressed by investigating several scaling predictions of perfect fluid hydrodynamics [15,25,28–30].

In the hydrodynamic model, elliptic flow can result from pressure gradients due to the initial spatial asymmetry or eccentricity $\epsilon = (\langle y^2 - x^2 \rangle)/(\langle y^2 + x^2 \rangle)$, of the high energy density matter in the collision zone. The initial entropy density $S(x, y)$, can be used to average over the x and y coordinates in the plane perpendicular to the collision axis, where x points along the impact vector and y is orthogonal. For a system of transverse size $\bar{R}$ ($1/\bar{R} = \sqrt{1/\langle x^2 \rangle + 1/\langle y^2 \rangle}$), this flow develops over a time scale $\sim \bar{R}/\langle c_s \rangle$, where c_s is the speed of sound. Thus, the initial energy density controls how much flow develops globally, while the detailed development of the flow patterns are largely controlled by ϵ and c_s.

An important prediction of perfect fluid hydrodynamics is that the relatively "complicated" dependence of azimuthal anisotropy on centrality, transverse momentum, rapidity, particle type, higher harmonics, etc., can be scaled to a single function [15,31]. Immediate consequences of this [15,25,28,31] are that: (i) v_2 scaling should hold for a broad range of impact parameters for which the eccentricity varies, i.e., $v_2(p_T)/\epsilon$ should be independent of centrality; (ii) $v_2(p_T)$ should be independent of colliding system size for a given eccentricity; and (iii) for different particle species, $v_2(\mathrm{KE}_T)$ at midrapidity should scale with the

transverse kinetic energy $KE_T = m_T - m$ [15], where m_T is the transverse mass.

We use high statistics v_2 data to test these scaling predictions and explore constraints for the range of validity of perfect fluid hydrodynamics. The measurements were made at $\sqrt{s_{NN}} = 200$ GeV with the PHENIX detector [32] at RHIC. Approximately 6.5×10^8 Au + Au and 8.0×10^7 Cu + Cu minimum-bias collisions were analyzed from the 2004 and 2005 running periods, respectively. The collision vertex z, along the beam direction was constrained to be within $|z| < 30$ cm. The event centrality for Au + Au collisions was determined via cuts in the space of beam-beam counter (BBC) versus zero degree calorimeter analog response [33]. For Cu + Cu only the amplitude of the BBC analog response was used. Charged hadrons were detected in the two central arms ($|\eta| \leq 0.35$). Track reconstruction used the drift chambers and two layers of multiwire proportional chambers with pad readout (PC1 and PC3) located at radii of 2m, 2.5, and 5 m, respectively [32].

The time-of-flight (TOF) detector positioned at a radial distance of 5.06 m, was used to identify pions ($\pi^{\pm}$), kaons ($K^{\pm}$), and (anti)protons ($\bar{p}$)p. The BBCs and TOF scintillators provided the global start and stop signals. These measurements were used in conjunction with the measured momentum and flight-path length to generate a mass-squared distribution [34]. A momentum dependent $\pm 2\sigma$ cut about each peak in this distribution was used to identify $\pi^{\pm}$, $K^{\pm}$ and ($\bar{p}$)p in the range $0.2 < p_T < 2.5$ GeV/c, $0.2 < p_T < 2.5$ GeV/c, and $0.5 < p_T < 4.5$ GeV/c, respectively. A track confirmation hit within a 2.5σ matching window in PC3/TOF served to eliminate most albedo, conversions, and resonance decays.

The differential elliptic flow measurements for charged hadrons and identified particles were obtained with the reaction plane method. This technique correlates the azimuthal angles of charged tracks with the azimuth of the event plane Φ_2, determined via hits in the two BBCs positioned symmetrically along the beam line, covering the pseudorapidity range $3 < |\eta| < 3.9$ [23]. A large η gap between the central arms and the particles used for reaction plane determination reduces the influence of possible nonflow contributions, especially those from dijets [35]. Values of v_2 were calculated via the expression $v_2 = \langle \cos[2(\phi_p - \Phi_2)] \rangle / \langle \cos[2(\Phi_2 - \Phi_{RP})] \rangle$, where the denominator is a resolution factor that corrects for the difference between the estimated Φ_2 and the true azimuth Φ_{RP} of the reaction plane [23,36]. The estimated resolution factor of the combined reaction plane from both BBCs [23] has an average of 0.33 (0.16) over centrality with a maximum of about 0.42 (0.19) for Au + Au (Cu + Cu). The estimated correction factor for the v_2 measurements (i.e., the inverse of the resolution factor) ranges from 2.4 (5.5) to 5.0 (13), for which relative systematic errors are estimated to be ~5% and ~10% for Au + Au and Cu + Cu, respectively.

Figure 1 shows the differential $v_2(p_T)$ for charged hadrons obtained in Au + Au and Cu + Cu collisions. The $v_2(p_T)$ results exhibit the familiar increase as collisions become more peripheral and the p_T increase [3–5]. We test these data for eccentricity scaling by dividing the differential values shown in Fig. 1 by the v_2 integrated over the p_T range 0.3–2.5 GeV/c for each of the indicated centrality selections. The hydrodynamic model predicts that this ratio is constant with centrality and independent of colliding system because ϵ is proportional to the p_T-integrated v_2 values (i.e., $\epsilon = k \times v_2$). The latter proportionality has been observed for Au + Au collisions [37,38]. A Glauber model estimate of ϵ [38] gives $k = 3.1 \pm 0.2$ for the cuts employed in this analysis. This method of scaling leads to a scale invariant variable and cancels the systematic errors associated with estimates of the reaction plane resolution and the eccentricity. It contrasts the methodologies of Refs. [39,40] which calculate ϵ directly for different model assumptions.

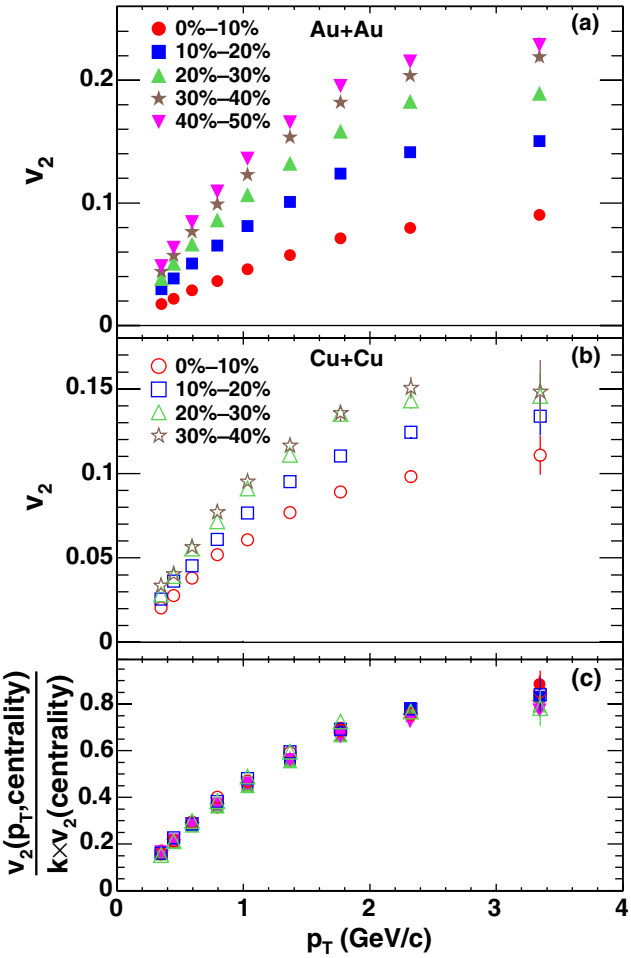

FIG. 1 (color online). v_2 vs p_T for charged hadrons obtained in (a) Au + Au and (b) Cu + Cu collisions for the centralities indicated. (c) v_2(centrality, p_T) divided by $k = 3.1$ (see text) times the p_T-integrated value v_2(centrality) for Au + Au and Cu + Cu.

The resulting scaled $v_2(p_T)$ values for Cu + Cu and Au + Au collisions, are shown in Fig. 1(c). To facilitate later comparisons with the model calculations of Ref. [25], they are divided by $k = 3.1$. These scaled values are clearly independent of the colliding system size and show essentially perfect scaling for the full range of centralities (or ϵ) and p_T selections presented [41]. The scaled v_2 are also in accord with the scale invariance of perfect fluid hydrodynamics [25,29], which suggests that rapid local thermalization [9,10] is achieved. It is noteworthy that similarly robust scaling for the p_T-integrated v_2 is not observed [39,40]. This is probably due to methodological differences in the evaluation of ϵ.

The magnitude of v_2/ϵ depends on c_s [25]. As a reasonable first approximation we compare our measured v_2/ϵ at an integrated $\langle p_T \rangle = 0.45$ GeV/c and the results of Fig. 2 of [25] to obtain $c_s \sim 0.35 \pm 0.05$. Note that this $\langle p_T \rangle$ value accounts for p_T threshold differences and the calculations are done at fixed $b = 8$ fm and constant c_s. Thus, since we expect the speed of sound to vary as a function of time, one might view this c_s value as the approximate average value over the time period $2\,\bar{R}/c_s$, the time over which the flow develops. This value suggests an effective EOS, which is softer than that for the high-temperature QGP [42], but does not reflect a very strong first order phase transition in which matter-flow is significantly slowed or stalled.

Figures 2 and 3 show that the distinctive features of the v_2 for identified particles provide another detailed set of scaling tests. Figure 2(a) shows a comparison of the measured differential anisotropy $v_2(p_T)$, for several particle species obtained in minimum-bias Au + Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV. The results are in good agreement (better than 3%) with those of our previous measurements [23]. The values for neutral kaons (K^0_s), lambdas (Λ), and the cascades (Ξ) show results from the STAR Collaboration [24,43]. The STAR v_2 values were multiplied by the factor 1.1 to account for a small difference between the average centralities for minimum-bias events from the two experiments. PHENIX and STAR $v_2(p_T)$ results [for $\pi^{\pm}$, $p(\bar{p})$ and K] for 10% centrality bins are essentially identical.

The comparison in Fig. 2(a) shows the well-known particle identification (PID) ordering of $v_2(p_T)$ at both low and high p_T values. At low p_T ($p_T \lesssim 2$ GeV/c), one can see rather clear evidence for mass ordering. If this aspect of v_2 is driven by a hydrodynamic pressure gradient, the prediction is that the differential v_2 values observed for each particle species should scale with KE_T. The pressure gradient that drives elliptic flow is directly linked to the collective kinetic energy of the emitted particles. For higher values of p_T ($p_T \sim 2$–4 GeV/c), Fig. 2(a) indicates that mass ordering is broken and v_2 is more strongly dependent on the quark composition of the particles than on their mass, which has been attributed to the dominance of the quark coalescence mechanism for $p_T \sim 2-4$ GeV/c [22–24].

Figure 2(b) shows the same v_2 data presented in Fig. 2(a) plotted as a function of KE_T. Note that KE_T is a robust scaling variable because it takes into account relativistic effects, which are especially important for the lightest particles. In contrast to the PID ordering observed in Fig. 2(a), all particle species scale to a common set of elliptic flow values for $\mathrm{KE}_T \lesssim 1$ GeV, confirming the strong influence of hydrodynamic pressure gradients. For $\mathrm{KE}_T \gtrsim 1$ GeV, this particle mass scaling (observed for all particle species) gives way to a clear splitting into a meson branch (lower v_2) and a baryon branch (higher v_2). Since both of these branches show rather good scaling separately, we interpret this as an initial hint for the degrees of freedom in the flowing matter at an early stage.

Figure 3 shows the results obtained after quark number scaling of the v_2 values shown in Fig. 2. That is, v_2, p_T, and KE_T are divided by the number of constituent quarks n_q for

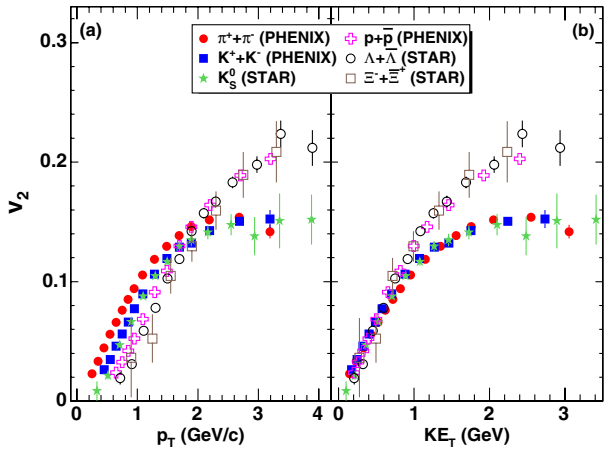

FIG. 2 (color online). (a) v_2 vs p_T and (b) v_2 vs KE_T for identified particle species obtained in minimum-bias Au + Au collisions. The STAR data are from Refs. [24,43].

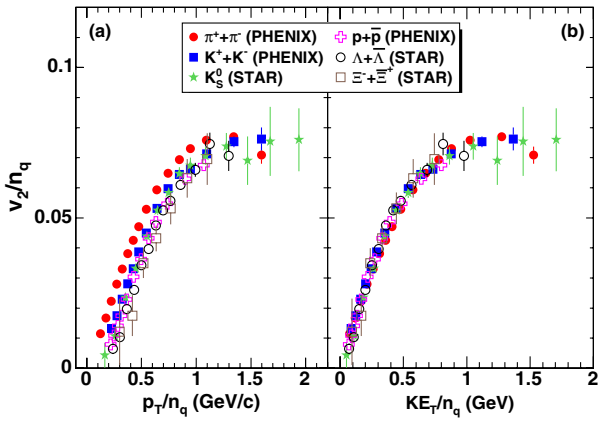

FIG. 3 (color online). (a) v_2/n_q vs p_T/n_q and (b) v_2/n_q vs KE_T/n_q for identified particle species obtained in minimum-bias Au + Au collisions. The STAR data are from Refs. [24,43].

mesons ($n_q = 2$) and baryons ($n_q = 3$). Figure 3(a) indicates rather poor scaling for $p_T/n_q \lesssim 1$ GeV/c and much better scaling for $p_T/n_q \gtrsim 1.3$ GeV/c, albeit with large error bars. The relatively large scaling violation observed for pions indicate that this particle species does not fit the simple quark coalescence picture of Refs. [22–24]. In contrast, Fig. 3(b) shows excellent scaling over the full range of KE_T/n_q values. We interpret this as an indication of the inherent quarklike degrees of freedom in the flowing matter. These degrees of freedom are gradually revealed as KE_T increases above ~1 GeV [cf. Fig. 2(b)] and are apparently hidden by the strong hydrodynamic mass scaling, which predominates at low KE_T. The fact that v_2/n_q shows such good scaling over the entire range of KE_T/n_q and does not for p_T/n_q, serves to highlight the fact that hydrodynamic mass scaling is preserved over the domain of the linear increase in KE_T. Figure 3(b) should serve to distinguish between different quark coalescence models.

In summary, we have presented the results from detailed tests of hydrodynamic scaling of azimuthal anisotropy in Au + Au and Cu + Cu collisions at $\sqrt{s_{\mathrm{NN}}} = 200$ GeV. For a broad range of centralities, eccentricity scaling is observed for charged hadrons for both the Cu + Cu and Au + Au systems. For a given eccentricity, v_2 is also found to be independent of colliding system size. The observed scaling for identified particles in Au + Au collisions, coupled with ϵ scaling, gives strong evidence for hydrodynamic scaling of v_2 over a broad selection of the elliptic flow data. For $\mathrm{KE}_T \sim 1$–4 GeV universal hydrodynamic scaling is violated, but baryons and mesons are found to scale separately. Quark number scaling (v_2/n_q vs KE_T/n_q) in this domain leads to comprehensive overall scaling of the data, with substantially better scaling behavior than that found for v_2/n_q vs p_T/n_q. The scaling with valence quark number may indicate a requirement of a minimum number of objects in a localized space that contain the prerequisite quantum numbers of the hadron to be formed. Whether the scaling further indicates these degrees of freedom are present at the earliest time is in need of more detailed theoretical investigation.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. Abstract. The effect of the final state Coulomb interaction on particles produced in Pb + Pb collisions at 158 AGeV/c has been investigated in the WA98 experiment through the study of the π^-/π^+ and K^-/K^+ ratios measured as a function of $m_{\rm T} - m_0$. While the ratio for kaons shows no significant $m_{\rm T}$ dependence, the π^-/π^+ ratio is enhanced at small $m_{\rm T} - m_0$ values with an enhancement that increases with centrality. A silicon pad detector located near the target is used to estimate the contribution of hyperon decays to the π^-/π^+ ratio. The comparison of results with predictions of the RQMD model in which the Coulomb interaction has been incorporated allows to place constraints on the time of the pion freeze-out.

1 Introduction

The distributions of negatively and positively charged pions produced in heavy ion collisions exhibit significant differences at low transverse kinetic energy (or transverse mass), $m_{\rm T} - m_\pi = \sqrt{p_{\rm T}^2 + m_\pi^2} - m_\pi$. These differences are evident in the behaviour of the ratio of their yields $R_\pi = \pi^-/\pi^+$. The study of charged particle production in Au + Au collisions at SIS (1 AGeV) [1] and AGS (10.8 AGeV) [2–4] shows that for central collisions R_π rises at low $m_{\rm T}$ at both collision energies. At the same time, for peripheral collisions at the AGS, R_π does not depend on $m_{\rm T}$. At 1 AGeV R_π is about 2.9 for $m_{\rm T} - m_\pi$ near zero and its integrated value is $R_\pi = 1.9 \pm 0.1$. The large integrated value at 1 AGeV can be explained by isobar decays and reflects the N/Z asymmetry of the colliding system. The very sharp rise at low $m_{\rm T}$ on the other hand points toward significant Coulomb interactions between charged pions and the remaining nuclear charge distribution (acceleration of π^+ and deceleration of π^-). At 10.8 AGeV and higher energy the isobar contribution to R_π becomes insignificant and it is expected that mainly the Coulomb interaction distorts the R_π ratio. The NA44 experiment has published data on R_π measured in central Pb + Pb collisions at 158 AGeV [5]. A prominent enhancement of R_π at small $m_{\rm T}$ was observed. NA44 has also measured R_π in S + S and S + Pb collisions at 200 AGeV/c, where the ratio remains constant at $m_{\rm T} - m_\pi < 0.5\,{\rm GeV}/c^2$ [5]. At high energies (AGS and SPS) the contribution from strange particle decay can significantly affect the measured pion distribution. The hyperon contribution is influenced by the detector acceptance and the pion vertex reconstruction properties. The excess of hyperon over anti-hyperon yield in heavy ion collisions also leads to an enhancement of R_π at low transverse kinetic energy.

Several dedicated models [6–11] describe the pion ratio detected by the NA44 collaboration in Pb + Pb collisions through the electromagnetic interaction induced by the large amount of charge of the participating protons. The authors of the dynamical model of [6] argue that the R_π enhancement at small momenta depends mainly on the time of freeze-out and extract a freeze-out time of about 7 fm/c. They also predict the corresponding ratio for kaons, $R_K = K^-/K^+$, to be smaller by a factor of m_K/m_π. However, this overestimates the NA44 kaon measurement. This discrepancy is explained as due to the much larger absorption of K^- on nucleons ($K^- + N \to \Lambda + \pi$) than for K^+. For a detector located at mid-rapidity this model predicts a small reduction of the R_π enhancement with respect to the NA44 result measured near rapidity $y_{\rm CMS} = 1$ in the center of mass system. On the other hand, in another model [11] the enhancement of the ratio strongly increases towards mid-rapidity, reaching the value of 2.5. In [9] it is concluded that the influence of the Coulomb force should be computed within an event simulator which takes into account a more accurate description of the space-time evolution of the collision.

Initial results from the SPS experiment WA98 on the measurement of the π^-/π^+ ratio in central Pb + Pb collisions were reported in [12]. The enhancement of R_π at $m_{\rm T} - m_\pi < 50\,{\rm MeV}/c^2$ measured with the two independent tracking arms of WA98 located nearer to mid-rapidity than the NA44 spectrometer was reported to be significantly smaller than that measured by NA44 [5].

In this paper we present the π^-/π^+ ratio as a function of centrality for 158 AGeV/c Pb + Pb collisions. The background pion contribution from hyperon decays is determined and removed by use of vertex information from a silicon detector located near to the target to obtain the ratio of pions that originate in the target. The yields of electrons and positrons are analysed at low momentum where they can be clearly identified through time-of-flight. Their yields provide a check of the normalization of the opposite sign yields at the lowest transverse momenta. They also confirm the validity of estimates of the electron and positron contaminations to the measured pion distributions at higher momenta. The K^-/K^+ratio is also presented for central collisions. The results are compared with predictions of the RQMD 2.4 model [13] in which final state Coulomb interactions have been added. Within the uncertainties of the hyperon decay contribution the results are found to be compatible with predictions of the RQMD model in which the average pion freeze-out time is 15 fm/c for central collisions. Possible modifications of the final state predicted by RQMD, necessary to improve agreement with the measured π^-/π^+ ratios, are investigated and discussed.

2 Experimental setup and data analysis

The CERN SPS experiment WA98 [14] combined photon and hadron spectrometers with other large acceptance detectors that measured a number of global variables on an event-by-event basis. Figure 1 shows the experimental layout during the 158 AGeV ^{208}Pb beam run period in 1996 with a 0.239 g/cm^2 Pb target.

The Mid-Rapidity Calorimeter, MIRAC [15], measured the collision transverse energy ($E_{\rm T}$) in the pseudorapidity

[a] awes@mail.phy.ornl.gov

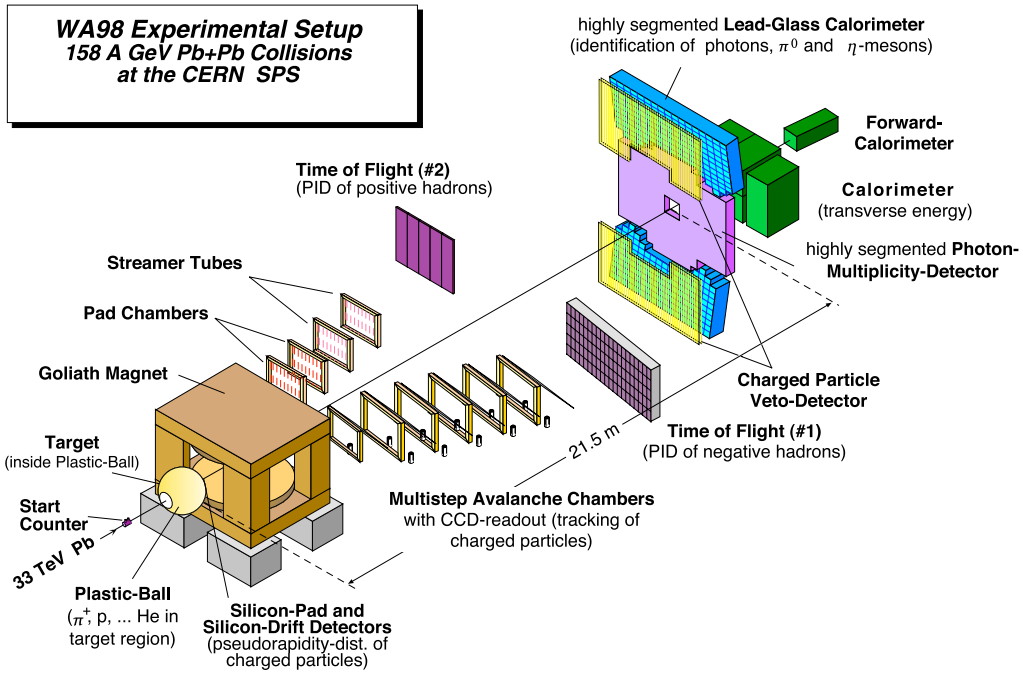

Fig. 1. The WA98 experimental setup

interval $3.5 < \eta < 5.5$. The minimum bias trigger required $E_{\mathrm{T}} \gtrsim 5$ GeV and a valid signal from the beam counters. The measured $\mathrm{d}\sigma/\mathrm{d}E_{\mathrm{T}}$ distribution is used for the calculation of the collision centrality. The minimum bias cross section for the run period used in this analysis is $\sigma_{\mathrm{mb}} = 6451$ mb with an overall systematic error of less than 10%.

Two thin circular silicon wafer detectors were positioned at small distance downstream from the target, where charged particle trajectories were not affected by the magnetic field. A silicon pad multiplicity detector, SPMD [16], was located at a downstream distance of 32.85 cm. It was segmented into 184 azimuthal sectors and 22 pseudorapidity rings in the range $2.35 < \eta < 3.75$, and maintained pad occupancy below 20%. The SPMD measured the energy deposited in each pad. A silicon drift detector, SDD [17], was located at a distances of 12.5 cm from the target. Its position resolution was 25 and 35 μm in the azimuthal and radial coordinates, respectively. The acceptance of the two detectors overlapped in the pseudorapidity interval $2.35 < \eta < 3.4$. The two detectors were used for precise reconstruction of the vertex position of the Pb + Pb primary collision. For that purpose straight lines going through each pair of hits in the SDD and SPMD were projected onto the target plane. The one dimensional spatial resolution was found to be better than 0.3 mm perpendicular to the beam line.

The WA98 experiment comprised two charged particle spectrometer arms located on the right (first arm) and the left (second arm, not used in the present analysis) facing downstream from the target, beyond a dipole magnet (Goliath) with 1.6 Tm bending power in the horizontal plane. The first tracking arm consisted of six Multistep Avalanche Chambers, MSAC, read out by CCD cameras equipped with two image intensifiers [18–20]. Each pixel of a CCD viewed a $3.1 \times 3.1\,\mathrm{mm}^2$ area of a chamber. In addition, a $4 \times 1.9\,\mathrm{m}^2$ time-of-flight wall positioned behind the chambers at a distance of 16.5 m from the target allowed for particle identification with a time resolution better than 120 ps. The TOF detector consisted of 480 scintillator counters with area $3.3 \times 48.5\,\mathrm{cm}^2$ and thickness 2 cm arranged in four rows [21]. Each counter was equipped with two PMTs, one at each end. The position of a hit along a scintillator bar was evaluated using two methods: the first used the time difference of signals obtained from the two ends of the scintillator bar, and the second used the ratio of their amplitudes. Both methods provide a spatial resolution of the order of 2.5 cm.

Tracks were selected which traverse all six MSAC chambers, have detected hits in at least four of them, and were associated with a TOF hit within a $6 \times 6\,\mathrm{cm}^2$ window. An additional momentum dependent time of flight cut was used to exclude misidentified pion, kaon, and proton tracks at a level better than 1%. The $(m_{\mathrm{T}} - m_{\pi})$-rapidity acceptance for pions generated by Monte Carlo is shown in Fig. 2.

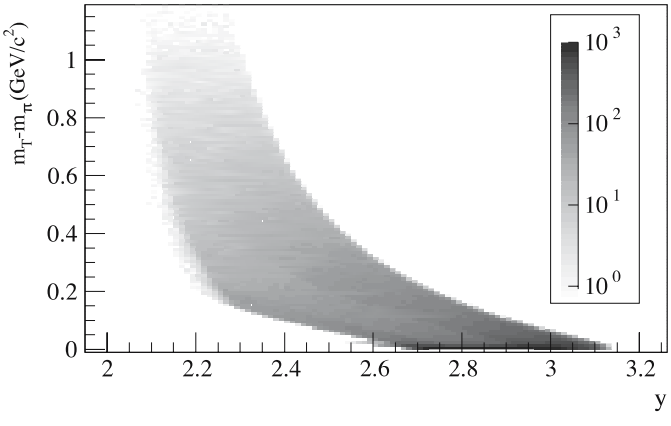

Fig. 2. Acceptance of the first tracking arm in the $(m_{\mathrm{T}} - m_{\pi}, y)$ plane for pions

The center of mass system rapidity is 2.9. The momentum resolution of the spectrometer was $\Delta p/p = 0.005$ at $p = 1.5\,\mathrm{GeV}/c$.

Positive and negative particles were detected in two sets of runs with opposite direction of the magnetic field. Data samples consisting of 0.58×10^6 π^- and 0.22×10^6 π^+ tracks satisfying all quality requirements were used for the ratio measurement.

Efficiency matrices were measured for a grid of 8×8 cells across each MSAC chamber and for several run periods. The overall tracking arm efficiency measured for negative particles was 2% less than that for positive particles due to chamber instabilities, however, there was no significant difference in the m_T dependence of the efficiencies. The detailed analysis of the π^- and K^- measurement in the first tracking arm has been presented in a separate paper [22].

3 Method of simulation

Simulations have been used in this analysis to estimate the different contributions to the measured R_π and R_K ratios, and to compare with the measured results. A detailed description of the primary collisions, of the Coulomb final state interactions, and of the particle propagation through the experimental setup has been simulated.

The primary Pb + Pb collisions were simulated with the RQMD 2.4 model [13] event generator which reproduces well the light strange baryon yield measured by the WA97 experiment [23], but does not include Coulomb interactions. In RQMD the particles are treated semiclassically over the complete evolution of the system. This allows the calculation of the Coulomb forces between each particle pair as an "afterburner" applied to the RQMD output. The electromagnetic interaction of a particle i with another charged particle j was calculated as described in [24] by

$$m_i \frac{\mathrm{d}u_i^\mu}{\mathrm{d}\tau} = \sum_{j \neq i} \frac{e_i}{c} F_{ij}^{\mu\nu} u_i^\nu \,, \tag{1}$$

where j runs over all charged particles of the system. Here particle i has mass m_i, charge e_i and 4-velocity $u_i = (1, \mathbf{v})/\sqrt{1-\mathbf{v}^2}$. The tensor $F_{ij}^{\mu\nu}$ is given by

$$F_{ij}^{\mu\nu} = \frac{e_j}{c} \frac{X^\mu u_j^\nu - X^\nu u_j^\mu}{\left(\frac{1}{c^2} \left(u_j^\lambda X^\lambda \right)^2 - X_\lambda X^\lambda \right)^{3/2}} \,, \tag{2}$$

where X^λ is the relative 4-distance between particles i and j. The forces are calculated at each time step of the system evolution and the positions and momenta of the particles are updated with the effect of the Coulomb forces only for those particles which have undergone their last collision. RQMD events with Coulomb interactions added were used as input to the detector simulation. Delta electrons produced by Pb ions in the target material before the collision were also simulated through the detector response.

The GEANT 3.21 program [25] was used for the detector simulation. The target, beam line, Goliath magnet, SDD and SPMD detectors, and tracking arm have been described in detail. For the track reconstruction the same procedure as used in the treatment of real data was employed. For every hit in the tracking arm all information on the particle and all its predecessors was stored for further analysis so that the history of every track could be traced back to the moment of the primary collision.

4 Experimental results

4.1 Centrality selection

The R_π ratio was studied for six centrality intervals defined by the transverse energy E_T measured with the MIRAC. The value of b may be estimated from the measured E_T according to the equation

$$\pi b^2 = \int_{E_\mathrm{T}}^{\infty} (\mathrm{d}\sigma/\mathrm{d}E_\mathrm{T})\,\mathrm{d}E_\mathrm{T} \,, \tag{3}$$

where $\mathrm{d}\sigma/\mathrm{d}E_\mathrm{T}$ is the experimentally measured distribution. Systematic comparisons of $\mathrm{d}\sigma/\mathrm{d}E_\mathrm{T}$ with predictions of VENUS 4.12 [26] and extraction of the number of participating nucleons or number of binary collisions are given in [27]. Table 1 lists the centrality intervals used in this analysis.

4.2 Particle ratios

The two tracking arms of WA98 provide two independent measurements of the pion ratio and have been shown to be consistent [12]. This study focuses on an analysis of the data obtained by the first tracking arm, whose acceptance for pions is shifted by about 0.5 of a unit of rapidity closer to the target fragmentation region relative to the acceptance of the second arm. This provides more favourable conditions for π/K separation in the region of large transverse mass where the normalization of the ratios is performed. At

Table 1. Centrality intervals defined according to the amount of E_T measured in MIRAC. The number of participants was calculated with VENUS 4.12

Centrality interval number	E_T (GeV)	$\sigma/\sigma_\mathrm{mb}$ (%)	Impact parameter (fm)	Number of participants
1	34.5–130	36.8–70.2	8.6–12.0	34–136
2	130–180	28.0–36.8	7.5–8.6	136–179
3	180–240	19.6–28.0	6.3–7.5	179–231
4	240–325	10.1–19.6	4.5–6.3	231–306
5	325–400	3.58–10.1	2.7–4.5	306–364
6	> 400	< 3.58	< 2.7	> 364

low p_T it allows better rejection of electrons through time-of-flight and a significantly larger number of tracks pass through the active area of the SPMD than is the case for the second arm. Figure 3 shows the R_π ratio normalized at transverse kinetic energy between 0.3 and 0.76 GeV/c^2 for the six centrality selections of Table 1. It should be noted that the Coulomb interaction effect on the ratio is strongly reduced and the contribution from hyperon decays is absent in the normalization region.

The e^-/e^+ ratio can be used as a check of the absolute normalization of the R_π ratio. For $0.8 < p < 1.2$ GeV/c electron and positron tracks are well identified through time-of-flight. As imposed by the tracking arm acceptance these tracks have transverse momenta below 50 MeV/c. Since both electrons and positrons originate mainly from photon conversions in the target material their yields should be identical, except for a small additional electron contribution from the production of delta electrons. These purely electromagnetic processes are well understood, so that the ratio e^-/e^+ is expected to be reproduced in simulation with an accuracy of order 1%. The e^-/e^+ ratio is presented in Fig. 4 as a function of centrality and compared to predictions. For each centrality the e^-/e^+ ratio is normalized with the same normalization used for the corresponding π^-/π^+ ratio in Fig. 3. Any difference between data and simulation is a measure of the systematic error in the normalization of the measured R_π distributions of Fig. 3. Summed over all centrality bins the difference between data and simulation of the e^-/e^+ ratio is $-0.8 \pm 1.2\%$, consistent with the expected accuracy of the comparison. This result indicates that the systematic error on the absolute normalization of R_π introduced by normalization of the ratio in the region $0.3 < m_T - m_\pi < 0.76$ GeV/c^2 is small, and that the normalization error is dominated by the statistical error of the data used for the normalization (shown by the dotted lines in Fig. 3).

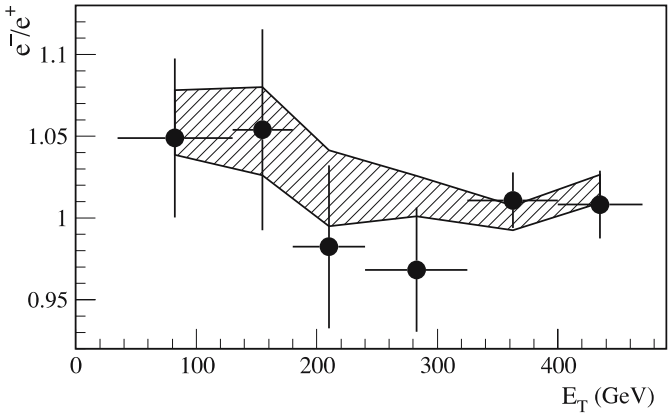

Fig. 4. MIRAC E_T dependence of the e^-/e^+ ratio. The normalization is the same as for the π^-/π^+ ratio. Data are shown by *filled circles*. The *hatched band* indicates the statistical uncertainty (Mean ± RMS) of the RQMD prediction

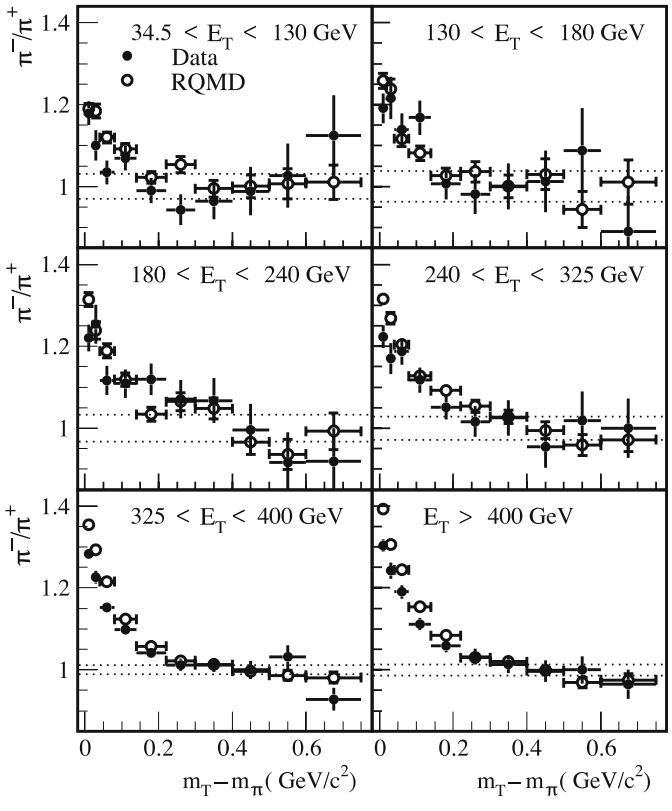

Fig. 3. The ratio R_π vs. $m_T - m_\pi$ for several Pb + Pb collision centrality intervals defined by E_T measured in the MIRAC. Data (*filled circles*) compared with predictions from RQMD including the Coulomb interaction (*open circles*). The ratios are arbitrarily normalized to 1.0 in the region $0.3 < m_T - m_\pi < 0.76$ GeV/c^2. The statistical errors are shown by the *error bars* on the *points*. The *dotted lines* indicate the statistical error on the normalization of the data. The RQMD normalization errors are about half as large

The ratio for kaons R_K measured under the same experimental conditions is presented in Fig. 5 for the 10% most central collisions. The kaon ratio shows no signifi-

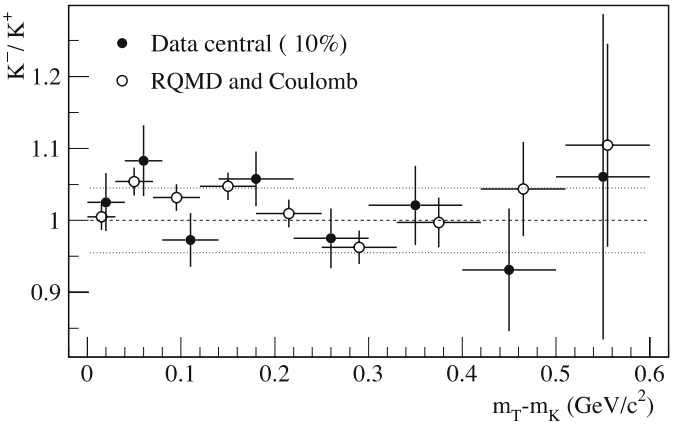

Fig. 5. The kaon ratio for the 10% most central Pb + Pb collisions. Data (*filled circles*) are compared with predictions from the RQMD model with Coulomb interactions included (*open circles*). The ratios are arbitrarily normalized to 1.0 in the region $0.3 < m_T - m_K < 0.6$ GeV/c^2. Errors are as described for Fig. 3

cant dependence on transverse kinetic energy. The lack of enhancement at low transverse mass is consistent with RQMD simulations with Coulomb final state interactions. The acceptance for the lowest transverse mass is located near kaon rapidity $y = 1.8$ in the laboratory system. For $m_{\mathrm{T}} - m_K > 0.2\,\mathrm{GeV}/c^2$ the average rapidity is about $y = 2.15$.

4.3 Hyperon contribution

Pions from hyperon decays have a much steeper transverse momentum spectrum than directly produced pions. Since strange hyperons are more abundantly produced than anti-strange hyperons, the π^-/π^+ ratio will be enhanced at low m_{T} due to this difference. In order to study the Coulomb effect on the directly produced pions, it is necessary to estimate and remove the hyperon contributions.

The silicon pad multiplicity detector has been used to estimate the yield of identified tracks that do not track back to the target vertex, and thus may be attributed to products of strange or anti-strange hadron decays. All pads of the SPMD that overlap with a $4 \times 4\,\mathrm{mm}^2$ window, centered at the point where the extrapolation of the track towards the target intersects the SPMD plane, were selected. The summed energy loss in the pad window is denoted as S, and given in units of the energy loss of a minimum ionizing particle in the silicon wafer of the SPMD. S therefore gives an estimate of the number of minimum ionizing particles traversing the SPMD within the pad window. Simulation indicates that the mean value over a large set of tracks for pion tracks originating in the target is $\langle S \rangle = 0.89$, while for tracks from hyperon and K^0_S decays $\langle S \rangle = 0.17$ and 0.20, respectively. This is because tracks that originate from hyperon or K^0_S decays either traverse the SPMD far from the pad indicated by the extrapolation, or do not traverse it at all (produced downstream of the SPMD). Thus, tracks from hyperon decays will be suppressed by roughly a factor of $0.89/0.17 \approx 5$ with the SPMD hit requirement.

In the case of high pad occupancy the energy loss S_1 measured in the SPMD window associated with the track contains a significant contribution S_2 from spurious tracks. The value of S_2 is estimated by the measured energy loss in a window of the same size centered at a location far from the extrapolated track location (in particular, at a location rotated by 12° in azimuth). The RQMD simulation indicates that $\langle S' \rangle = \langle S_1 - S_2 \rangle$ provides a good estimate of $\langle S \rangle$ for each kind of track.

According to RQMD predictions, in the region of transverse kinetic energy above $0.3\,\mathrm{GeV}/c^2$ the contribution of hyperon decays to the pion yield is expected to be below 1%, due to the hyperon decay kinematics. In this region, most of the tracks originate from the target, with less than 8% contribution from K_S decays. Therefore, we may consider these tracks a relatively clean selection of directly produced pions and use them to estimate the quality of the description of the SPMD response in the simulation. As shown in Fig. 6, the extracted number of particles traversing the SPMD $\langle S_1 - S_2 \rangle$ coincides with simulation within errors while the SPMD occupancy varies by more than a factor of 5 between the most peripheral and most central bins. Mean values of $\langle S_1 - S_2 \rangle = 86.7 \pm 1.4\%$ and $\langle S_1 - S_2 \rangle = 85.4 \pm 0.9\%$ are extracted for positiviely and negatively charged pions, respectively.

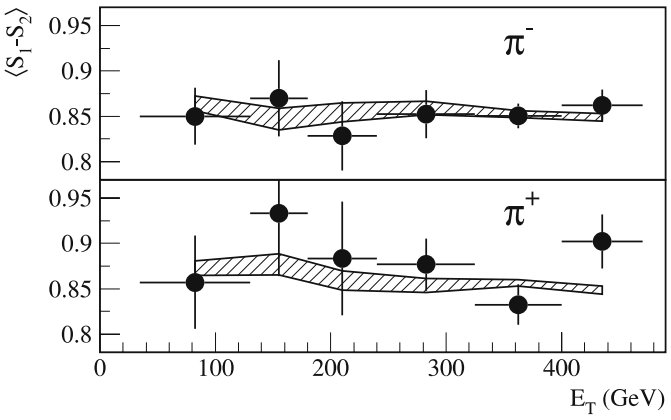

Fig. 6. The corrected average number of minimum ionizing particles, $\langle S' \rangle = \langle S_1 - S_2 \rangle$, as a function of centrality, in the associated SPMD region for negative and positive pions with $m_{\mathrm{T}} - m_\pi > 0.3\,\mathrm{GeV}/c^2$. The results are compared to simulations shown by the *hatched regions*

For tracks whose extrapolation traverses the SPMD the quantities $R_{\mathrm{g}} = \pi^-/\pi^+$ and $R_{\mathrm{SPMD}} = S'^-/S'^+$ are defined, where S'^- and S'^+ are sums of $S_1 - S_2$ values for negative and positive pion tracks identified by the tracking arm. In the case of equal hyperon fractions of the pion yield for both charges one expects $R_{\mathrm{SPMD}} \approx R_{\mathrm{g}}$. The behaviour of R_{g} and R_{SPMD} as a function of transverse kinetic energy for the 10% most central collisions is shown in Fig. 7. Both distributions have the same normalization chosen to give $R_{\mathrm{g}} = 1$ at $m_{\mathrm{T}} - m_\pi > 0.3\,\mathrm{GeV}/c^2$.

Since the contribution to S from hyperon decay tracks is smaller than for tracks originating in the target, a deviation of R_{SPMD} from R_{g} is an indication of different hyperon fractions in the two charge samples. The observed lower

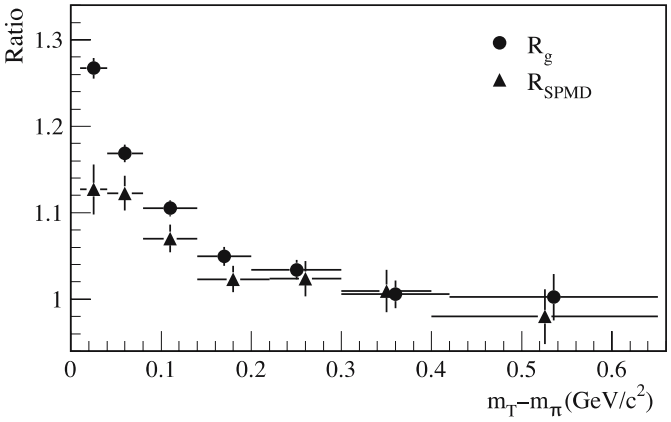

Fig. 7. R_{SPMD} (*triangles*) and R_{g} (*circles*) for the 10% most central events. See text for definitions of R_{SPMD} and R_{g}. Both distributions are normalized to 1.0 for R_{g} at $m_{\mathrm{T}} - m_\pi > 0.3\,\mathrm{GeV}/c^2$

value of R_{SPMD} in comparison to R_{g} for small m_{T} indicates a larger fraction of tracks from hyperon decays in the measured π^- distribution relative to the π^+ distribution. To quantify this difference the quantity $(R_{\mathrm{g}} - R_{\mathrm{SPMD}})/R_{\mathrm{g}}$ is extracted and compared with RQMD simulation as a function of $m_{\mathrm{T}} - m_{\pi}$ in Fig. 8 and as a function of collision centrality in Fig. 9 for $m_{\mathrm{T}} - m_{\pi} < 140\,\mathrm{MeV}/c^2$, where the excess becomes significant. Within errors it is seen that the RQMD simulation provides a good description of the contribution of strange baryon decays to the pion ratio.

The yield distributions of light strange and anti-strange baryons have been reported by the WA97 collaboration [24] and also shown to be successfully reproduced by RQMD calculations. Based on this fact, and on the comparisons of Figs. 8 and 9, the RQMD simulation results have been used to correct the measured pion ratios R_{π} shown in Fig. 3 for the hyperon decay contributions to obtain the corrected ratios R'_{π} of pions originating in the target. For this purpose, for each of the π^- and π^+ yields, the fraction of the pion yield from strange hadron decays has been estimated from RQMD simulation and removed from the total yield. Figure Fig. 10 shows the corrected pion ratios $R'_{\pi} = \pi^-/\pi^+$.

At low momenta the e^- and e^+ tracks have been separated from pions through time-of-flight and their abundances are found to be in agreement with simulation. At high momenta e^- and e^+ tracks cannot be separated from pions and their relative yields have been estimated from simulation. The ratio R'_{π} of pions originating from the target has also been corrected for e^- and e^+ misidentified as pions at high momenta. According to simulation this e^- and e^+ contamination weakens the enhancement of the pion ratio by about 2% for the lowest m_{T}. The corrected ratios R'_{π} shown in Fig. 10 can be used for comparison of the π^-/π^+ ratio with predictions from models including the decay of the η and other short lived resonances.

In Fig. 11 the dependence of the corrected pion ratio R'_{π} on the collision centrality is shown for two intervals of pion transverse kinetic energy: below $40\,\mathrm{MeV}/c^2$ and between 40 and $140\,\mathrm{MeV}/c^2$. The error due to normalization is included in the error bars. Predictions from RQMD calculations with Coulomb interactions included are also shown. Both the measured results and the RQMD predic-

Data (*filled circles*) are compared with predictions from RQMD including the Coulomb interaction (*open circles*). The ratios are arbitrarily normalized to 1.0 in the region $0.3 < m_{\mathrm{T}} - m_{\pi} < 0.76\,\mathrm{GeV}/c^2$. Errors are as described for Fig. 3

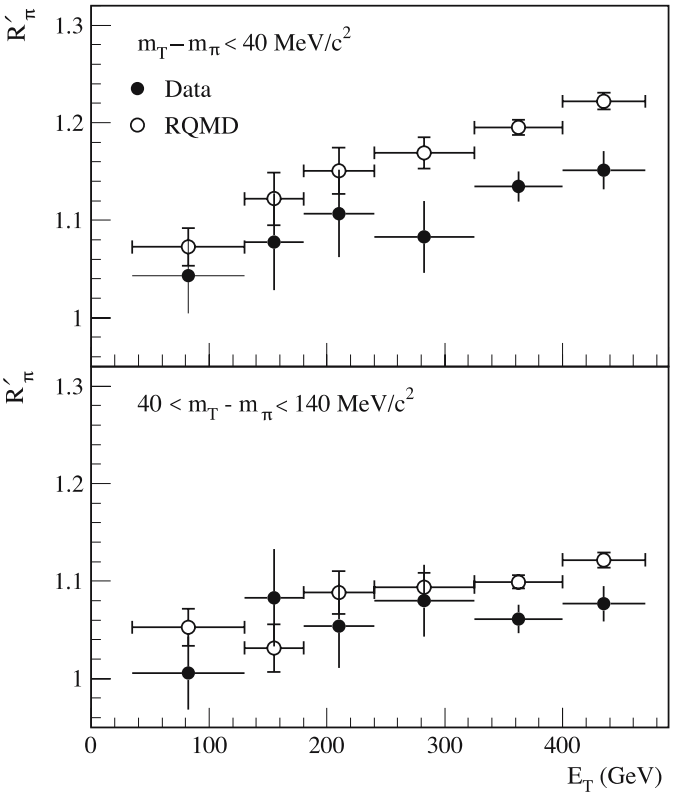

Fig. 11. Centrality dependence of the corrected charged pion ratio for pions originating from the target for $m_{\mathrm{T}} - m_{\pi} < 40\,\mathrm{MeV}/c^2$ and $40 < m_{\mathrm{T}} - m_{\pi} < 140\,\mathrm{MeV}/c^2$. Data (*filled circles*) are compared with predictions from RQMD calculations (*open circles*)

tions show a smooth increase of the pion ratio with increasing centrality. As expected, the ratio tends to a value of unity for peripheral collisions. However, RQMD is seen to overpredict the measured pion ratio with a discrepancy that grows with decreasing transverse mass.

5 Modified Coulomb calculations

Several parameters of the collision, such as the total participant charge at central rapidity, its transverse expansion velocity, and the freeze-out time, affect the π^-/π^+ ratio [6]. In order to investigate the sensitivity of the pion ratio to the collision parameters, the Coulomb calculations were repeated under alternative scenarios following minor modifications of the RQMD output. For this study RQMD events from central Pb + Pb collisions with impact parameter $b < 4.5$ fm were used.

In the first modification, the RQMD baryon rapidity density was adjusted. Since the value of $\mathrm{d}N/\mathrm{d}y$ for protons around mid-rapidity for central Pb + Pb collisions as measured by the NA44 [28] and NA49 [29] experiments is lower than the RQMD prediction by about 30%, the RQMD Coulomb interaction from baryons should be reduced accordingly. The corresponding reduction of the baryon Coulomb source was implemented in the calculation by weighting the Coulomb charge of all baryons during all stages of the collision by the ratio of measured to predicted proton $\mathrm{d}N/\mathrm{d}y$ distributions. This baryon rapidity density correction (BRDC) reduces the ratio at the lowest $m_{\mathrm{T}} - m_{\pi}$ bin by 3% (Fig. 12). Since this correction is based on a discrepancy between RQMD and experimental measurements, further calculations use this modified baryon Coulomb charge rapidity density.

To estimate the sensitivity of the pion ratio to the freeze-out time the application of the Coulomb interaction was simply delayed. The mean time of pion freeze-out at $|y_{\mathrm{CMS}}| < 1$ in the central Pb + Pb RQMD events is 15 fm/c. For demonstration, a 2 fm/c delay was added during which time the particles move freely after freeze-out on their final RQMD trajectories. After propagating freely for 2 fm/c the pions are then subjected to the Coulomb interactions. At $m_{\mathrm{T}} - m_{\pi} < 40\,\mathrm{MeV}/c^2$ the resulting ratio shown in Fig. 12 by triangles is reduced with respect to the unmodified RQMD result by 5%. This total reduction of the ratio is similar in magnitude to the difference between the data and the unmodified RQMD simulation results of Fig. 11. Alternatively, increased collective flow in RQMD would result in a larger freeze-out volume and a reduced Coulomb interaction, with a similarly improved agreement with the measurements.

In Fig. 13 the pion ratio measured in this experiment for the 10% most central Pb + Pb collisions is compared with that reported by the NA44 collaboration [5]. Neither RQMD calculations, nor the previously mentioned models [6, 11], predict the observed difference in the two measurements. This could indicate an earlier pion freeze-out in the center of mass rapidity region near $y = 1$ (NA44) relative to that near $y = 0$ (WA98).

The measured K^-/K^+ ratio (Fig. 5) does not show any significant m_{T} dependence. This is consistent with the data of the NA44 collaboration and with RQMD predictions. The kaon ratio enhancement induced through the

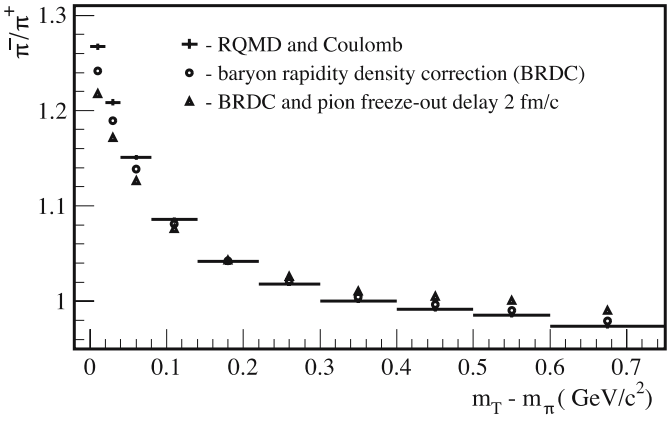

Fig. 12. The pion yield ratio π^-/π^+ at mid-rapidity ($1 < |y_{\mathrm{CMS}}|$). Predictions from RQMD with final state Coulomb interaction unmodified (*crosses*), with BRDC (*circles*), and with BRDC and pion freeze-out delayed an additional 2 fm/c (*triangles*)

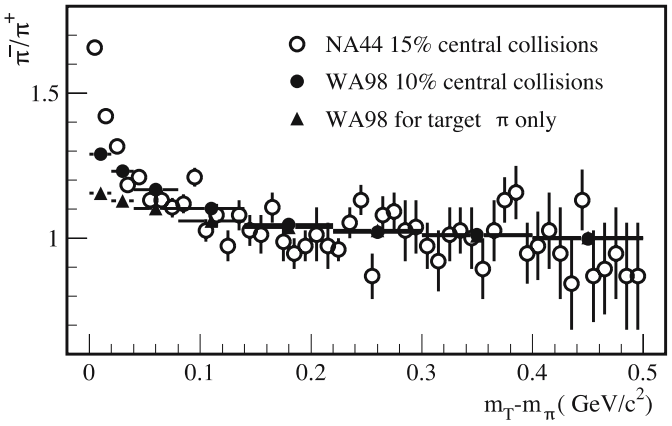

Fig. 13. Comparison of NA44 data (*open circles*) and WA98 data (*filled circles*) for the 10% most central collisions. The ratio for pions originating in the target is also shown (*triangles*)

Coulomb interaction is expected to be less than that for pions by a factor equal to their mass ratio m_π/m_K [7]. However, according to RQMD predictions without Coulomb correction, the kaon ratio has a $\sim 6\%$ drop at low transverse kinetic energy as a result of the greater amount of absorption of K^- than K^+. This large absorption effect must be taken into account when investigating Coulomb effects in the analysis of the kaon ratio data.

6 Discussion and conclusions

The π^-/π^+ ratio has been measured as a function of transverse mass and centrality in Pb + Pb collisions at 158 AGeV/c. The hyperon decay contribution has been deduced and shown to result in an increase of the pion ratio at low m_T that is responsible for about half of the enhancement of π^- relative to π^+ in central collisions, and an even larger fraction of the enhancement in peripheral collisions. The RQMD model was shown to agree with the measured hyperon decay contributions. The hyperon decay contributions have been removed from the measured ratios to extract the ratios for directly emitted pions.

The low m_T enhancement of the π^-/π^+ ratio, after removal of the hyperon decay contribution, increases with collision centrality and tends to zero for the most peripheral events (see Fig. 10). This observation is consistent with the hypothesis that the enhancement is due to the Coulomb interaction induced by the net positive charge of the participant protons. The same behaviour is observed in the framework of RQMD model simulations that include final state Coulomb interactions. However, the RQMD simulation overpredicts the observed enhancement in the ratio by a factor of about 1.5.

Investigations of the RQMD model predictions suggest that rather small modifications of the properties of the participant fireball are necessary to obtain good agreement with the data. For example, good agreement can be achieved after reduction of the baryon rapidity charge density predicted by RQMD according to the NA44 and NA49 proton measurements, together with a small increase of the mean pion freeze-out time (such as an increase from an average of 15 fm/c to 17 fm/c). According to RQMD predictions, the transverse flow velocities of heavy particles are less than those of pions [30]. A slight increase of the baryon transverse flow velocity would have a similar effect as the delay of the freeze-out time. In both cases, the system disperses over a larger volume before freeze-out, which reduces the Coulomb field and, therefore, the π^-/π^+ ratio. Based on comparisons with the RQMD model calculations, the results suggest a relatively large value of the mean freeze-out time for pions (~ 15 fm/c) in central Pb + Pb collisions.

(Received 26 May 2006; published 26 March 2007)

Emission source functions are extracted from correlation functions constructed from charged pions produced at midrapidity in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The source parameters extracted from these functions at low k_T give first indications of a long tail for the pion emission source. The source extension cannot be explained solely by simple kinematic considerations. The possible role of a halo of secondary pions from resonance emissions is explored.

DOI: 10.1103/PhysRevLett.98.132301 PACS numbers: 25.75.Ld, 25.75.Dw

Collisions between ultrarelativistic heavy ions can lead to extremely high energy-density nuclear matter [1]. The decay dynamics of this matter is strongly influenced by the nuclear equation of state (EOS) and possibly by a deconfined phase [2]. An emitting system which undergoes a strong first order phase transition is expected to show a much larger space-time extent than would be expected if the system remained in the hadronic phase throughout the collision process [3]. Indeed, several hydrodynamical calculations show such an increase for particle emission sources [3,4], provided hadronization does not occur via a supercooled state [5]. It has also been suggested that the shape of the emission source function can provide signals for a second order phase transition and whether or not particle emission occurs near to the critical end point in the QCD phase diagram [6].

Interferometry studies provide important information on the emission source function for particles produced in nuclear reactions ranging from elementary collisions [e^+e^- and $(\bar{p})pp$] to those involving very heavy ions [7–9]. Recent studies span the beam energies $\sqrt{s_{NN}} \sim$ 2–200 GeV [10–13]. A common theme for these papers is the extraction of the widths of emission source functions which are assumed to be Gaussian. Also, Coulomb effects on the correlation function are usually assumed to be separable [14]. Such an approach was followed earlier in an analysis which used the Bowler-Sinyukov 3D Hanbury Brown and Twiss (HBT) method to probe for a possible long-lived source [15]. The rms widths so obtained for each dimension of the source $R_{\rm long}$, $R_{\rm side}$, and $R_{\rm out}$ gave no evidence for such emissions, suggesting that the sound speed is not zero during an extended hadronization period.

In this Letter we exploit the model-independent imaging technique of Brown and Danielewicz [16,17] to make a more detailed study of both the shape and the space-time characteristics of the pion emission source function. The method uses a numerical calculation of the two particle wave function, which includes final-state interactions (FSI), to produce an inversion matrix that operates on the correlation function to produce the corresponding source function. The technique has been used to address only a few data sets [18,19] at relativistic beam energies.

Measurements were made with the PHENIX detector [20] at the Relativistic Heavy Ion Collider (RHIC). Charged pions were detected in the two central arms ($|\eta| \leq 0.35$). Track reconstruction was accomplished via pattern recognition using the drift chamber (DC) followed by two layers of multiwire proportional chambers with pad readout located at radii of 2, 2.5, and 5 m [20]. Particle momenta were measured with the resolution $\delta p/p = 0.7\% \oplus 1.0\% p$ (GeV/c). Very good pion identification (PID) was achieved with a 2σ cut about the pion peak in the squared-mass distribution for $p_T \lesssim 2.0$ GeV/c and $p_T \lesssim 1$ GeV/c in the time of flight (TOF) and the electromagnetic calorimeter (EMC), respectively. The event centrality was determined using the PHENIX beam-beam counter and the zero degree calorimeter [21]. Approximately 22×10^6 Au + Au events were analyzed to study several centrality and p_T selections.

Two-pion interferometry correlations were obtained via the correlation function $C(q) = N_{\rm cor}(q)/N_{\rm mix}(q)$, where the numerator is the relative momentum distribution of particle pairs from the same event (foreground pairs) and the denominator is the relative momentum distribution of particle pairs obtained from mixed events (background pairs). Here, $q = \frac{1}{2}\sqrt{-(p_1 - p_2)^2}$ is half of the relative momentum between the two particles in the pair c.m. frame (PCMS). p_1 and p_2 are the momentum 4-vectors of each particle in the pair and $C(q) \equiv 1$ for large q values where final-state interactions are negligible. Track-pair cuts similar to those of Ref. [12] were applied to foreground and background pairs, respectively. That is, pairs

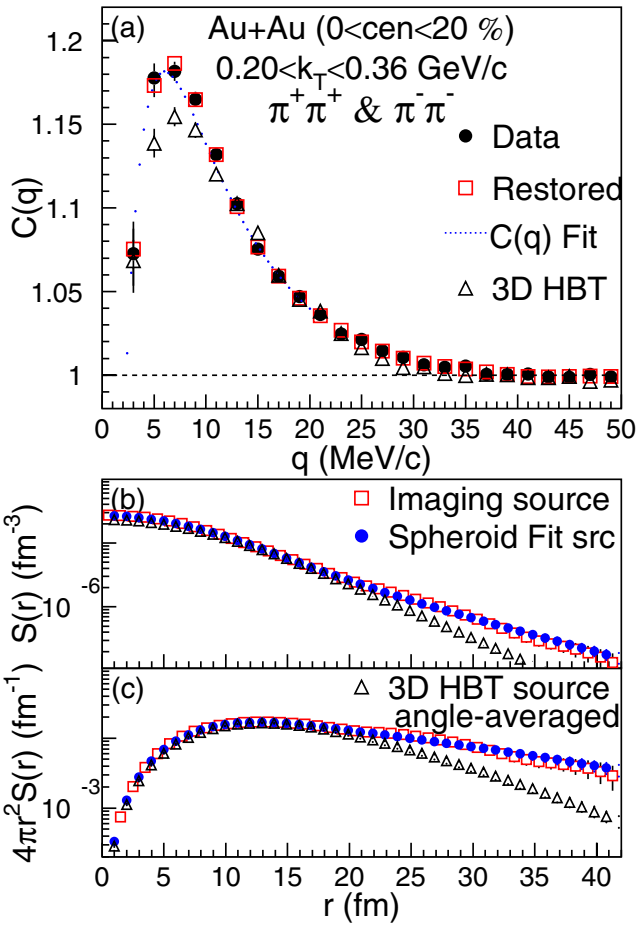

FIG. 1 (color online). [(upper, (a)] (●) Correlation function, $C(q)$, for $\pi^+\pi^+$ and $\pi^-\pi^-$ pairs; (□) restored correlation from imaging technique; (dotted line) direct correlation fitting; (△) 1D angle-averaged correlation of 3D correlation function. (lower) 1D source function (b) $S(r)$ and (c) $4\pi r^2 S(r)$: (□) imaging; (●) spheroid fit to correlation function; (△) angle-averaging of 3D-Gaussian source function. Systematic errors are less than size of data points.

within 5 cm in the beam direction ($\Delta Z_{\rm DC}$) and 0.02 radians in azimuthal angle ($\Delta\phi_{\rm DC}$) in the DC were eliminated from the pair sample to remove ghost tracks, and pairs within $0.0 < \Delta\phi_{\rm DC} < 0.1$ radians for $\Delta Z_{\rm DC} > 5$ cm were removed to avoid an inefficient region. The latter set of cuts were supplemented with the removal of pairs having a separation $\Delta R \leq 14$ cm and ≤ 16 cm in the TOF and EMC, respectively. Systematic variations of all of these cuts were explored to determine systematic error estimates; very little influence on the extracted correlation functions was found. Careful studies of the influence of momentum resolution on the correlation function were also made, as in [22]. The maximum effect was found to be $\sim$0.4% change in the correlation function at low q values, so it was neglected.

The filled circles in Fig. 1(a) show the one-dimensional (1D) correlation function $C(q)$, for a centrality of 0%–20% and for $0.20 < k_T = \frac{1}{2}(p_{T,1} + p_{T,2}) < 0.36$ GeV/c. The characteristic enhancement for $q \lesssim 25$ MeV/c reflects a combination of Bose-Einstein statistics and the FSI between pion pairs. The correlation function is not Coulomb corrected because the FSI (including Coulomb but no strong interaction) is included in the imaging and fitting procedure as described below.

The 1D correlation function and source function $S(r)$ (the probability of emitting a pair of particles at a separation r in the PCMS frame) are related via the 1D Koonin-Pratt equation [23]:

$$C(q) - 1 = 4\pi \int dr r^2 K_0(q, r) S(r). \quad (1)$$

The angle-averaged kernel $K_0(q, r)$ encodes the FSI and is given in terms of the final-state wave function $\Phi_{\mathbf{q}}(\mathbf{r})$, as $K_0(q, r) = \frac{1}{2}\int d[\cos(\theta_{\mathbf{q},\mathbf{r}})][|\Phi_{\mathbf{q}}(\mathbf{r})|^2 - 1]$, where $\theta_{\mathbf{q},\mathbf{r}}$ is the angle between $\mathbf{q}$ and $\mathbf{r}$ [17]. The procedure for the inversion of Eq. (1) to obtain $S(r)$ is also given in Ref. [17].

The open squares in Fig. 1(b) show the source function obtained from the correlation function presented in Fig. 1(a). As a cross-check of the imaging procedure, a restored correlation function was generated via Eq. (1) with the extracted source function as input. The open squares and filled circles in Fig. 1(a) indicate excellent consistency between the measured and restored correlation functions. The 1D source function, cf. Fig. 1(b), points to a Gaussian-like pattern at small r and a previously unresolved "tail" at large r. The robustness of this tail was established via an extensive array of tests including its dependence on pair and PID cuts, and on momentum resolution; no variation outside of the stated error bars was found.

This new observation of a tail is made more transparent via a comparison with the source function constructed from the parameters ($R_{\rm long}$, $R_{\rm side}$, $R_{\rm out}$, and λ), obtained in an earlier 3D HBT analysis [15]. The procedures outlined in Ref. [17] were employed to construct this source function (see Fig. 1). The measured and 3D angle-averaged correlation functions differ for $q \lesssim 15$ MeV/c as do the respective source functions for $r \gtrsim 17$ fm. The imaged source function exhibits a more prominent tail than the angle-averaged 3D HBT source function. This difference could stem from the Gaussian shape assumption employed in the 3D HBT analysis. The 3D Gaussian fitting procedure by construction is sensitive only to the main component of $S(r)$, and thus would not be capable of resolving fine structure at small-q/large-r. Given the fact that the volume element increases quadratically with pair separation, this difference is considerable as shown in Fig. 1(c), where the radial probabilities $[4\pi r^2 S(r)]$ are compared. The open triangles in Fig. 1(a) clearly indicate that the differences in the source functions reflect an important disparity in the corresponding correlation functions for $q \lesssim 10$–15 MeV.

Parameters of the source function for different assumed shapes were extracted via direct fits to the correlation function. Filled circles in Figs. 1(b) and 1(c) show the source function obtained from such a fit for a spheroidal shape [17],

$$S(r) = \frac{\lambda R_{\rm eff} \times e^{-(r^2/4R_T^2)} \mathrm{erfi}\left(\frac{r}{2R_{\rm eff}}\right)}{(8\pi R_T^2 R_0 r)}, \quad \text{for } R_0 > R_T, \quad (2)$$

where $R_{\rm eff} = 1/\sqrt{(1/R_T^2 - 1/R_0^2)}$, R_T is the radius of the spheroid in two perpendicular spatial dimensions and $R_0 = a \times R_T$ is the radius in the third spatial dimension; a is a scale factor. The long axis of the spheroid is assumed to be oriented in the out direction of the Bertsch-Pratt coordinate system. The fraction of pion pairs which contribute to the source λ is given by the integral of the normalized source function over the full range of r.

The procedure for making a direct fit to the correlation function involves the determination of a set of values for the spheroid parameters of Eq. (2), which reproduce the observed correlation function when the resulting source function is inserted into Eq. (1). The minimization package MINUIT was used to minimize the χ^2 between the observed and calculated correlation function. The χ^2/ndf value so obtained was $\sim$1. The dotted curve in Fig. 1(a) shows the fit to the data. The resulting source function shown in Figs. 1(b) and 1(c) indicates very good agreement with that obtained via the imaging technique. This shape parametrization is not unique; an essentially indistinguishable source was also obtained for a fit performed with a Gaussian plus modified exponential [24] shape. The simpler spheroid parametrization was chosen for the discussion below.

The spheroidal source function [Eq. (2)] can be approximated by a short-range Gaussian source $S_{\rm sr}(r)$;

$$S_{\rm sr}(r) \sim \lambda e^{-r^2[(1/6R_T^2)+(1/12R_0^2)]}/(8\pi\sqrt{\pi}R_T^2 R_0), \quad (3)$$

for small r, and a long-range source $S_{\rm lr}(r)$ for

$r \gg 2R_T R_0/\sqrt{R_0^2 - R_T^2}$ given by

$$S_{\rm lr}(r) \sim \lambda R_0 e^{-r^2/4R_0^2}/[4\pi\sqrt{\pi}(R_0^2 - R_T^2)r^2]. \quad (4)$$

Thus, the emission source shown in Figs. 1(b) and 1(c) can be interpreted to reflect a short-range Gaussian source of radius $R_{\rm sr} = \sqrt{3R_T^2R_0^2/(2R_0^2 + R_T^2)} = R_T\sqrt{3a^2/(2a^2 + 1)}$ and a long-range tail of extended space-time extent $R_{\rm lr} = R_0$. The fraction of pairs associated with these sources $\lambda_{\rm sr} = \lambda a^2[3/(2a^2 + 1)]^{3/2}$ and $\lambda_{\rm lr} = (\lambda - \lambda_{\rm sr})$ are obtained from Eq. (3) and the conservation of pairs, respectively.

Source functions were extracted via imaging and spheroid fits for several k_T and centrality selections, in order to map the regions in k_T and centrality where the long-range tail is prominent. Representative results are shown in Fig. 2 for the indicated cuts. The experimental and restored correlation functions, compared in Figs. 2(a) and 2(b), indicate good agreement within the statistics, as do the corresponding source functions shown in Figs. 2(c) and 2(d).

Figure 3 gives a more complete summary of the extracted source parameters. Systematic errors obtained via variations of pair cuts in the analysis are 0.12 fm, 1.0 fm, 0.35, and 0.03 for $R_{\rm sr}$, $R_{\rm lr}$, a, and λ, respectively. The centrality and k_T dependence of the rms radius of the short-range source $R_{\rm sr}$ is similar (within 10%) to that obtained for $R_{\rm long}$ and $R_{\rm side}$ in an earlier analysis [15], cf. Figs. 3(a) and 3(d). The long-range source shows an effective radius $R_{\rm lr} = a \times R_T$, which is ~2–3.5 times $R_{\rm sr}$. The ratio $R_{\rm lr}/R_{\rm sr}$ is also maximal for low k_T and the most central collisions. The fraction of pairs exhibiting these characteristics is given by the λ values shown in Figs. 3(c) and 3(f); for central collisions, maximum prominence is shown for low k_T pairs.

A central question is the origin of the long-range contribution to the emitting source. Instantaneous freeze-out of a source with $R_{\rm out}/R_{\rm side} \sim 1$ in the longitudinal comoving system (LCMS) would give a maximum kinematic boost so that $R_{\rm lr} = R_{\rm out} = \gamma \times R_T$ in the PCMS. Thus, the values for a and γ, shown in Fig. 3(b), can be directly compared. At low k_T, γ is seen to be significantly less than a. Thus, a simple kinematic transformation from the LCMS to PCMS cannot account for the observed source parameters at this k_T.

Could a composite particle emission source comprised of a central core and a halo of long-lived resonances account for the observations? For such emissions, the pairing between pions from the core and secondary pions from the halo is expected to dominate the long-range emissions [25]. If it is assumed that this halo includes only ω decay ($c\tau \sim 24$ fm), one may compare the ω yield with a simple estimate of the fraction of pion pairs associated with the short- and long-range sources. Using the a and γ values in Fig. 3(b), $\lambda_{\rm sr} \sim 0.22$–$0.32$,

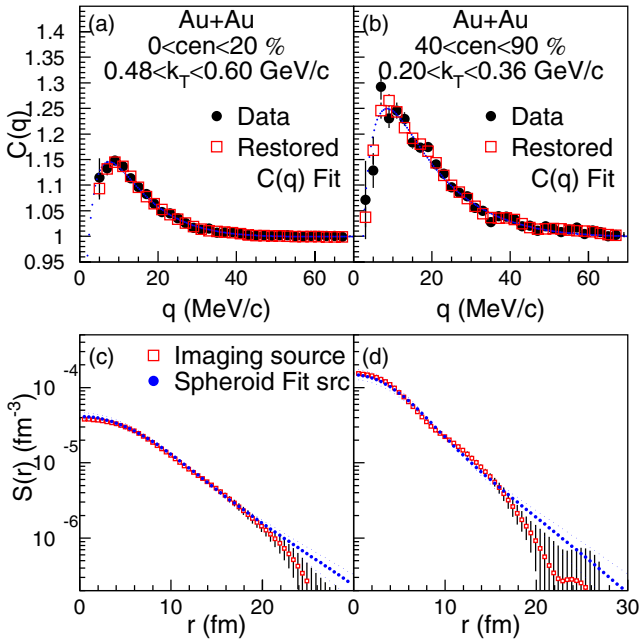

FIG. 2 (color online). (upper) Correlation functions, $C(q)$, for $\pi^+\pi^+$ and $\pi^-\pi^-$ pairs and (lower) corresponding source functions, $S(r)$ for (a), (c) high k_T most central collisions; (b), (d) low k_T peripheral collisions. Error bars indicate statistical errors with symbols as in Fig. 1.

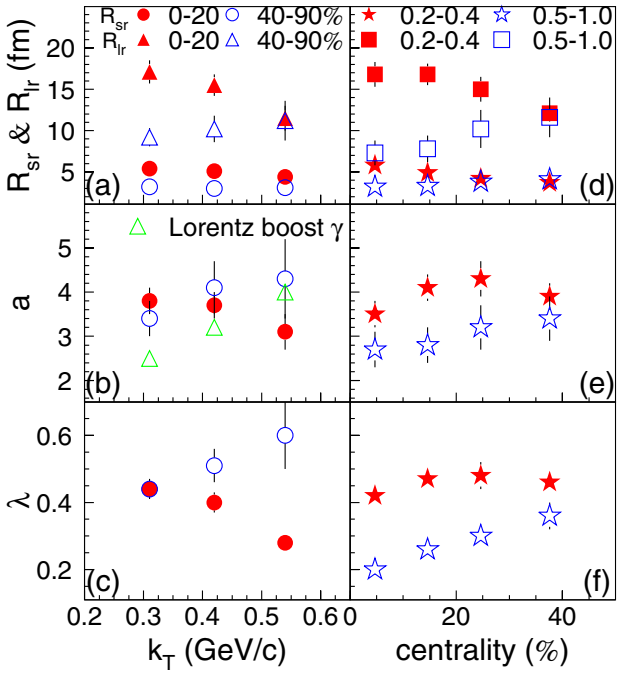

FIG. 3 (color online). (left) k_T dependence of extracted spheroidal source parameters for pion source functions (a) $R_{\rm sr}$, $R_{\rm lr}$, (b) a, and (c) λ for (filled symbols) most central collisions; (open symbols) peripheral collisions. (right) Centrality dependence of same parameters for (★) low k_T (0.2–0.4 GeV/c); (☆) high k_T (0.5–1.0 GeV/c).

$\lambda_{\rm lr} \sim 0.23$–$0.13$, and $\lambda_{\rm lr}/\lambda_{\rm sr} \sim 0.4$–$1.0$ for the lowest k_T. The preliminary values for $\omega/\pi^- = 0.1$ from Ref. [26] give an estimate for $\lambda_{\rm lr}/\lambda_{\rm sr} \sim 2 \times 0.1/\sqrt{\lambda_{\rm sr}} \sim 0.35$–$0.43$ which lies at the lower end of the estimates obtained from the source parameters. (A significant change in the value for ω/π^- would alter this conclusion.) Therefore, it is plausible that a maximal kinematic boost combined with a halo of ωs could account for $\lambda_{\rm lr}/\lambda_{\rm sr}$. However, the steep centrality dependence of the radius of the long-range source inferred from Figs. 3(d) and 3(e) is not compatible with an essentially flat dependence expected for significant ω resonance contribution.

In summary, we have made the first extraction of the full 1D emission source function for pions in Au + Au collisions at RHIC ($\sqrt{s_{NN}} = 200$ GeV). This source function points to separate but prominent contributions from short-range emissions and a long-range tail of larger space-time extent than has been previously observed. This tail cannot be explained solely by simple kinematic considerations associated with a frame transformation from the LCMS to the PCMS. Further studies are required to determine the origin of this tail and whether or not it is related to a phase transition.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We thank S. Pratt and P. Danielewicz for their interest and input. The properties of jets produced in $p + p$ collisions at $\sqrt{s} = 200$ GeV are measured using the method of two-particle correlations. The trigger particle is a leading particle from a large transverse momentum jet while the associated particle comes from either the same jet or the away-side jet. Analysis of the angular width of the near-side peak in the correlation function determines the jet-fragmentation transverse momentum j_T. The extracted value, $\sqrt{\langle j_T^2 \rangle} = 585 \pm 6(\text{stat}) \pm 15(\text{sys})$ MeV$/c$, is constant with respect to the trigger particle transverse momentum, and comparable to the previous lower $\sqrt{s}$ measurements. The

†PHENIX Spokesperson: zajc@nevis.columbia.edu

width of the away-side peak is shown to be a convolution of j_T with the fragmentation variable, z, and the partonic transverse momentum, k_T. The $\langle z \rangle$ is determined through a combined analysis of the measured π^0 inclusive and associated spectra using jet-fragmentation functions measured in e^+e^- collisions. The final extracted values of k_T are then determined to also be independent of the trigger particle transverse momentum, over the range measured, with value of $\sqrt{\langle k_T^2 \rangle} = 2.68 \pm 0.07(\text{stat}) \pm 0.34(\text{sys})$ GeV/c.

I. INTRODUCTION

The goal of this paper is to explore the systematics of jet production and fragmentation in $p + p$ collisions at $\sqrt{s} =$ 200 GeV by the method of two-particle azimuthal correlations. Knowledge of the jet-fragmentation process is useful not only as a reference measurement for a similar analysis in Au + Au collisions, but can be used as a stringent test of perturbative QCD (pQCD) calculations beyond leading order.

The two-particle azimuthal correlations method worked well at ISR energies ($\sqrt{s} = 63$ GeV) and below [1–3], where it is difficult to directly reconstruct jets, but has not been attempted at higher values of $\sqrt{s}$. This method is also suitable for jet-analysis in heavy-ion data where the large particle multiplicity severely interferes with direct jet reconstruction.

With the beginning of RHIC operation, heavy-ion physics entered a new regime, where pQCD phenomena can be fully explored. High-energy partons materializing into hadronic jets can be used as sensitive probes of the early stage of heavy-ion collisions. Measurements carried out during the first three years of RHIC operation at $\sqrt{s_{\text{NN}}} =$ 130 and 200 GeV exhibit many new and interesting features. The high-p_T particle yield was found to be strongly suppressed in Au + Au central collisions [4–6]. Furthermore, the nonsuppression of the high-p_T particle yield in d + Au induced collisions [7–10] confirmed that the suppression can be fully attributed to the final state interaction of high-energy partons with an extremely opaque nuclear medium formed in Au + Au collisions at RHIC.

Other striking features found in RHIC data are the large asymmetry of particle azimuthal distributions which is attributed to sizable elliptic flow [11,12] and the observation of the apparent disappearance of the back-to-back jet correlation in central Au + Au collisions [13].

Many of the above mentioned observations can be explained by a large opacity of the medium produced in central Au + Au collisions which causes the scattered partons to lose energy via coherent (Landau-Pomeranchuk-Migdal [14]) gluon bremsstrahlung [15–18]. It is expected that the medium effect will cause the apparent modification of fundamental properties of hard-scattering like broadening of intrinsic parton transverse momentum k_T [19,20] and modification of jet fragmentation [21]. Thus the measurement of jet fragmentation properties and intrinsic parton transverse momentum k_T for $p + p$ collisions presented here provides a baseline for comparison to the results in heavy-ion collisions, helping to disentangle the complex processes of propagation and possible fragmentation of partons within the excited nuclear medium.

This paper is organized as follows: Sec. II discusses the method of two-particle correlations and the relations between jet properties and the angular correlation between parton fragments. The details of the PHENIX experiment relevant to this analysis are outlined in Section III. Section IV deals with the analysis of the correlation functions extracted from the $p + p$ data and an evaluation of the $\langle j_T \rangle$ and $\langle k_T \rangle$ quantities. The combined analysis of the inclusive and associated p_T-distributions is discussed in Sec. V and the sensitivity of the associated p_T-distributions to the fragmentation function is discussed in Sec. VI. Section VII presents the resulting values of the partonic transverse momenta k_T corrected for the mean momentum fraction $\langle z_t \rangle$. Section VIII summarizes the results from this paper.

II. JET ANGULAR CORRELATIONS

Jets are produced in the hard scattering of two partons [22–25]. The overall $p + p$ hard-scattering cross section in ''leading logarithm'' pQCD is the sum over parton reactions $a + b \rightarrow c + d$ (e.g. $g + q \rightarrow g + q$) at parton-parton center-of-mass (c.m.) energy $\sqrt{\hat{s}}$,

$$\frac{d^3\sigma}{dx_1 dx_2 d\cos\theta^*} = \frac{1}{s}\sum_{ab} f_a(x_1) f_b(x_2) \frac{\pi \alpha_s^2(Q^2)}{2x_1 x_2} \Sigma^{ab}(\cos\theta^*), \tag{1}$$

where $f_a(x_1)$, $f_b(x_2)$, are parton distribution functions, the differential probabilities for partons a and b to carry momentum fractions x_1 and x_2 of their respective protons (e.g. $u(x_2)$), and where θ^* is the scattering angle in the parton-parton c.m. system. The parton-parton c.m. energy squared is $\hat{s} = x_1 x_2 s$, where $\sqrt{s}$ is the c.m. energy of the $p + p$ collision. The parton-parton c.m. system moves with rapidity $y = (1/2)\ln(x_1/x_2)$ in the $p + p$ c.m. system.

Equation (1) gives the p_T spectrum of outgoing parton c (emitted at θ^*), which then fragments into hadrons, e.g. a π^0. The fragmentation function $D_c^{\pi^0}(z, \mu^2)$ is the probability for a π^0 to carry a fraction $z = p^{\pi^0}/p^c$ of the momentum of outgoing parton c. Equation (1) must be summed over all subprocesses leading to a π^0 in the final state. The parameter μ^2 is an unphysical ''factorization'' scale intro-

duced to account for collinear singularities in the structure and fragmentation functions [26,27], which will be ignored for the purposes of this paper.

In this formulation, $f_a(x_1)$, $f_b(x_2)$, and $D_c^{\pi^0}(z)$ represent the ''long-distance phenomena'' to be determined by experiment; while the characteristic subprocess angular distributions, $\Sigma^{ab}(\cos\theta^*)$, and the coupling constant, $\alpha_s(Q^2) = \frac{12\pi}{25\ln(Q^2/\Lambda^2)}$, are fundamental predictions of QCD [28–30] for the short-distance, large-Q^2, phenomena. The momentum scale $Q^2 \sim p_T^2$ for the scattering subprocess, while $Q^2 \sim \hat{s}$ for a Compton or annihilation subprocess, but the exact meaning of Q^2 tends to be treated as a parameter rather than a dynamical quantity.

Figure 1 shows a schematic view of a hard-scattering event. The transverse momentum of the outgoing scattered parton is

$$p_T = p_T^* = \frac{\sqrt{\hat{s}}}{2}\sin\theta^*. \tag{2}$$

The two scattered partons propagate nearly back-to-back in azimuth from the collision point and fragment into the jetlike spray of final state particles [see Fig. 1(a) where only one fragment of each parton is shown).

It was originally thought that parton collisions were collinear with the $p + p$ collision axis so that the two emerging partons would have the same magnitude of transverse momenta pointing opposite in azimuth.

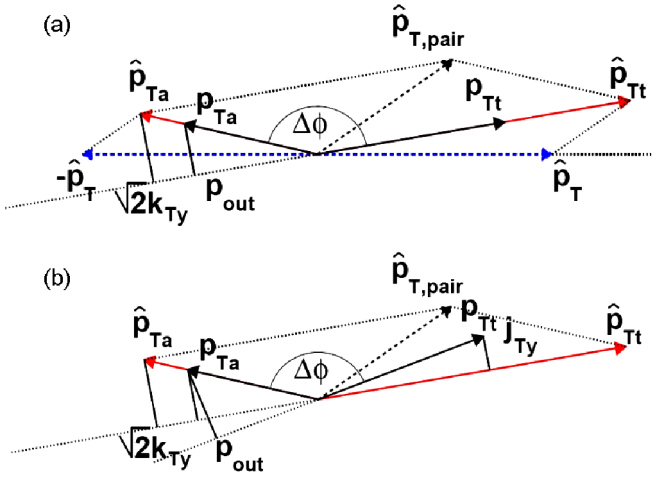

FIG. 1 (color online). (a) Schematic view of a hard-scattering event in the plane perpendicular to the beam. Two scattered partons with transverse momenta $\hat{p}_T$ in the partons' center-of-mass frame are seen in the laboratory frame to have a momenta $\hat{p}_{Tt}$ and $\hat{p}_{Ta}$. The net pair transverse momentum $\hat{p}_{T,pair}$ pair corresponds to the sum of the $\vec{k}_T$-vectors of the two colliding partons. The trigger and associated jet fragments producing high-p_T particles are labeled as p_{Tt} and p_{Ta}. The projection of $\vec{k}_T$ perpendicular to $\hat{p}_{Tt}$ is labeled as k_{Ty}. The transverse momentum component of the away-side particle $\vec{p}_{Ta}$ perpendicular to trigger particle $\vec{p}_{Tt}$ is labeled as p_{out}. (b) The same schematics as in (a), but the jet-fragmentation transverse momentum component j_{Ty} of the trigger jet is also shown.

However, it was found [3] that each of the partons carries initial transverse momentum $\vec{k}_T$, originally described as ''intrinsic'' [31]. This results in a momentum imbalance (the partons' p_T are not equal) and an acoplanarity (the transverse momentum of one jet does not lie in the plane determined by the transverse momentum of the second jet and the beam axes). The jets are noncollinear having a net transverse momentum $\langle p_T^2\rangle_{pair} = 2\cdot\langle k_T^2\rangle$.

It is important to emphasize that the $\langle k_T\rangle$ denotes the effective magnitude of the apparent transverse momentum of each colliding parton. The net transverse momentum of the outgoing parton-pair is $\sqrt{2}\cdot\langle k_T\rangle$. The naive expectation for the pure intrinsic parton transverse momentum based on nucleon constituent quark mass is about $\approx$ 300 MeV/c [31,32]. However, the measurement of net transverse momenta of diphotons, dileptons, or dijets over a wide range of center-of-mass energies gives $\langle k_T\rangle$ as large as 5 GeV/c [33]. It is common to think of the net transverse momentum of a dilepton or dijet pair as composed of 3 components:

$$\frac{\langle p_T^2\rangle_{pair}}{2} = \langle k_T^2\rangle = \langle k_T^2\rangle_{intrinsic} + \langle k_T^2\rangle_{soft} + \langle k_T^2\rangle_{NLO}, \tag{3}$$

where the intrinsic part refers to the possible ''fermi motion'' of the confined quarks or gluons inside a proton, the NLO part refers to the power law tail at large values of $p_{T_{pair}}$ due to the radiation of an initial state or final state hard gluon, which is divergent as the momentum of the radiated gluon goes to zero, and the soft part refers to the actual Gaussian-like distribution observed as $p_{T_{pair}} \to 0$, which is explained by resummation [34].

In the discussion below we will assume that the two components of the vector $\vec{k}_T$, k_{Tx} and k_{Ty} are Gaussian distributed with equal standard deviations $\sigma_{1parton,1D}$, in which case $k_T^2 = k_{Tx}^2 + k_{Ty}^2$ is distributed according to a 2-dimensional (2D) Gaussian [33]. For the net transverse momentum of the jet pair, $\langle p_T^2\rangle_{pair} = \sigma^2_{2partons,2d} = 2\sigma^2_{1parton,2d}$. Note that the principal difference between the 1 and 2 dimensional Gaussians is that $\langle k_{Tx}\rangle = \langle k_{Ty}\rangle = 0$, while $\langle k_T\rangle \neq 0$ since $\vec{k}_T$ is a 2D radius vector.

The two components of k_T result in different experimentally measurable effects. k_{Ty} leads to the acoplanarity of the dijet pair while k_{Tx} makes the momenta of the jets unequal which results in the smearing of the steeply falling p_T spectrum. This causes the measured inclusive jet or single particle cross section to be larger than the pQCD value given by Eq. (1). This was observed in the original discovery of high p_T particle production at the CERN ISR in 1972 [35] and led to much confusion until the existence and effects of k_T were understood.

Before the advent of QCD, the invariant cross section for the hard-scattering of the electrically charged partons of deeply inelastic scattering was predicted for $p + p$ collisions to follow a general scaling form [22,36]:

$$E\frac{d^3\sigma}{d^3p} = \frac{1}{p_{\mathrm{T}}^n}F(x_T) = \frac{1}{\sqrt{s}^n}G(x_T), \tag{4}$$

where $x_T = 2p_{\mathrm{T}}/\sqrt{s}$. The cross section has two factors, a function $F(x_T)$ ($G(x_T)$) which "scales," i.e. depends only on the ratio of momenta, and a dimensioned factor, $1/p_{\mathrm{T}}^n$ ($1/\sqrt{s}^n$), where n equals 4 for QED, and for LO-QCD [Eq. (4)], analogous to the $1/q^4$ form of Rutherford scattering. The structure and fragmentation functions are all in the $F(x_T)$ ($G(x_T)$) term. The original high p_T measurements at CERN [35] and Fermilab [37], showed beautiful x_T scaling, but with a value of $n = 8$ instead of $n = 4$, for values of $3 \le p_{\mathrm{T}} \le 7$ GeV/c. Later measurements at larger p_{T} showed the correct scaling in agreement with pQCD and it was realized that the value $n = 8$ at lower values of p_{T} and $\sqrt{s}$ was produced by the $k_{T\mathrm{x}}$ smearing [23,24]. More recently, the deviation of π^0 and direct photon inclusive cross sections measurements from pQCD predictions has been used to derive the values of k_T required to bring the measured and smeared pQCD predictions into agreement [33].

A more direct method to determine k_{Ty} is to measure the acoplanarity of the dijet pair. Such measurements were originally performed at the CERN-ISR using two-particle correlations [1–3,31]. The same method will be used in the present work.

Hard-scattering in $p + p$ collisions at $\sqrt{s} = 200$ GeV is detected by triggering on a π^0 with transverse momentum $p_{\mathrm{T_t}} \ge 3$ GeV/c; and the properties of jets are measured using the method of two-particle correlations. The trigger π^0 is a leading particle from a large transverse momentum jet while the associated particle comes from either the same jet or the away-side jet. We will analyze an outgoing dijet pair, with trigger jet transverse momentum magnitude $\hat{p}_{\mathrm{Tt}}$ which fragments to a trigger particle with transverse momentum $\vec{p}_{\mathrm{Tt}}$, and an away-side jet transverse momentum magnitude of $\hat{p}_{\mathrm{Ta}}$ which fragments to a particle with transverse momentum $\vec{p}_{\mathrm{Ta}}$. The average transverse momentum component of the away-side particle $\vec{p}_{\mathrm{Ta}}$ perpendicular to trigger particle $\vec{p}_{\mathrm{Tt}}$ in the azimuthal plane is labeled as p_{out}. If the magnitude of the jet transverse fragmentation momentum j_{T} [Fig. 1(a)] is neglected, the magnitude of $\sqrt{2}k_{\mathrm{Ty}}$ can be related to p_{out}: $\sqrt{2}k_{\mathrm{Ty}} = p_{\mathrm{out}}\hat{p}_{\mathrm{Ta}}/p_{\mathrm{Ta}} \equiv p_{\mathrm{out}}/z_{\mathrm{a}}$. Thus the measurement of p_{out} and the knowledge of the fragmentation variable (z_{a}) determines the magnitude of the parton's transverse momentum k_{T}.

The smearing of the steeply falling parton $\hat{p}_{\mathrm{T}}$ spectrum by the k_{Tx} distribution tends to make the trigger jet transverse momentum $\hat{p}_{\mathrm{Tt}}$ larger than the away-jet transverse momentum $\hat{p}_{\mathrm{Ta}}$. The component of the net transverse momentum of the parton pair along the trigger direction is smeared by $\sqrt{2}k_{T\mathrm{x}}$ such that

$$\langle(\hat{p}_{\mathrm{Tt}} - \hat{p}_{\mathrm{Tax}})^2\rangle = 2\langle k_{\mathrm{Tx}}^2\rangle = \langle k_{\mathrm{T}}^2\rangle. \tag{5}$$

For a flat $\hat{p}_T$ spectrum, the smearing would average to zero so that there would be no net shift in the transverse momentum spectrum:

$$\langle\hat{p}_{\mathrm{Tt}} - \hat{p}_{\mathrm{T}}\rangle = \langle\hat{p}_{\mathrm{T}} - \hat{p}_{\mathrm{Tax}}\rangle = 0. \tag{6}$$

However, due to the steeply falling $\hat{p}_{\mathrm{T}}$ spectrum, the k_{Tx} smearing results in a net imbalance of the jet-pair towards the trigger direction. In the limit when k_{T} is collinear with the trigger jet and with the requirement of the Lorentz invariance of $\hat{s}$ ($\hat{p}_{\mathrm{T}}^2 = \hat{p}_{\mathrm{Tt}}\hat{p}_{\mathrm{Ta}}$) it is easy to see that

$$\langle\hat{p}_{\mathrm{Tt}} - \hat{p}_{\mathrm{T}}\rangle = \left\langle\frac{\hat{p}_{\mathrm{Tt}}}{\hat{p}_{\mathrm{T}}}(\hat{p}_{\mathrm{T}} - \hat{p}_{\mathrm{Ta}})\right\rangle \simeq \frac{1}{2}\langle\hat{p}_{\mathrm{Tt}} - \hat{p}_{\mathrm{Ta}}\rangle > 0. \tag{7}$$

We denote the imbalance of $\hat{p}_{\mathrm{Ta}}$ and $\hat{p}_{\mathrm{Tt}}$ by the quantity

$$\hat{x}_{\mathrm{h}} = \langle\hat{p}_{\mathrm{Ta}}\rangle/\langle\hat{p}_{\mathrm{Tt}}\rangle. \tag{8}$$

Jet fragments have a momentum $\vec{j}_{\mathrm{T}}$ perpendicular to the partonic transverse momentum [Fig. 1(b)]. This vector is again a two-dimensional vector with one component perpendicular to the jet transverse axis, $\vec{j}_{\mathrm{T}}$, in the transverse plane and the other component perpendicular to the jet transverse axis in the longitudinal plane (defined by the beam and jet axes). The component of $\vec{j}_{\mathrm{T}}$ projected onto the azimuthal plane is labeled as j_{Ty}. The magnitude of $\langle j_{\mathrm{Ty}}\rangle$, the mean value of j_{T} projected into the plane perpendicular to the jet thrust (see Appendix A), measured at lower energies [1] has been found to be p_{T} independent and $\approx$ 400 MeV/c, consistent with measurements in e^+e^- collisions [38,39].

This analysis uses two-particle azimuthal correlation functions to measure the average relative angles between a trigger π^0 and an associated charged hadron. The angular width of the near- and away-side peak in the correlation function is used to extract the value of $\langle j_{\mathrm{T}}^2\rangle$ and $\hat{x}_{\mathrm{h}}^{-1}\langle z_{\mathrm{t}}\rangle \times \sqrt{\langle k_{\mathrm{T}}^2\rangle}$. An analysis of the associated yields is used to confirm the fragmentation function which provides the $\langle z_{\mathrm{t}}\rangle$ and $\langle z_{\mathrm{a}}\rangle$ values used for $\langle k_{\mathrm{T}}^2\rangle$ extraction. The details on the PHENIX experiment relevant to this analysis follow.

III. EXPERIMENTAL DETAILS

The PHENIX experiment consists of four spectrometer arms—two around mid-rapidity (the central arms) and two at forward rapidity (the muon arms)—along with a set of global detectors. The layout of the PHENIX experiment during the 2003 RHIC run is shown in Fig. 2.

Each central arm covers the pseudorapidity range $|\eta| <$ 0.35 and 90 degrees in azimuthal angle ϕ. In each of the central arms, charged particles are tracked by a drift chamber (DC) positioned from 2.0 to 2.4 m radially outward from the beam axis and 2 or 3 layers of pixel pad chambers (PC1, PC2, PC3 located at 2.4 m, 4.2 m, 5 m in the radial direction, respectively). Particle identification is provided

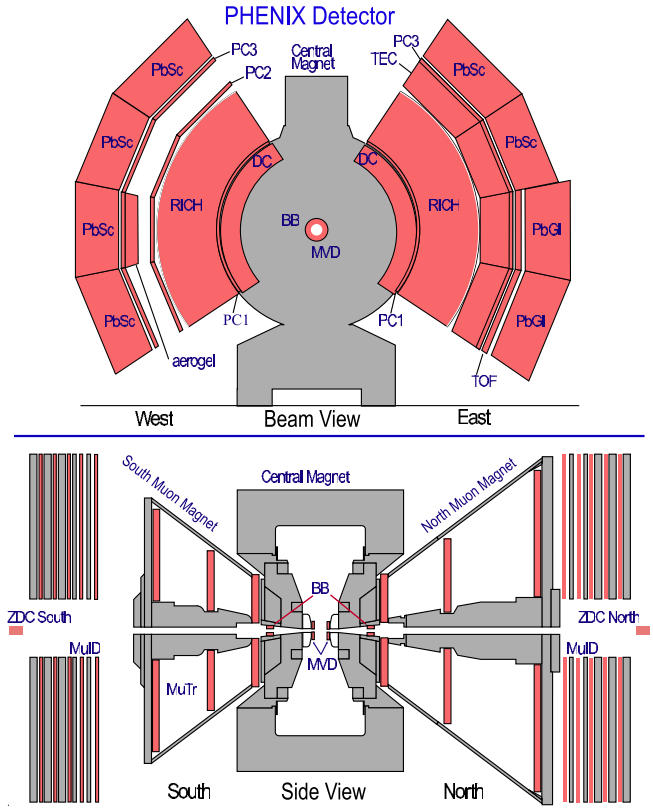

FIG. 2 (color online). The PHENIX experimental layout for the 2003 Au + Au run. The top panel shows the PHENIX central arm spectrometers viewed along the beam axis. The bottom panel shows a side view of the PHENIX muon arm spectrometers and the position of the global detectors (BBC and ZDC).

by ring imaging Čerenkov counters (RICH), a time of flight scintillator wall (TOF), and two types of electromagnetic calorimeters (EMCal), lead scintillator (PbSc) and lead glass (PbGl). The magnetic field for the central arm spectrometers is axially symmetric around the beam axis. Its component parallel to the beam axis has an approximately Gaussian dependence on the radial distance from the beam axis, dropping from 0.48 T at the center to 0.096 T (0.048 T) at the inner (outer) radius of the DC. A pair of zero-degree calorimeters (ZDC) and a pair of beam-beam counters (BBC) were used for global event characterization. Further details about the design and performance of PHENIX can be found in [40–42].

A $p + p$ data sample corresponding to an integrated luminosity 0.35 pb^{-1} at $\sqrt{s} = 200$ GeV has been used for the present analysis. It contains a minimum bias (MB) sample of 121 M events and a high-p_T triggered sample of 50 M events. The MB trigger is obtained from the charge multiplicity in the two BBCs situated at large pseudorapidity ($\eta \approx \pm(3.0\text{–}3.9)$). The BBCs were also used to determine the collision vertex, which is limited to a ± 30 cm range in this analysis. The high-p_T trigger requests an additional discrimination on sums of the analog signals from nonoverlapping, 2×2 groups of adjacent EMCal towers situated at mid-rapidity ($|\eta| < 0.35$) equivalent to an energy deposition of 750 MeV [43]. The analysis has been performed separately on the two data sets and no trigger selection bias was found within the quoted errors.

Neutral pions, which are used as trigger particles, are detected by the reconstruction of their $\gamma\gamma$ decay channel. Photons are detected in the EMCal, which has a timing resolution of ≈ 100 ps (PbSc) and ≈ 300 ps (PbGl) and energy resolution of $\sigma_E/E = 1.9\% \oplus 8.2\%/\sqrt{E(\text{GeV})}$ (PbSc) and $\sigma_E/E = 0.8\% \oplus 8.4\%/\sqrt{E(\text{GeV})}$ (PbGl). In order to improve the signal/background ratio we require the minimum hit energy >0.3 GeV, a shower profile cut as described in [41], and no accompanying hit in the RICH detector, which serves as a veto for conversion electrons. A sample of the invariant mass distribution of photon pairs detected in the EMCal is shown in Fig. 3.

Charged particles are reconstructed in each PHENIX central arm using a drift chamber, followed by two layers of multiwire proportional chambers with pad readout [40]. Particle momenta are measured with a resolution $\delta p/p = 0.7\% \oplus 1.1\% p\,(\text{GeV}/c)$. A confirmation hit is required in PC3. We also require that no signal in the RICH detector is associated with these tracks. These requirements eliminate charged particles which do not originate from the event vertex, such as beam albedo and weak decays, as well as conversion electrons.

High momentum charged pions (above the RICH Čerenkov threshold) are identified using the RICH and EMCal detectors. Candidate tracks must be associated

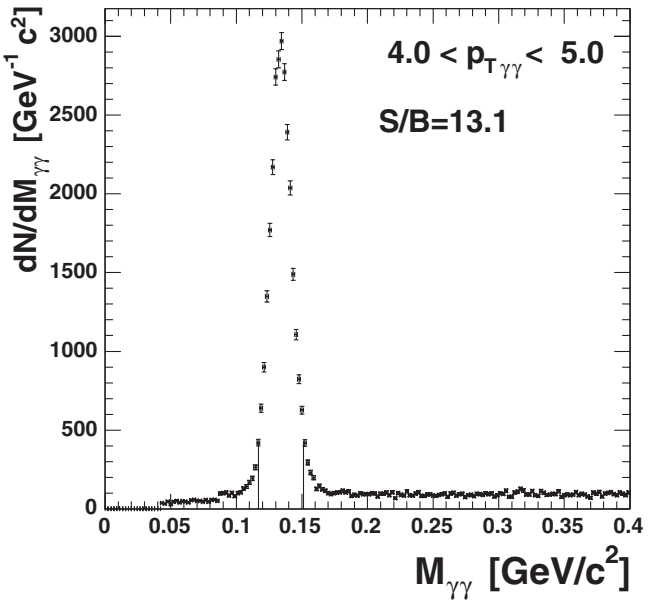

FIG. 3. The measured $\gamma\gamma$ invariant mass distribution for pair p_T in $4 < p_{T\gamma\gamma} < 5$ GeV/c. The peak is fitted with a Gaussian. The signal/background ratio within 2σ of the mean ranges from ≈ 6 at p_T of 3 GeV/c up to ≈ 15 at 8 GeV/c.

with a hit in the RICH [44], which corresponds to a minimum momentum of 18 MeV/c for electrons, 3.5 GeV/c for muons, and 4.9 GeV/c for charged pions. In a previous PHENIX publication [45], we have shown that charged particles with reconstructed p_T above 4.9 GeV/c, which have an associated hit in the RICH, are dominantly charged pions and background electrons from photon conversions albedo. The efficiency for detecting charged pions rises quickly past 4.9 GeV/c, reaching an efficiency of >90% at $p_T > 6$ GeV/c.

To reject the electron background in the charged pion candidates, the shower information at the EMCal is used. Since most of the background electrons are genuine low p_T particles that were misreconstructed as high p_T particles, simply requiring a large deposition of shower energy in the EMCal is effective in suppressing the electron background. In this analysis, a momentum- dependent energy cut on the EMCal is applied

$$\mathrm{E}\ \ (\mathrm{GeV}) > 0.3 + 0.15 p_T. \tag{9}$$

In addition to this energy cut, the shower shape information [41] is used to further separate the broad hadronic showers from the narrow electromagnetic showers and hence reduce the conversion backgrounds. The difference of the EM shower and hadronic shower is typically characterized by a χ^2 variable [41],

$$\chi^2 = \sum_i \frac{(\mathrm{E}_i^{\mathrm{meas}} - \mathrm{E}_i^{\mathrm{pred}})^2}{\sigma_i^2}, \tag{10}$$

where $\mathrm{E}_i^{\mathrm{meas}}$ is the energy measured at tower i and $\mathrm{E}_i^{\mathrm{pred}}$ is the predicted energy for an electromagnetic particle of total energy $\sum_i \mathrm{E}_i^{\mathrm{meas}}$.

In this analysis we use the probability calculated from this χ^2 value for an EM shower, ranging from 0 to 1 with a flat distribution expected for an EM shower, and a peak around 0 for an hadronic shower.

Figure 4 shows the probability distribution for pion and electron candidates, each normalized to one. The pion candidates were required to pass the energy cut and the electrons were selected using particle ID cuts similar to that used in [46]. The electron distribution is relatively flat, while the charged pion distribution peaks at 0. A cut of shower shape probability <0.2 selects pions above the energy cut with an efficiency of $\gtrsim 80\%$. Detailed knowledge of the pion efficiency is not necessary, since we present in this paper the per trigger pion conditional-yield distributions, for which this efficiency cancels out.

Since the energy and shower shape cuts are independent of each other, we can fix one cut and then vary the second to check the remaining background level from conversions. The energy cut in Eq. (9) is chosen such that the raw pion yield is found to be insensitive to the variation in the shower shape probability. Figure 5 shows the raw pion spectra for EMCal-RICH triggered events as a function of p_T, with the above cuts applied. The pion turn on from

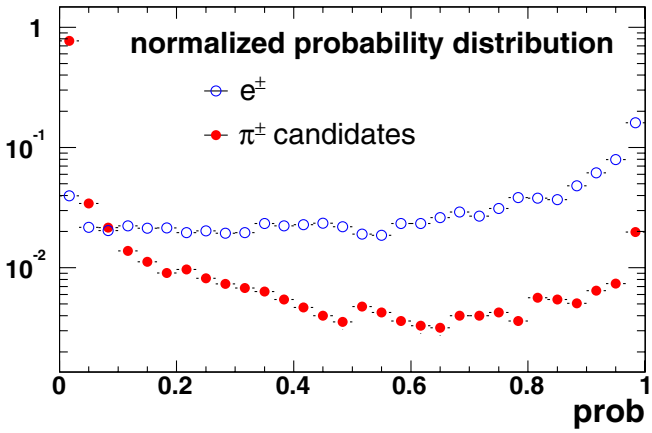

FIG. 4 (color online). The probability distribution for charged pion candidates and electrons derived from the EM shower shape using identified electrons and pions. The integrals have been normalized to one.

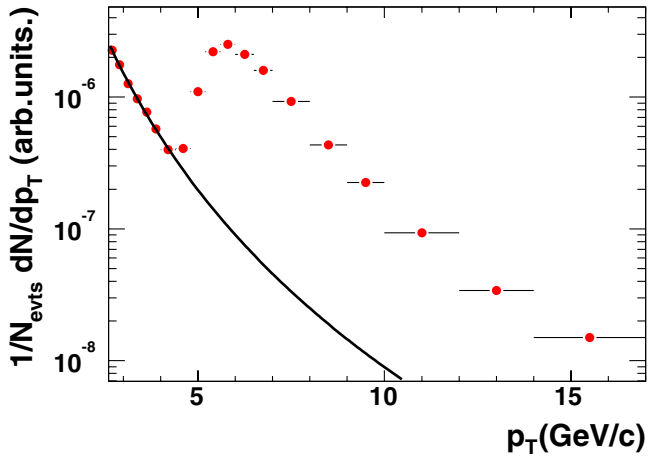

FIG. 5 (color online). The raw charged pion transverse momentum spectrum, with the final cuts applied. The level of the remaining background is estimated from an extrapolation from low-p_T and is shown as a black line.

4.9–7 GeV/c is clearly visible. Below p_T of 5 GeV/c, the remaining background comes mainly from the random association of charged particles with hits in the RICH detector. The background level is less than 5% from 5–16 GeV/c, which is the p_T range for the charged pion data presented in this paper.

IV. CORRELATION FUNCTION

The analysis uses two-particle azimuthal correlation functions between a neutral pion and an associated charged hadron to measure the distribution of the azimuthal angle difference $\Delta\phi = \phi_t - \phi_a$ (see Fig. 6). Whenever a π^0 was found in an event, the real, $dN_{\mathrm{uncorr}}/d\Delta\phi$, and mixed, $dN_{\mathrm{mix}}/d\Delta\phi$, distributions for given p_{Tt} (π^0) and p_{Ta} (charged hadron) were accumulated (upper panel of Fig. 6). Mixed events were obtained by randomly selecting

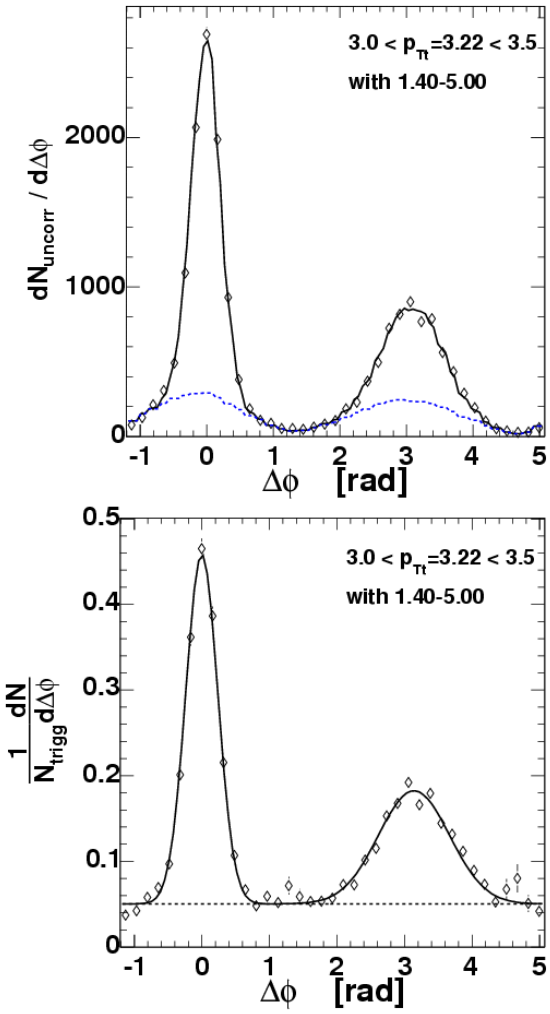

FIG. 6 (color online). An example of the correlation functions for $3 < p_{\mathrm{Tt}} < 3.5$ GeV/c and associated particles in $1.4 < p_{\mathrm{Ta}} < 5$ GeV/c. (upper) Unnormalized pair-yield distribution plotted with the fit function which is two Gaussians modulated by the pair detection efficiency derived from the mixed distribution (dashed line). (lower) Per π^0 trigger yield distribution corrected for the pair detection efficiency. Dashed line represents the constant term in the fit.

each member of a particle pair from different events having similar vertex position. Then the mixed event distribution was used to correct the correlation function for effects of the limited PHENIX azimuthal acceptance and for the detection efficiency, to the extent that it remains constant over the data sample.

We fit the raw $dN_{\mathrm{uncorr}}/d\Delta\phi$ distribution with the product

$$\frac{dN_{\mathrm{uncorr}}}{d\Delta\phi} = \frac{1}{\mathcal{N}} \frac{dN_{\mathrm{mix}}}{d\Delta\phi} \cdot (C_0 + C_1 \cdot f_{\mathrm{near}}(\Delta\phi) + C_2 \cdot f_{\mathrm{away}}(\Delta\phi)), \tag{11}$$

where the mixed event distribution is normalized to 2π ($\mathcal{N} = \sum dN^i_{\mathrm{mix}}/d\Delta\phi$ see dashed line on the upper panel of Fig. 6), C_{0-2} are constant factors to be determined from the fit, $f_{\mathrm{near}}(\Delta\phi)$ and $f_{\mathrm{away}}(\Delta\phi)$ are the near- and away-side peak fit functions, respectively. Traditionally, the Gaussian functions, around $\Delta\phi = 0$ and around $\Delta\phi = \pi$, are used for $f_{\mathrm{near}}(\Delta\phi)$ and $f_{\mathrm{away}}(\Delta\phi)$. This leaves a total of five free parameters to be determined - the areas and widths of the above two Gaussians: Y_{N}, σ_{N} for the near-angle component and Y_F, σ_{A} for the away-angle component and the constant term describing an uncorrelated distribution of particle pairs which are not associated with jets. However, the assumption of the Gaussian shape of the angular correlation induced by jet fragmentation is justified only in the high-p_{T} region where the relative angles are small. In order to access also a lower p_{T} region we used an alternative parameterization of $f_{\mathrm{near}}(\Delta\phi)$ and $f_{\mathrm{away}}(\Delta\phi)$ which will be discussed later in the text.

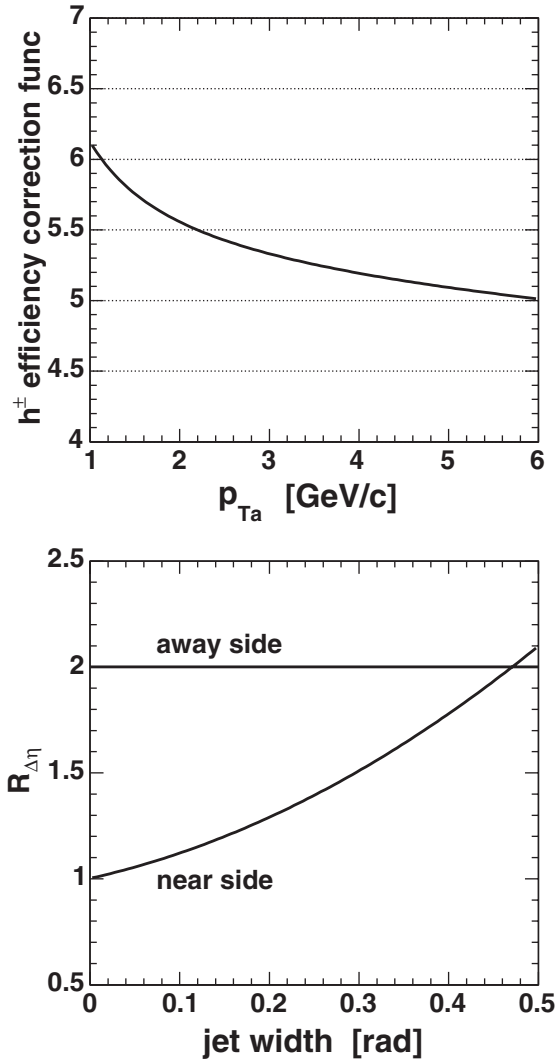

FIG. 7. (upper) Inclusive charged hadron efficiency correction function. (lower) η acceptance correction factor for loss of jet pairs outside the limited η-acceptance of the PHENIX experiment.

The normalized correlation function was constructed as a ratio of real and mixed distributions multiplied by η-acceptance correction factor $R_{\Delta\eta}$, divided by p_T-dependent efficiency correction $\epsilon(p_T)$ (see upper panel of Fig. 7) and divided by the number of π^0 triggers.

$$\frac{1}{N_{\rm trigg}}\frac{dN}{d\Delta\phi} = \frac{R_{\Delta\eta}}{N_{\rm trigg}\epsilon(p_T)}\frac{dN_{\rm uncorr}(\Delta\phi)/d\Delta\phi}{dN_{\rm mix}(\Delta\phi)/d\Delta\phi}\cdot\mathcal{N}. \tag{12}$$

The $R_{\Delta\eta}$ correction factor which accounts for limited η acceptance of the PHENIX experiment (see right panel of Fig. 7) for the near-side yield, with an assumption that the angular jet width is the same in $\Delta\eta$ and in $\Delta\phi$, can be written as

$$R_{\Delta\eta} = \frac{1}{\frac{1}{\sqrt{2\pi\sigma_N^2}}\int_{-0.7}^{0.7}\exp(-\frac{\Delta\eta}{2\sigma_N^2})acc(\Delta\eta)d\Delta\eta}, \tag{13}$$

where $acc(\Delta\eta)$ represent the PHENIX pair acceptance function in $|\Delta\eta|$. It can be obtained by convolving two flat distributions in $|\Delta\eta| < 0.35$, so $acc(\Delta\eta)$ has a simple triangular shape: $acc(\Delta\eta) = (0.7 - |\Delta\eta|)/0.7$. For the away-side yield the corresponding $R_{\Delta\eta}$ is

$$\mathrm{R}_{\Delta\eta} = \frac{2(0.7)}{\int_{-0.7}^{0.7}\mathrm{acc}(\Delta\eta)d\Delta\eta} = 2. \tag{14}$$

$R_{\Delta\eta}$ equals 2, because the pair efficiency has a triangular shape in $|\Delta\eta| < 0.7$, which results in 50% average efficiency when the real jet-pair distribution is flat in $|\Delta\eta| < 0.7$. Figure 8 and Table I show the normalized correlation functions for various $p_{\rm Tt}$ and $p_{\rm Ta}$.

For two particles with transverse momenta $p_{\rm Tt}$, $p_{\rm Ta}$ from the same jet, the width of the near-side correlation distribution can be related to the RMS value of the j_T vector component, $j_{\rm Ty}$, perpendicular to the parton momentum as

$$\sigma_N^2 = \langle\Delta\phi^2\rangle = \left\langle\left(\frac{j_{\rm Ty}}{p_{\rm Ta}}\right)^2 + \left(\frac{j_{\rm Ty}}{p_{\rm Tt}}\right)^2\right\rangle, \tag{15}$$

where we assume $\langle j_{\rm Ty}^2\rangle \ll p_{\rm Tt}^2$ and $p_{\rm Ta}^2$ and thus the arcsine function can be approximated by its argument and we

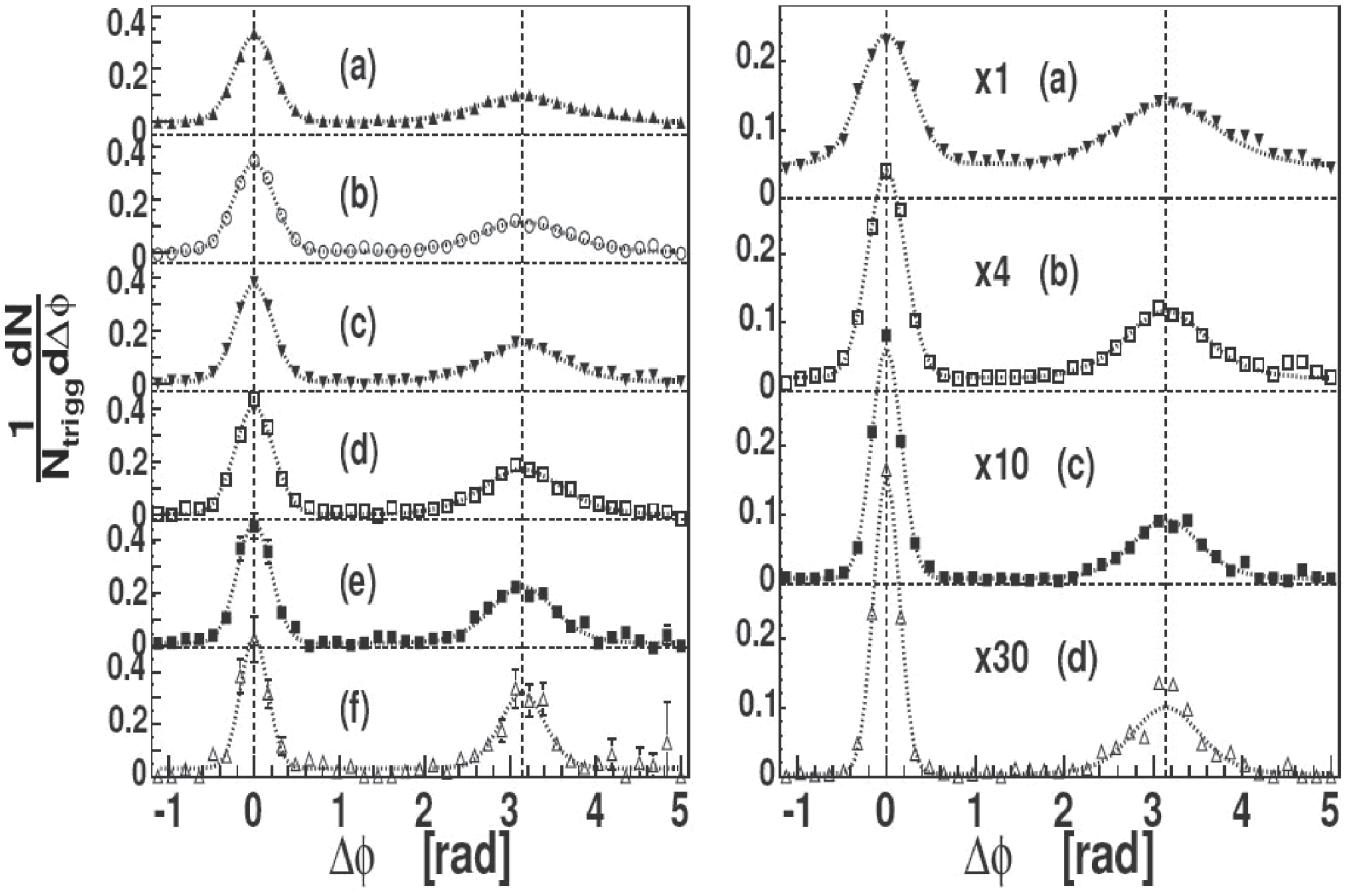

FIG. 8. (left) Measured yield of charged hadrons with away-side transverse momentum $1.4 < p_{\rm Ta} < 5.0$ GeV/c associated with a trigger π^0 of transverse momenta given in in Table I. (right) Measured yield of charged hadrons associated with a trigger π^0 of fixed transverse momentum $3.0 < p_{\rm Tt} < 10.0$ GeV/c and the away-side transverse momenta given in Table I. The dashed lines corresponds to the fit of two Gaussian functions representing the trigger (t) jet and away-side (a) jet correlation. The χ^2 (d.o.f.) σ_N and $\sqrt{\langle p_{\rm out}^2\rangle}$ values extracted from these fits are tabulated in Table I.

TABLE I. The χ^2 (d.o.f.) σ_N and $\sqrt{\langle p_{\rm out}^2\rangle}$ values extracted for the correlation function shown in Fig. 8. All units in rad and GeV/c. Only the statistical errors are shown.

(f) 6.5–8.0	31.6	$0.16 \pm 1 \times 10^{-2}$	0.64 ± 0.06				

can solve for [47]

$$\sqrt{\langle j_{\rm T}^2\rangle} = \sqrt{2\langle j_{\rm Ty}^2\rangle} \simeq \sqrt{2}\frac{p_{\rm Tt}p_{\rm Ta}}{\sqrt{p_{\rm Tt}^2 + p_{\rm Ta}^2}}\sigma_{\rm N}. \quad (16)$$

In order to extract $\langle|k_{\rm Ty}|\rangle$, or $\langle k_{\rm T}^2\rangle$, we start with the relation [1,31] between the magnitude of $p_{\rm out}$ (see Fig. 1),

$$p_{\rm out} = p_{\rm Ta}\sin\Delta\phi, \quad (17)$$

which is the transverse momentum component of the away-side particle $\vec{p}_{\rm Ta}$ perpendicular to trigger particle $\vec{p}_{\rm Tt}$ in the azimuthal plane (see Fig. 1), and $k_{\rm Ty}$:

$$\langle|p_{\rm out}|\rangle^2 = x_{\rm E}^2[2\langle|k_{\rm Ty}|\rangle^2 + \langle|j_{\rm Ty}|\rangle^2] + \langle|j_{\rm Ty}|\rangle^2, \quad (18)$$

where

$$x_{\rm E} = -\frac{\vec{p}_{\rm Tt}\cdot\vec{p}_{\rm Ta}}{p_{\rm Tt}^2} = -\frac{p_{\rm Ta}\cos\Delta\phi}{p_{\rm Tt}} \simeq \frac{z_{\rm a}\hat{p}_{\rm Ta}}{z_{\rm t}\hat{p}_{\rm Tt}} \quad (19)$$

represents the fragmentation variable of the away-side jet. [2,3] We note however, that [31] explicitly neglected $\langle z_{\rm t}\rangle = \langle p_{\rm Tt}/\hat{p}_{\rm Tt}\rangle$ in the formula at ISR energies, where $\langle z_{\rm t}\rangle \simeq 0.85$, while it is not negligible at $\sqrt{s} = 200$ GeV. Furthermore, as mentioned earlier, the average values of trigger and associated jet momenta are generally not the same. There is a systematic momentum imbalance due to $k_{\rm T}$-smearing of the steeply falling parton momentum distribution. The event sample with a condition of $p_{\rm Tt} > p_{\rm Ta}$ is dominated by configurations where the $k_{\rm T}$-vector is parallel to the trigger jet and antiparallel to the associated jet and $\langle\hat{p}_{\rm Tt} - \hat{p}_{\rm Ta}\rangle \neq 0$. Here we introduce the hadronic variable $x_{\rm h}$ in analogy to the partonic variable $\hat{x}_{\rm h}$

$$x_{\rm h} \equiv \frac{p_{\rm Ta}}{p_{\rm Tt}}, \qquad \hat{x}_{\rm h} = \hat{x}_{\rm h}(\langle k_{\rm T}^2\rangle, x_{\rm h}) \equiv \frac{\langle\hat{p}_{\rm Ta}\rangle}{\langle\hat{p}_{\rm Tt}\rangle}. \quad (20)$$

The detailed discussion on the magnitude of this imbalance is given later. In order to derive the relation between the magnitude of $p_{\rm out}$ and $k_{\rm T}$ let us first consider the simple case where we have neglected both trigger and associated $\langle j_{\rm T}\rangle$ [see panel (a) on Fig. 1]. In this case one can see that

$$\langle|p_{\rm out}|\rangle|_{j_{\rm Tt}=j_{\rm Ta}=0} \equiv \langle|p_{\rm out}|\rangle_{00} = \sqrt{2}\langle|k_{\rm Ty}|\rangle\frac{p_{\rm Ta}}{\langle\hat{p}_{\rm Ta}\rangle}$$
$$= \sqrt{2}\langle|k_{\rm Ty}|\rangle\langle z_{\rm t}\rangle\frac{x_{\rm h}}{\hat{x}_{\rm h}}.$$

Rewriting the formula for $p_{\rm out}$ in terms of RMS we get

$$\sqrt{\langle p_{\rm out}^2\rangle_{00}} = \langle z_{\rm t}\rangle\sqrt{\langle k_{\rm T}^2\rangle}\frac{x_{\rm h}}{\hat{x}_{\rm h}},$$

where we have taken $\langle k_{\rm T}^2\rangle = \langle 2k_{\rm Ty}^2\rangle$.

However, the jet fragments are produced with finite jet transverse momentum $j_{\rm T}$. The situation when the trigger particle is produced with $j_{\rm Tty} > 0$ GeV/c and the associated particle with $j_{\rm Tay} = 0$ GeV/c is shown in Fig. 1(b). The $p_{\rm out}$ vector picks up an additional component

$$\langle p_{\rm out}^2\rangle|_{j_{\rm Tt}>0, j_{\rm Ta}=0} = \left[\langle p_{\rm out}^2\rangle_{00} + \frac{\langle j_{\rm Tty}^2\rangle}{p_{\rm Tt}^2}(p_{\rm Ta}^2 - \langle p_{\rm out}^2\rangle_{00})\right]$$
$$\times \frac{p_{\rm Tt}^2 - \langle j_{\rm Tty}^2\rangle}{p_{\rm Tt}^2}.$$

With an assumption of $j_{\rm Tty} \ll p_{\rm Tt}$ we found that

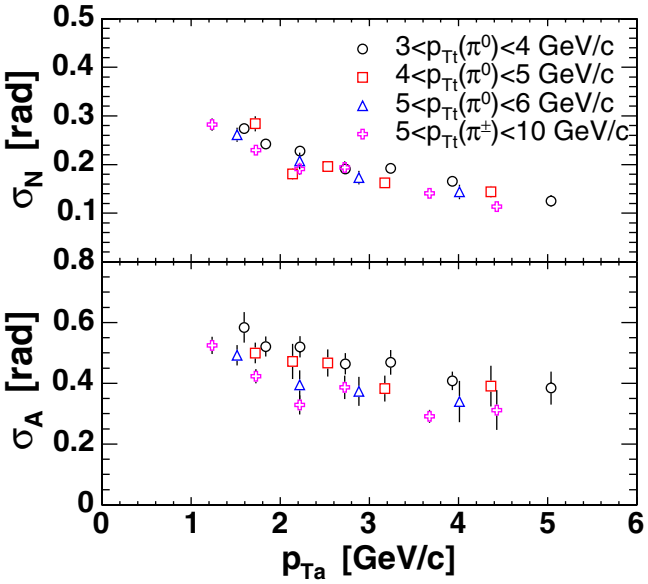

FIG. 9 (color online). (top) The width of the near-side peak $\sigma_{\rm N}$ with $p_{\rm Ta}$ for various values of $p_{\rm Tt}$ as indicated in legend. (bottom) The width of the far-side peak $\sigma_{\rm A}$ with $p_{\rm Ta}$ for the same $p_{\rm Tt}$ selection. The data values are given in Table II.

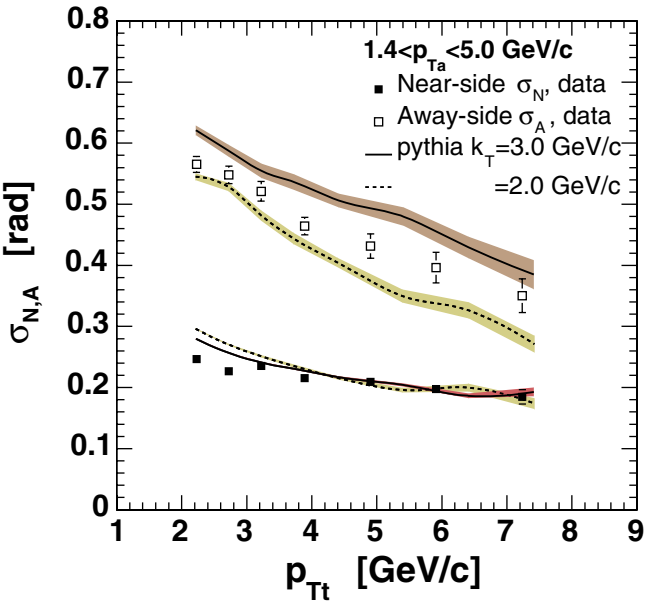

FIG. 10 (color online). The near-side (squares) and away-side (circles) width as a function or trigger-π^0 p_{Tt}. The associated charged particle momenta are in the $1.4 < p_{\mathrm{Ta}} < 5.0$ GeV/c region. The curves are from a PYTHIA calculation with the values of k_{T} indicated. The data values are given in Table III.

$$\langle p_{\mathrm{out}}^2\rangle|_{j_{\mathrm{Tt}}>0,j_{\mathrm{Ta}}=0} = x_{\mathrm{h}}^2\left[\langle z_{\mathrm{t}}\rangle^2\langle k_{\mathrm{T}}^2\rangle\frac{1}{\hat{x}_{\mathrm{h}}^2} + \langle j_{\mathrm{T_{ty}}}^2\rangle\right].$$

We include j_{Ta} in the same approximation, $j_{\mathrm{Tay}} \ll p_{\mathrm{Ta}}$, i.e. collinearity of j_{Ta} and p_{out} with result

$$\langle p_{\mathrm{out}}^2\rangle = x_{\mathrm{h}}^2\left[\langle z_{\mathrm{t}}\rangle^2\langle k_{\mathrm{T}}^2\rangle\frac{1}{\hat{x}_{\mathrm{h}}^2} + \langle j_{\mathrm{Tty}}^2\rangle\right] + \langle j_{\mathrm{Tay}}^2\rangle \qquad (21)$$

and we solve for $\langle z_{\mathrm{t}}\rangle\sqrt{\langle k_{\mathrm{T}}^2\rangle}/\hat{x}_h$

$$\frac{\langle z_{\mathrm{t}}\rangle\sqrt{\langle k_{\mathrm{T}}^2\rangle}}{\hat{x}_{\mathrm{h}}} = \frac{1}{x_{\mathrm{h}}}\sqrt{\langle p_{\mathrm{out}}^2\rangle - \langle j_{\mathrm{Tay}}^2\rangle - x_{\mathrm{h}}^2\langle j_{\mathrm{Tty}}^2\rangle}.$$

If we assume no difference between j_{Tt} and j_{Ta} then we have

TABLE III. The σ_{N} and σ_{A} values shown in Fig. 10. All units in rad and GeV/c. Only the statistical errors are shown.

7.23	0.185 ± 0.012	0.350 ± 0.028

$$\frac{\langle z_{\mathrm{t}}(k_{\mathrm{T}},x_{\mathrm{h}})\rangle\sqrt{\langle k_{\mathrm{T}}^2\rangle}}{\hat{x}_{\mathrm{h}}(k_{\mathrm{T}},x_{\mathrm{h}})} = \frac{1}{x_{\mathrm{h}}}\sqrt{\langle p_{\mathrm{out}}^2\rangle - \langle j_{\mathrm{Ty}}^2\rangle(1+x_{\mathrm{h}}^2)}. \qquad (22)$$

All quantities on the right-hand side of Eq. (22) can be directly extracted from the correlation function. The correlation functions are measured in the variable $\Delta\phi$ in bins of p_{Tt} and p_{Ta} (e.g. see Fig. 8), and the rms of the near and away peaks σ_{N} and σ_{A} are extracted. We tabulated σ_{N} and σ_{A} for many combinations of p_{Tt} and p_{Ta} (see Figs. 9 and 10 and Tables II and III).

Initially, we used the approximation $\sqrt{\langle p_{\mathrm{out}}^2\rangle} \sim p_{\mathrm{Ta}}\sin\sigma_{\mathrm{A}}$ in Eq. (22). However, we have noticed that this approximation and other approximations for $\sqrt{\langle p_{\mathrm{out}}^2\rangle}$ proposed e.g. in Ref. [48] (see Appendix B) are inadequate for $\sigma_{\mathrm{A}} > 0.4$ radians, so we do not use σ_{A} to calculate k_{T}.

We extract $\sqrt{\langle p_{\mathrm{out}}^2\rangle}$ directly for all values of p_{Tt} p_{Ta} (even for wide bins in p_{Ta} using the $\langle p_{\mathrm{Ta}}\rangle$ of the bin) by fitting the correlation function in the $\pi/2 < \Delta\phi < 3\pi/2$ region by

$$\frac{dN_{\mathrm{away}}}{d\Delta\phi}\Big|_{\pi/2}^{3\pi/2} = \frac{dN}{dp_{\mathrm{out}}}\frac{dp_{\mathrm{out}}}{d\Delta\phi} = \frac{-p_{\mathrm{Ta}}\cos\Delta\phi}{\sqrt{2\pi\langle p_{\mathrm{out}}^2\rangle}\,\mathrm{Erf}\left(\frac{\sqrt{2}p_{\mathrm{Ta}}}{\sqrt{\langle p_{\mathrm{out}}^2\rangle}}\right)}\exp\left(-\frac{p_{\mathrm{Ta}}^2\sin^2\Delta\phi}{2\langle p_{\mathrm{out}}^2\rangle}\right), \qquad (23)$$

where we assumed a Gaussian distribution in p_{out}. We still use a Gaussian function in $\Delta\phi$ in the near-angle peak to

TABLE II. Measured widths of the near- and away-angle $\pi^0 - h^{\pm}$ correlation peaks for various trigger particle momenta, as shown in Fig. 9. Only the statistical errors are shown.

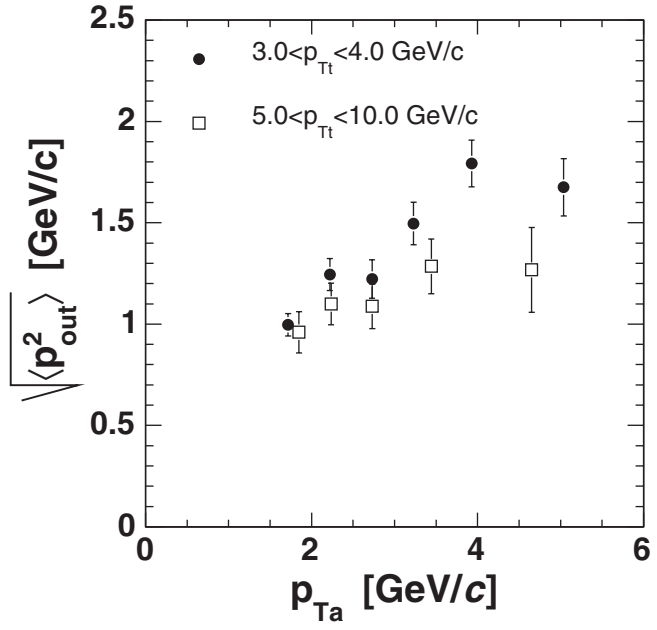

FIG. 11. Extracted values of $\sqrt{\langle p_{\rm out}^2\rangle}$ for $3.0 < p_{\rm Tt} < 4.0$ and $5.0 < p_{\rm Tt} < 10.0$ GeV/c for various values of $p_{\rm Ta}$ using the direct $p_{\rm out}$ extraction method based on fitting the away-side peak by Eq. (23).

extract $\sqrt{\langle j_{\rm T}^2\rangle}$. The $\sqrt{\langle p_{\rm out}^2\rangle}$ values extracted from the fit of the functional form (23) are shown in Figs. 11 and 12 and Table IV.

The per-trigger yields as a function of $p_{\rm Tt}$ for fixed associated $1.4 < p_{\rm Ta} < 5.0$ GeV/c bin are shown in Fig. 13 and Table V. There is a distinct behavior of the near-side yield which varies with trigger $p_{\rm Tt}$ much less than the away-side yield. For the away-side, this reflects the fact that the particle detected in the fixed associated bin are produced from the lower z region of the fragmentation function for events with higher trigger $p_{\rm Tt}$. For the near-side jet, this multiplicity increase is reduced due to the fact that with increasing $p_{\rm Tt}$ the near-side jet energy increases; however, at the same time the larger fraction of this energy is taken away by the more energetic trigger particle. Thus the relative change in z is smaller on the near side.

In order to extract $\langle z_{\rm t}\rangle$ and $\hat{x}_{\rm h}$ knowledge of the fragmentation function is needed; a detailed discussion is given in following sections.

A. $\sqrt{\langle j_{\mathrm{T}}^2\rangle}$ and $\hat{x}_{\mathrm{h}}^{-1}\langle z_{\mathrm{t}}\rangle\sqrt{\langle k_T^2\rangle}$ results

The measurement is performed in two different kinematical regimes; first the transverse momentum of the trigger particle, p_{Tt}, is fixed and the peak width is measured for different values of associated particle transverse momenta p_{Ta} (Fig. 9). (Note that in the region of overlap, the data are in excellent agreement with a previous measurement [9].) In the second case, particle pairs with a fixed associated bin $1.4 < p_{\mathrm{Ta}} < 5.0$ GeV/c and various p_{Tt} are selected (Fig. 10). It is evident that both near and away-side correlation peaks in all cases reveal a decreasing trend with p_{Ta} and p_{Tt}.

However, the asymptotic behavior of σ_{N} and σ_{A} is different. Whereas the magnitude of σ_{N}, according to Eq. (16), should vanish for large values of p_{Tt} and p_{Ta}, the σ_{A} according to Eq. (22) should be approximately constant around $\hat{x}_{\mathrm{h}}^{-1}\langle z_{\mathrm{t}}\rangle\sqrt{\langle k_{\mathrm{T}}^2\rangle}/p_{\mathrm{Tt}}$ for large values of p_{Ta}.

TABLE VI. The $\sqrt{\langle j_{\mathrm{T}}^2\rangle}$ values shown in Figs. 14 and 15. All units in rad and GeV/c. Only the statistical errors are shown.

$1.4 < p_{\mathrm{Ta}} < 5.0$		$3 < p_{\mathrm{Tt}} < 4$	
p_{Tt}	$\sqrt{\langle j_{\mathrm{T}}^2\rangle}$	p_{Ta}	$\sqrt{\langle j_{\mathrm{T}}^2\rangle}$

$4 < p_{\mathrm{Tt}} < 5$		$5 < p_{\mathrm{Tt}} < 6$	
p_{Ta}	$\sqrt{\langle j_{\mathrm{T}}^2\rangle}$	p_{Ta}	$\sqrt{\langle j_{\mathrm{T}}^2\rangle}$
1.72	0.643 ± 0.036	1.52	0.529 ± 0.030
2.14	0.492 ± 0.032	2.22	0.581 ± 0.049
2.53	0.608 ± 0.035	2.88	0.590 ± 0.047
3.17	0.590 ± 0.032	4.01	0.603 ± 0.063
4.36	0.631 ± 0.052		

The $\langle z_{\mathrm{t}}\rangle$ and $\hat{x}_{\mathrm{h}}$ quantities are implicitly p_{Ta} dependent, however, their ratio is roughly ~1 so that the asymptotic value of $\sigma_{\mathrm{A}}|_{p_{\mathrm{Ta}}\to\infty} \sim \langle k_{\mathrm{T}}^2\rangle/p_{\mathrm{Tt}}$.

Extracted values of $\langle j_{\mathrm{T}}^2\rangle$ as a function of p_{Ta} and p_{Tt} according to Eq. (16) are shown in Fig. 14 and 15 and Table VI. All $\langle j_{\mathrm{T}}^2\rangle$ values are constant in the explored region ($p_{\mathrm{Ta}} > 1.5$ GeV/c). It is expected that $\langle j_{\mathrm{T}}^2\rangle$ can not remain constant for arbitrarily small values of p_{Ta} because of the phase space limitation. In the region where

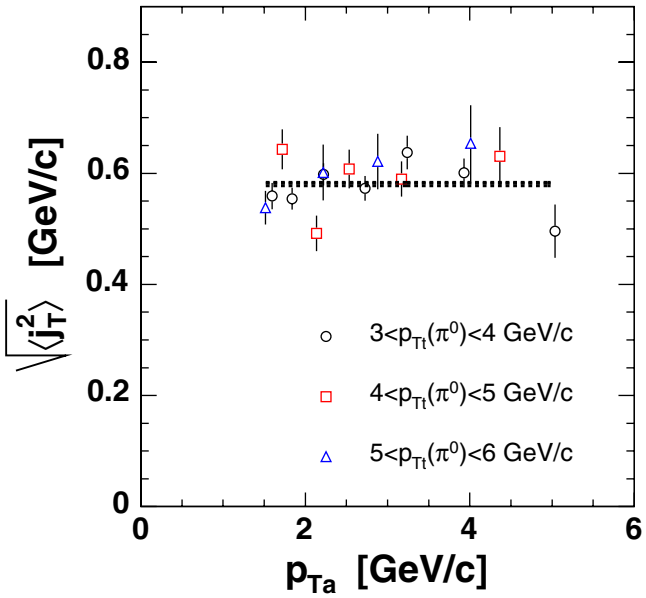

FIG. 14 (color online). $\sqrt{\langle j_{\mathrm{T}}^2\rangle}$ values calculated according Eq. (16). The dashed line represents a fit to a constant in the $1.5 < p_{\mathrm{Ta}} < 5$ GeV/c region. The data values are shown in Table VI.

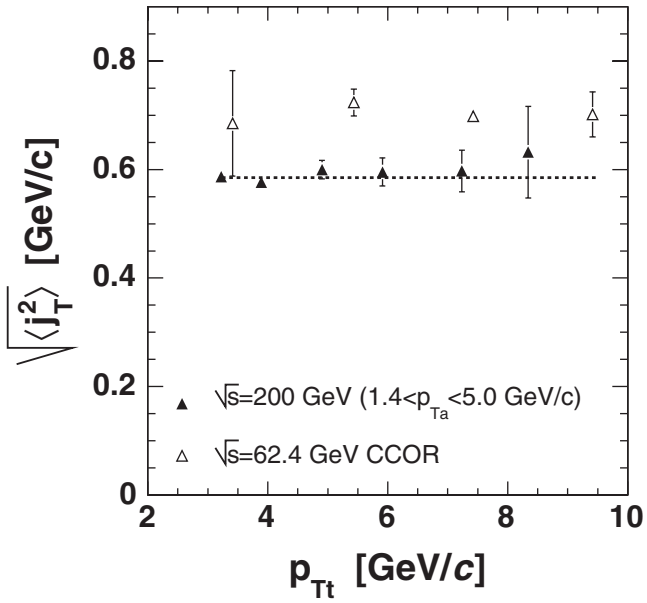

FIG. 15. Averaged values of $\sqrt{\langle j_{\mathrm{T}}^2\rangle}$ in ($1.5 < p_{\mathrm{Ta}} < 5$ GeV/c) as a function of the trigger transverse momentum p_{Tt} (solid triangles). The CCOR values measured at $\sqrt{s} = 62.4$ GeV shown by open triangles. The data values are shown in Table VI.

$p_{\mathrm{Ta}} \leq \sqrt{\langle j_T^2 \rangle}$, the magnitude of the j_{T}-vector is truncated, similar to the "seagull effect" [49]. Since the $\sqrt{\langle j_{\mathrm{T}}^2 \rangle}$ values are on the order of 600 MeV/c, we assume that the phase space limitation can be safely neglected for $p_{\mathrm{Ta}} > 1.5$ GeV/c and extract the value of $\sqrt{\langle j_{\mathrm{T}}^2 \rangle}$ averaged over p_{Ta} and p_{Tt}:

$$\sqrt{\langle j_{\mathrm{T}}^2 \rangle} = 585 \pm 6(\mathrm{stat}) \pm 15(\mathrm{sys})\ \mathrm{MeV/c}. \qquad (24)$$

The systematic error originates from the finite momentum resolution and Eq. (16) where we assume that the arcsine function can be approximated by its argument. For the angular width of the near-angle peak (see Fig. 9 and 10) it corresponds to an uncertainty of order of 3%.

The independence of $\langle j_T^2 \rangle$ on either p_{Tt} or $\sqrt{s}$ has been observed by the CCOR experiment in the range $\sqrt{s} =$ 31–62.4 GeV [1]. The $\langle j_{\mathrm{T}}^2 \rangle$ values at $\sqrt{s} = 62.4$ GeV (open triangles on Fig. 15) are systematically larger then values found in this analysis. The discrepancy should not be taken as significant, as CCOR used a slightly different technique than in this paper. CCOR extracted the $\langle j_{\mathrm{T}}^2 \rangle$ values from measurements of $\langle |p_{\mathrm{out}}| \rangle$ for different values of the x_E variable Eq. (19). According to Eq. (18) the $\langle |p_{\mathrm{out}}| \rangle^2$ magnitude should depend linearly on x_{E}^2; and the $\langle |j_{\mathrm{Ty}}| \rangle$ value was extracted from the intercept of the $\langle p_{\mathrm{out}}^2 \rangle(x_{\mathrm{E}})$ fit at $x_{\mathrm{E}} = 0$, rather than from a measurement of σ_{N}.

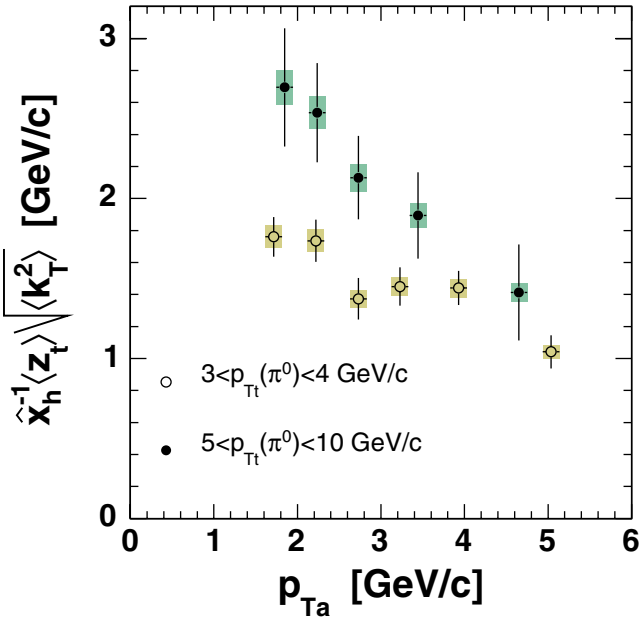

FIG. 16 (color online). $\hat{x}_{\mathrm{h}}^{-1}\langle z_{\mathrm{t}} \rangle \sqrt{\langle k_{\mathrm{T}}^2 \rangle}$ values calculated according to Eq. (22) for trigger π^0 in $3 < p_{\mathrm{Tt}} < 4$ GeV/c and $5 < p_{\mathrm{Tt}} < 6$ GeV/c as a function of p_{Ta}. The systematic uncertainties are indicated by the shaded boxes.

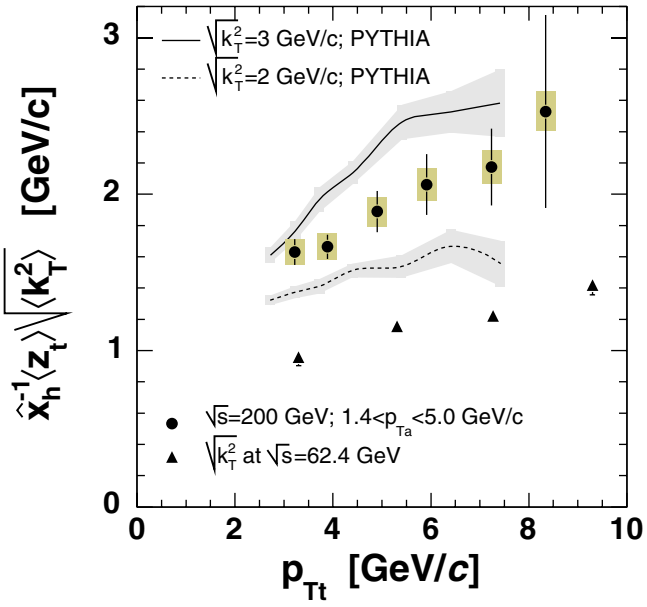

FIG. 17 (color online). The same calculation according Eq. (22) for fixed associated bin $1.4 < p_{\mathrm{Ta}} < 5.0$ GeV/c as a function of p_{Tt}. The systematic errors indicated by colored rectangles. The $\sqrt{\langle k_T^2 \rangle}$ results obtained by CCOR Collaboration at $\sqrt{s} = 62.4$ GeV [1] displayed by solid triangles.

Knowing the $\langle j_{\mathrm{T}}^2 \rangle$ and $\langle p_{\mathrm{out}}^2 \rangle$ values, we used Eq. (22) to determine $\hat{x}_{\mathrm{h}}^{-1}\langle z_t \rangle \sqrt{\langle k_{\mathrm{T}}^2 \rangle}$ (see Fig. 16 and Fig. 17). The systematic error was estimated with Monte Carlo simulations to be on the order of 5%. The main source of systematic error originates from the assumption [Eqs. (16) and (21)] of the relative smallness of $\langle j_{\mathrm{T}}^2 \rangle$, collinearity between p_{out} and j_{Tay} and from the limited momentum resolution discussed in Sec. III.

The p_{Ta} dependence of the extracted $\hat{x}_{\mathrm{h}}^{-1}\langle z_t \rangle \sqrt{\langle k_{\mathrm{T}}^2 \rangle}$ (Fig. 16) reveals a strikingly decreasing trend. It was originally expected that by fixing the value of p_{Tt}, the kinematics of the hard scattering (i.e. $\hat{p}_{\mathrm{Tt}} \simeq \hat{p}_{\mathrm{Ta}}$) would be fixed, independently of the value of p_{Ta}. Various values of p_{Ta} would then sample the $\hat{p}_{\mathrm{Ta}}$ fragmentation function, and the value of $\hat{x}_{\mathrm{h}}^{-1}\langle z_{\mathrm{t}} \rangle \langle k_{\mathrm{T}}^2 \rangle$ was expected to be constant. It is evident that this assumption is not quite correct.

A similar line of argument applies also for the rising trend when p_{Ta} is fixed and p_{Tt} varies (Fig. 17). It is interesting to note that the CCOR $\sqrt{\langle k_{\mathrm{T}}^2 \rangle}$ values measured at $\sqrt{s} = 62.4$ GeV (open triangles on Fig. 17) reveal a similar rising trend. However, the rising trend of $\hat{x}_{\mathrm{h}}^{-1}\langle z_{\mathrm{t}} \rangle \times \sqrt{\langle k_{\mathrm{T}}^2 \rangle}$ with p_{Tt} and falling with p_{Ta} suggests that the variation of $\sqrt{\langle k_{\mathrm{T}}^2 \rangle}$ with p_{Tt} seen by the CCOR Collaboration [1] may be indicative of the $\langle z_{\mathrm{t}} \rangle \hat{x}_{\mathrm{h}}^{-1}$ variation which was there neglected [50]. In order to understand

variation of $\langle z_t \rangle$ and $\hat{x}_h^{-1}$ we have to explore the process of dijet fragmentation.

V. FRAGMENTATION FUNCTIONS

We have shown in Eq. (22) that the width of the away-side correlation peak is related to the product of $\hat{x}_h^{-1}\langle z_t \rangle \times \sqrt{\langle k_T^2 \rangle}$. In order to evaluate $\langle z_t \rangle$, knowledge of the scattered parton $\hat{p}_T$ spectrum and fragmentation function is required.

Fragmentation functions from e^+e^- collisions, weighted by the appropriate hard-scattering constituent cross sections and Q^2 evolution could in principle be used. However, it was originally thought that the shape of the fragmentation function could be deduced from present measurements using the combined analysis of the inclusive trigger p_{Tt} and associated particle p_{Ta} distributions. Although this idea turned out to be incorrect, we will follow this line of reasoning for a while as it is instructive.

Generally, the invariant cross section for inclusive hadron production from jets can be parametrized in the following way. First, we assume that the number of parton fragments (consider only pions for simplicity) at a given p_T corresponds to the sum over all contributions from parton momenta, $\hat{p}_T$ from $p_T < \hat{p}_T < \sqrt{s}/2$. The joint probability of detecting a pion with $p_T = z\hat{p}_T$ originating from a parton with $\hat{p}_T$ can be written as

$$\frac{d^2\sigma_\pi}{\hat{p}_T d\hat{p}_T dz} = \frac{d\sigma_q}{\hat{p}_T d\hat{p}_T} \times D_\pi^q(z) = f_q(\hat{p}_T) \times D_\pi^q(z). \quad (25)$$

Here we use $f_q(\hat{p}_T)$ to represent the final state scattered-parton invariant spectrum $d\sigma_q/\hat{p}_T d\hat{p}_T$ and $D_\pi^q(z)$ to represent the fragmentation function. The first term in Eq. (25) can be viewed as a probability of finding a parton with transverse momentum $\hat{p}_T$ and the second term corresponds to the probability that the parton fragments into a particle of momentum $p_T = z\hat{p}_T$. With a simple change of variables from $\hat{p}_T$ to $p_T = z\hat{p}_T$, we obtain the joint probability of a pion with p_T which is a fragment with momentum fraction z from a parton with $\hat{p}_T = p_T/z$:

$$\frac{d^2\sigma_\pi}{p_T dp_T dz} = f_q\left(\frac{p_T}{z}\right) \cdot D_\pi^q(z)\frac{1}{z^2}. \quad (26)$$

The p_T and z dependences do not factorize. However, the p_T spectrum may be found by integrating over all values of $\hat{p}_T \geq p_T$ to $\hat{p}_T\,\mathrm{max} = \sqrt{s}/2$, which corresponds to values of z from $x_T = 2p_T/\sqrt{s}$ to 1.

$$\frac{1}{p_T}\frac{d\sigma_\pi}{dp_T} = \int_{x_T}^1 f_q\left(\frac{p_T}{z}\right) \cdot D_\pi^q(z)\frac{dz}{z^2}. \quad (27)$$

Alternatively, for any fixed value of p_T one can evaluate the $\langle z(p_T) \rangle$, integrated over the parton spectrum:

$$\langle z(p_T) \rangle = \frac{\int_{x_T}^1 z D_\pi^q(z) f_q(p_T/z)\frac{dz}{z^2}}{\int_{x_T}^1 D_\pi^q(z) f_q(p_T/z)\frac{dz}{z^2}}. \quad (28)$$

From the scaling properties of QCD and from the shape of the π^0 invariant cross section itself, which is a pure power law for $p_T \geq 3$ GeV/c [43], one can deduce that $f_q(\hat{p}_T)$ should have a power law shape, $f_q(\hat{p}_T) = A\hat{p}_T^{-n}$. In this case the hadron spectrum also has a power law shape because

$$\frac{1}{p_T}\frac{d\sigma_\pi}{dp_T} \approx \int_{x_T}^1 A D_\pi^q(z) \cdot \left(\frac{p_T}{z}\right)^{-n}\frac{dz}{z^2} \approx \frac{A}{p_T^n}\int_{x_T}^1 D_\pi^q(z) \cdot z^{n-2} dz \quad (29)$$

and the last integral depends only weakly on p_T due to the small value of x_T. For small parton $\hat{p}_T$ (below 3–4 GeV/c) the power law shape is no longer valid, but the region $p_T <$ 3 GeV/c is outside the scope of this paper. The $f_q(\hat{p}_T)$ should also diminish for very high $\hat{p}_T \rightarrow \sqrt{s}/2$ where the phase space available for hard parton production diminishes, again not relevant for the present purposes.

We used the power law parameterization for the final state scattered-parton invariant spectrum $f_q(\hat{p}_T) \propto \hat{p}_T^{-n}$ where n is a free parameter which can be determined from the fit of Eq. (27) to the measured π^0 cross section. There is, however, one more missing piece of information—the shape of the fragmentation function D_q^π. In an attempt to extract this information from the data, we have analyzed associated x_E-distributions, as shown in Table VII and Figs. 18–22.

A. "Scaling" variable x_E

It was expected [2] that the x_E variable, defined by Eq. (19), to first order, approximates the fragmentation function in the limit of high values of p_{Tt}, where there is sufficient collinearity between the trigger particle and the fragmenting parton. In this case where $j_T \ll p_{Tt}$ and $k_T \ll p_{Tt}$ one can assume that $p_{Tt} = \hat{p}_{Tt}/z_t$ and $x_E z_t = \hat{x}_h p_{Ta}\cos\Delta\phi/\hat{p}_{Ta} \simeq \hat{x}_h z_a$, and thus the slopes of $D(z_a)$ and x_E are related as

$$\langle z_a \rangle \approx \langle x_E \rangle \langle z_t \rangle \hat{x}_h^{-1}. \quad (30)$$

The x_E distributions of particles associated with trigger particles in the 3–8 GeV/c range of transverse momentum are plotted in Fig. 18. The dashed lines represent exponential fits. The slopes of these exponentials range from $-5.8 (3 < p_{Tt} < 4$ GeV/$c)$ to -7.8 (open symbols on Fig. 19). This is qualitatively and quantitatively different from the similar measurement done by CCOR Collaboration at $\sqrt{s} = 62.4$ GeV where the slopes of exponential fits to the x_E distributions were found to be ≈ -5.3 and independent of the trigger transverse momenta. That observation also supported the hypothesis of the x_E distribution being a good approximation of the fragmentation function. We also note that the x_E distributions are not quite exponential and at large values of x_E there is a tail similar to the power law tail of the single inclusive p_T distribution.

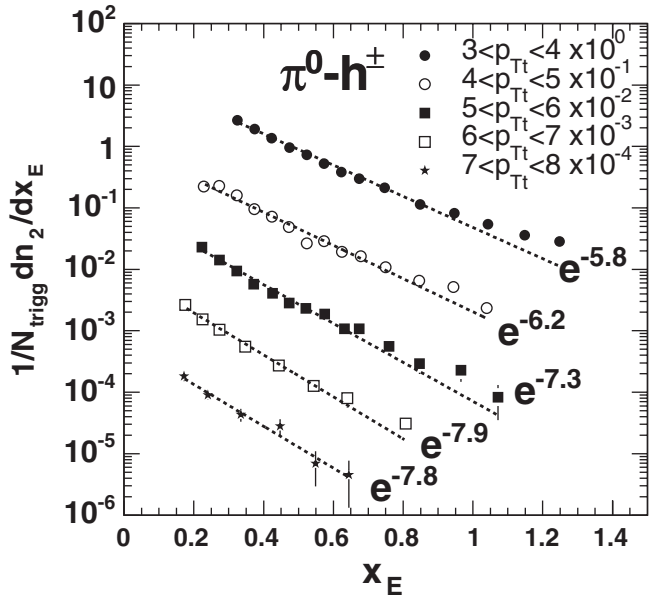

FIG. 18. The distribution of associated particles with x_E variable for various trigger particle p_{Tt} indicated in the legend. Exponential fits indicated by dashed lines.

The reason why the x_E distributions do not have the same slope for different p_{Tt} and why there is a ''power law'' tail at large x_E is the same as that which causes $\hat{x}_h^{-1}\langle z_t\rangle\sqrt{\langle k_T^2\rangle}$ to decrease with the associated particle transverse momentum. It turns out that by sampling different regions of p_{Ta} for fixed p_{Tt}, the average momentum of the parton fragmenting into a trigger particle, $\langle z_t\rangle$, also changes. This kind of trigger bias causes the hard-

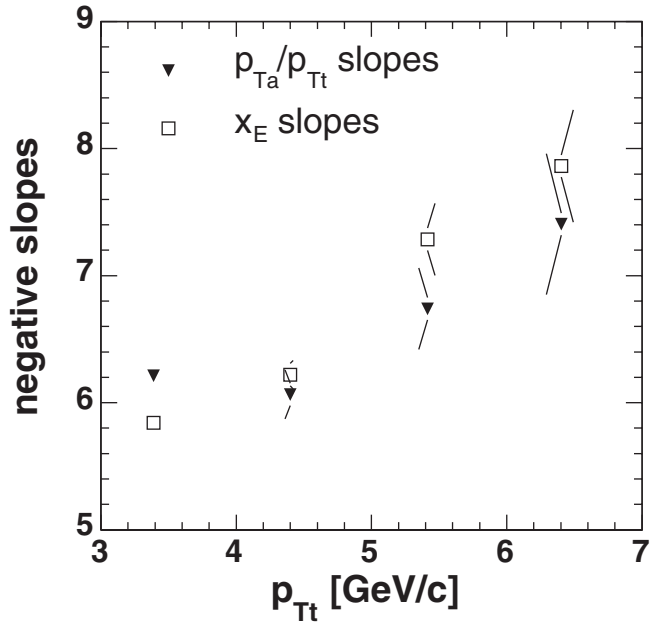

FIG. 19. The negative slope parameters extracted from the fit of a plain exponential function into a x_E (see Fig. 18) and p_{Ta}/p_{Tt} (see Fig. 20) distributions.

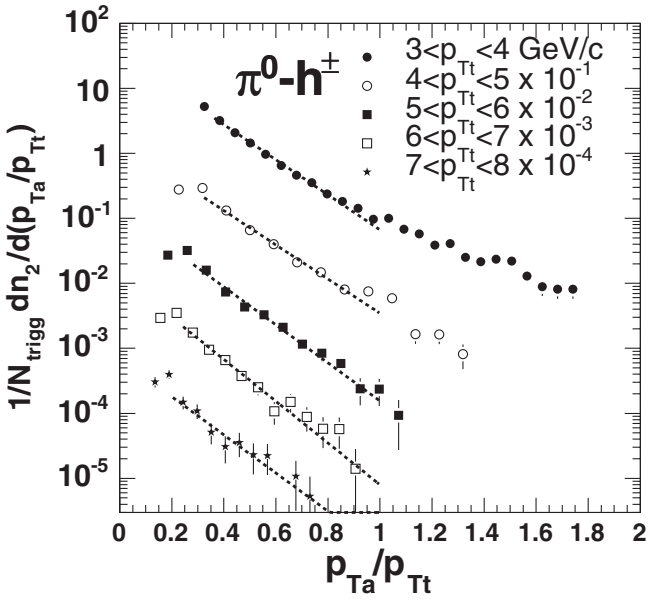

FIG. 20. The distribution of associated particles with p_{Ta}/p_{Tt} variable for various trigger particle p_{Tt} indicated in the legend. The distribution were fitted in the limited range $0.2 < p_{Ta}/p_{Tt} < 0.4$ by an exponential function (dashed lines).

scattering kinematics, the value of $\hat{p}_T$, to not be fixed for the case where p_{Tt} is fixed but p_{Ta} varies.

Taking this into account, one can not treat the associated x_E distribution as a rescaled fragmentation function, but rather as a folding of the two fragmentation processes of trigger and associated jets. The same line of arguments applies also for other two-particle variables, e.g. p_{Ta}/p_{Tt}, [51] used for an approximation of the fragmentation variable z (see Fig. 20). The negative slopes of an exponential fit in the $0.2 < p_{Ta}/p_{Tt} < 0.4$ range (solid symbols on Fig. 19) are, within the error bars, the same as for x_E.

In conclusion: the slope parameters extracted from associated x_E distributions reveal the rising trend with p_{Tt} which reflects the fact, that the different p_{Ta} samples not only different z_a but also different z_t.

The description of an associated distribution detected under the condition of the existence of a trigger particle requires an extension of the formulae discussed in Sec. V and is a subject of the next section.

VI. DIJET FRAGMENTATION

For the description of the detection of a single particle which is the result of jet fragmentation, recall Eq. (25)

$$\frac{d^2\sigma_\pi}{d\hat{p}_T dz_t} = \frac{d\sigma_q}{d\hat{p}_T} \times D_\pi^q(z_t) = \hat{p}_T f_q(\hat{p}_T) \times D_\pi^q(z_t) \equiv \Sigma_q(\hat{p}_T) \times D_\pi^q(z_t), \quad (31)$$

where we have now explicitly labeled the z of the trigger particle as z_t, and defined

$$\Sigma_q(\hat{p}_T) \equiv \hat{p}_T f_q(\hat{p}_T) = \frac{d\sigma_q}{d\hat{p}_T}. \quad (32)$$

When k_T smearing is introduced, configurations for which the high p_T parton pair is on the average moving towards the trigger particle are favored due to the steeply falling $\hat{p}_T$ spectrum, such that

$$\langle \hat{p}_{Tt} - \hat{p}_T \rangle \simeq \tfrac{1}{2}\langle \hat{p}_{Tt} - \hat{p}_{Ta} \rangle \equiv s(k_T)$$

with small variance σ_s^2, and we explicitly introduced $\hat{p}_{Tt}$ and $\hat{p}_{Ta}$ to represent the transverse momenta of the trigger and away partons. The single inclusive p_{Tt} spectrum is now given by

$$\frac{d^2\sigma_\pi}{d\hat{p}_{Tt}dz_t} = \Sigma'_q(\hat{p}_{Tt}) \times D_\pi^q(z_t) = \frac{z_t d^2\sigma_\pi}{dp_{T_t}dz_t}, \quad (33)$$

where the trigger parton $\hat{p}_{Tt}$ spectrum after k_T smearing is

$$\Sigma'_q(\hat{p}_{Tt}) \equiv \hat{p}_{Tt} f'_q(\hat{p}_{Tt}) = \frac{d\sigma_q}{d\hat{p}_{Tt}}. \quad (34)$$

Then, the conditional probability for finding the away-side parton with $\hat{p}_{Ta}$ and z_a, given $\hat{p}_{Tt}$ (and z_t), is

$$\left.\frac{dP(\hat{p}_{Ta}, z_a)}{d\hat{p}_{Ta}dz_a}\right|_{\hat{p}_{Tt}} = C(\hat{p}_{Ta}, \hat{p}_{Tt}, k_T) D_\pi^q(z_a),$$

where $C(\hat{p}_{Ta}, \hat{p}_{Tt}, k_T)$ represents the distribution of the transverse momentum of the away parton $\hat{p}_{Ta}$, given $\hat{p}_{Tt}$ and k_T, which can be written as

$$C(\hat{p}_{Ta}, \hat{p}_{Tt}, k_T) = \frac{1}{\sqrt{2\pi\sigma_s^2}} \times \exp\left(\frac{-[\hat{p}_{Ta} - (\hat{p}_{Tt} - 2s(k_T))]^2}{2\sigma_s^2}\right). \quad (35)$$

Then

$$\frac{d^4\sigma_\pi}{d\hat{p}_{Tt}dz_t d\hat{p}_{Ta}dz_a} = \frac{d^2\sigma_\pi}{d\hat{p}_{Tt}dz_t} \times \left.\frac{dP(\hat{p}_{Ta}, z_a)}{d\hat{p}_{Ta}dz_a}\right|_{\hat{p}_{Tt}}.$$

In general, $\sigma_s/s(k_T)$ is small (see Sec. VI B) so that $C(\hat{p}_{Ta}, \hat{p}_{Tt}, k_T)$ is well approximated by a δ function and we may take

$$\hat{p}_{Ta} = \hat{p}_{Tt} - 2s(k_T) = \hat{x}_h \hat{p}_{Tt},$$

so that

$$\frac{d^3\sigma_\pi}{d\hat{p}_{Tt}dz_t dz_a} = \Sigma'_q(\hat{p}_{Tt}) D_\pi^q(z_t) D_\pi^q(z_a),$$

where

$$z_a = \frac{p_{Ta}}{\hat{p}_{Ta}} = \frac{p_{Ta}}{\hat{x}_h \hat{p}_{Tt}} = \frac{z_t p_{Ta}}{\hat{x}_h p_{Tt}}.$$

Changing variables from $\hat{p}_{Tt}$, z_t to p_{Tt}, z_t as above, and similarly from z_a to p_{Ta}, we obtain

$$\frac{d^3\sigma_\pi}{dp_{Tt}dz_t dp_{Ta}} = \frac{1}{\hat{x}_h p_{Tt}} \Sigma'_q\left(\frac{p_{Tt}}{z_t}\right) D_\pi^q(z_t) D_\pi^q\left(\frac{z_t p_{Ta}}{\hat{x}_h p_{Tt}}\right), \quad (36)$$

where for integrating over z_t or finding $\langle z_t \rangle$ for fixed p_{Tt}, p_{Ta}, the minimum value of z_t is $z_t^{\min} = 2p_{Tt}/\sqrt{s} = x_{Tt}$ and the maximum value is

$$z_t^{\max} = \hat{x}_h \frac{p_{Tt}}{p_{Ta}} = \frac{\hat{x}_h}{x_h},$$

where $\hat{x}_h(p_{Tt}, p_{Ta})$ is also a function of k_T [Eq. (20)].

Thus, in order to evaluate $\hat{x}_h(p_{Tt}, p_{Ta})$ for use in Eq. (36), k_T must be known. We attack this problem by successive approximations. First we solve for k_T and $D_\pi^q(z)$ assuming $\hat{x}_h = 1$ as done at the ISR where the smearing correction was small. Then we solve for $\hat{x}_h(p_{Tt}, p_{Ta})$ with this value of k_T and iterate. On the first solution we solve only for $\Sigma'_q(\hat{p}_{Tt})$ while on the iteration we include the k_T smearing to solve for the unsmeared parton spectrum $\Sigma_{q(\hat{p}_T)} = \hat{p}_T f_q(\hat{p}_T)$ [Eq. (32)].

A. Sensitivity of the associated spectra to the fragmentation function

As discussed in Sec. V A, the associated x_E distribution was thought to approximate the fragmentation function of the away jet. Equation (36) can be transformed to the x_E distribution at fixed p_{Tt} with a change of variables from p_{Ta} to x_E followed by integration over z_t:

$$\frac{d^2\sigma}{dp_{Tt}dx_E} = \frac{dp_{Ta}}{dx_E} \times \frac{d^2\sigma}{dp_{Tt}dp_{Ta}} \simeq \frac{1}{\hat{x}_h} \int_{x_{Tt}}^{\hat{x}_h(p_{Tt}/p_{Ta})} D_\pi^q(z_t) D_\pi^q\left(\frac{z_t p_{Ta}}{\hat{x}_h p_{Tt}}\right) \Sigma'_q\left(\frac{p_{Tt}}{z_t}\right) dz_t. \quad (37)$$

We at first attempted to solve for the fragmentation function by simultaneous fits of the measured x_E distributions to Eq. (37) constrained by a fit of the inclusive invariant π^0 cross section to Eq. (27). There were difficulties with convergence.

The reason for the lack of convergence became apparent when we calculated x_E distributions according to Eq. (37) (Fig. 21) for two different fragmentation functions corresponding to quark and gluon jet fragmentation. A simple exponential parameterization was used and the slopes were obtained from the fit to the LEP data [52,53] (Fig. 22). For quark and gluon jets, we found $D_q(z) \approx \exp(-8.2 \cdot z)$ and $D_g(z) \approx \exp(-11.4 \cdot z)$ respectively. For the parton final state spectrum, we used $\Sigma'_q \propto \hat{p}_T^{-8}$. It is evident that the x_E distributions calculated for the quite different quark and gluon fragmentation functions do not differ significantly (the difference between solid and dashed lines on Fig. 21). Clearly, the x_E distributions are rather insensitive to the fragmentation functions of the away jet in contradiction to the previous conventional wisdom. The evidence of this explicit counter example led to attempts to perform the

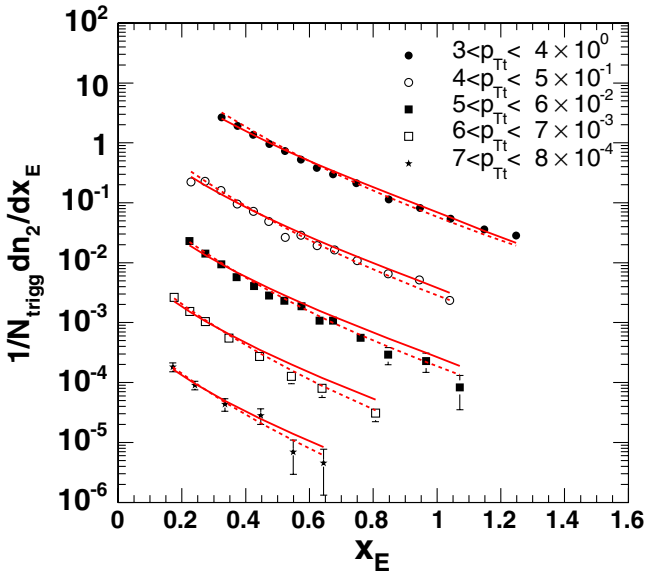

FIG. 21 (color online). The same x_E distributions as on Fig. 18 shown with calculations according to Eq. (37) for quark (solid lines) and for gluon (dashed lines) $D(z)$. An exponential approximation was used and the slopes for quark and gluon fragmentation function were obtained by fitting to LEP data [52,53] (see Fig. 22).

integrals of Eq. (33) and (36) analytically which straightforwardly confirmed the observation that the x_E distribution is not sensitive to the fragmentation function.

If the smeared trigger parton spectrum is taken as a power law,

$$\Sigma'_q\left(\frac{p_{\mathrm{Tt}}}{z_t}\right) = A\left(\frac{p_{\mathrm{Tt}}}{z_t}\right)^{-(n-1)}$$

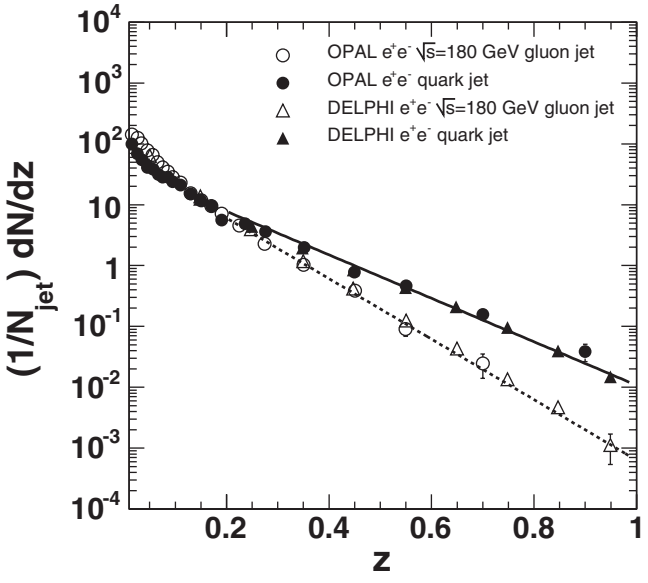

FIG. 22. Fragmentation function measured in e^+e^- collisions at $\sqrt{s} = 180$ GeV for gluon and quark jets. The solid and dashed lines represent the exponential fit in the $0.2 < z < 1$ region.

and the fragmentation function as an exponential, $D(z) = B\exp(-bz)$, then the integral of Eq. (36) over z_t becomes

$$\frac{d\sigma_\pi}{dp_{\mathrm{Tt}}dp_{\mathrm{Ta}}} = \frac{B^2}{\hat{x}_h}\frac{A}{p_{\mathrm{T_t}}^n}\int_{x_{\mathrm{T_t}}}^{\hat{x}_h(p_{\mathrm{Tt}}/p_{\mathrm{Ta}})} dz_t z_t^{n-1} \times \exp\left[-bz_t\left(1+\frac{p_{\mathrm{Ta}}}{\hat{x}_h p_{\mathrm{Tt}}}\right)\right], \quad (38)$$

which is an incomplete gamma function. Since $\hat{x}_h \sim 1$, we make the assumption that it is constant. Similarly, the integrals of Eqs. (29) and (33) are also incomplete gamma functions:

$$\frac{d\sigma_\pi}{dp_{\mathrm{Tt}}} = \frac{AB}{p_{\mathrm{T_t}}^{n-1}}\int_{x_{\mathrm{T_t}}}^1 dz_t z_t^{n-2}\exp[-bz_t]. \quad (39)$$

A reasonable approximation for the inclusive single, and two-particle cross sections is obtained by taking the lower limit to zero and the upper limit to infinity, leading to the replacement of the incomplete gamma functions by gamma functions, with the result that

$$\frac{d^2\sigma_\pi}{dp_{\mathrm{Tt}}dp_{\mathrm{Ta}}} \approx \frac{\Gamma(n)}{b^n}\frac{B^2}{\hat{x}_h}\frac{A}{p_{\mathrm{T_t}}^n}\frac{1}{(1+\frac{p_{\mathrm{Ta}}}{\hat{x}_h p_{\mathrm{Tt}}})^n}, \quad (40)$$

$$\frac{d\sigma_\pi}{dp_{\mathrm{Tt}}} \approx \frac{\Gamma(n-1)}{b^{n-1}}\frac{AB}{p_{\mathrm{T_t}}^{n-1}}, \quad (41)$$

where $\Gamma(n) = (n-1)\Gamma(n-1)$.

The conditional probability is just the ratio of the joint probability Eq. (40) to the inclusive probability Eq. (41), or

$$\left.\frac{dP_\pi}{dp_{\mathrm{Ta}}}\right|_{p_{\mathrm{Tt}}} \approx \frac{B(n-1)}{bp_{\mathrm{Tt}}}\frac{1}{\hat{x}_h}\frac{1}{(1+\frac{p_{\mathrm{Ta}}}{\hat{x}_h p_{\mathrm{Tt}}})^n}. \quad (42)$$

In the collinear limit, where $p_{\mathrm{Ta}} = x_E p_{\mathrm{Tt}}$:

$$\left.\frac{dP_\pi}{dx_E}\right|_{p_{\mathrm{Tt}}} \approx \frac{B(n-1)}{b}\frac{1}{\hat{x}_h}\frac{1}{(1+\frac{x_E}{\hat{x}_h})^n}. \quad (43)$$

The only dependence on the fragmentation function, in this approximation, is in the normalization constant B/b which equals $\langle m\rangle$, the multiplicity in the away-jet from the integral of the fragmentation function. The dominant term in Eq. (43) is the Hagedorn function $1/(1+x_E/\hat{x}_h)^n$, so that at fixed p_{Tt} the x_E distribution is predominantly a function only of x_E and thus does exhibit "x_E" scaling. Also, the Hagedorn function explains the "power law" tail at large x_E noted in Sec. VA. The reason that the x_E distribution is not very sensitive to the fragmentation function is that the integral over z_t for fixed p_{Tt} and p_{Ta} [Eq. (38)] is actually an integral over the jet transverse momentum $\hat{p}_{\mathrm{T_t}}$. However since both the trigger and away jets are always roughly equal and opposite in transverse momentum, integrating over $\hat{p}_{\mathrm{T_t}}$ simultaneously integrates over $\hat{p}_{\mathrm{T_a}}$, and thus also integrates over the away jet-fragmentation function. This can be seen directly by the

presence of z_t in both the same and away fragmentation functions in Eqs. (36) and (37), so that the integral over z_t integrates over both fragmentation functions simultaneously.

B. k_T smearing

In order to evaluate $\hat{x}_h(p_{Tt}, p_{Ta})$ and $\langle z_t \rangle$, k_T must be known. We attack this problem by successive approximations: first we solve for k_T assuming $\hat{x}_h = 1$ as done at the ISR, where the smearing correction was small. Then we iterate for finite k_T. The Gaussian approximation for the smearing function Eq. (35) does not work so well in the low $\hat{p}_T$ region. The product of the steeply falling parton distribution function and the fragmentation function is peaked at $z \approx 1$ preferring "small" parton momenta. We have developed more accurate description of the conditional yields taking into account the k_T smearing.

Let us consider the configuration depicted on Fig. 23. The two back-to-back partons in $\hat{s}$ frame undergo the Lorentz boost determined by net pair momentum

$$\vec{p}_{\,n} \equiv \vec{p}_{Tpair} \equiv \vec{\hat{p}}_{Tt} + \vec{\hat{p}}_{Ta} = \vec{k}_{Tt} + \vec{k}_{Ta}. \tag{44}$$

If we denote an angle between the unsmeared parton momentum and k_T-vector (or $\vec{p}_n$) as α (see Fig. 23) then we can write the conditional probability distribution of trigger parton momenta, $\hat{p}_{Tt}$, as

$$\left.\frac{d^3\sigma}{d\hat{p}_{Tt}d\alpha d\hat{p}_T}\right|_{p_{Tt},p_{Ta}} = \hat{p}_{Tt}\cdot\Sigma_q(\hat{p}_T)\cdot\hat{p}_n\cdot G(\hat{p}_n(\vec{r}_t)) \cdot D_\pi^q\!\left(\frac{p_{Tt}}{\hat{p}_{Tt}}\right)\frac{p_{Tt}}{\hat{p}_{Tt}^2}\cdot D_\pi^q\!\left(\frac{p_{Ta}}{\hat{p}_{Ta}(\vec{r}_t)}\right) \times \frac{p_{Ta}}{\hat{p}_{Ta}^2(\vec{r}_t)}, \tag{45}$$

where $G(\hat{p}_n) = \exp(-\hat{p}_n^2/2\langle k_T^2\rangle)$ describes the Gaussian probability distribution of the net pair momentum magnitude distribution, $\Sigma_q(\hat{p}_T)$ is the unsmeared parton momentum distribution, D_π^q is the fragmentation function and $\vec{r}_t = (\hat{p}_{Tt}, \phi, \hat{p}_T, k_T)$ is the phase space vector. The $\hat{p}_{Tt}$ is chosen to be an integration variable and $\hat{p}_{Ta}$ is fully determined by given values of $\hat{p}_{Tt}$, $\hat{p}_T$, angle ϕ and by the requirement of Lorentz invariance.

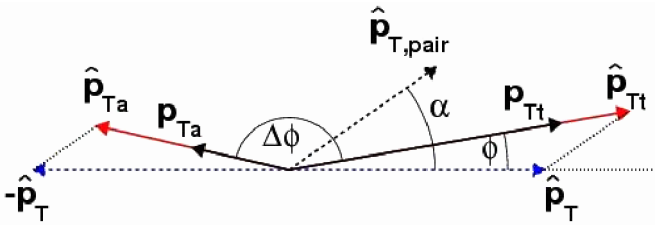

FIG. 23 (color online). Back-to-back partons in hard-scattering rest frame (back-to-back dashed arrows) with four-momenta $(\hat{p}_T, 0, 0, \hat{p}_T)$ and $(-\hat{p}_T, 0, 0, \hat{p}_T)$ in $(-,-,-,+)$ metrics moving along $\hat{p}_n$ ($\hat{p}_n = \hat{p}_{Tpair}$) for an event where detection of p_{Tt} and p_{Ta} is required (the j_T contribution is neglected). The $p_{Tt} > p_{Ta}$ condition implies that the events with $\hat{p}_n$ pointing more in the direction of p_{Tt} are selected.

In order to evaluate $\langle z_t(k_T)\rangle|_{p_{Tt},p_{Ta}}$ and $\hat{x}_h(k_T)|_{p_{Tt},p_{Ta}}$ we have to evaluate first the parton distribution for events where given p_{Tt} and p_{Ta} are detected. This conditional cross section can be expressed as a definite integral over the unobserved variables ϕ and $\hat{p}_T$ (see Fig. 23)

$$\begin{aligned}\left.\frac{d\sigma}{d\hat{p}_{Tt}}\right|_{p_{Tt},p_{Ta}} &= 2\int_0^{\sqrt{s}/2}\int_0^{\pi}\left.\frac{d^3\sigma}{d\hat{p}_{Tt}d\hat{p}_T d\phi}\right|_{p_{Tt},p_{Ta}} d\phi d\hat{p}_T \\ &= D_\pi^q\!\left(\frac{p_{Tt}}{\hat{p}_{Tt}}\right)\frac{2}{\hat{p}_{Tt}}\int_0^{\sqrt{s}/2}\Sigma_q(\hat{p}_T) \\ &\quad\times\int_0^{\pi}\hat{p}_n(\vec{r}_t)G(\hat{p}_n(\vec{r}_t)) \\ &\quad\cdot D_\pi^q\!\left(\frac{p_{Ta}}{\hat{p}_{Ta}(\vec{r}_t)}\right)\frac{1}{\hat{p}_{Ta}^2(\vec{r}_t)}\,d\phi d\hat{p}_T.\end{aligned} \tag{46}$$

The $d\sigma/d\hat{p}_{Ta}|_{p_{Tt},p_{Ta}}$ distribution can be derived from Eq. (46) just by rotation $\hat{p}_{Tt} \to \hat{p}_{Ta}$ and $\hat{p}_{Ta} \to \hat{p}_{Tt}$. The $\langle z_t(k_T)\rangle|_{p_{Tt},p_{Ta}}$ and $\hat{x}_h(k_T)|_{p_{Tt},p_{Ta}}$ quantities can then be evaluated as

$$\langle z_t(k_T)\rangle|_{p_{Tt},p_{Ta}} = \frac{\mathcal{Z}(1)}{\mathcal{Z}(0)}, \tag{47}$$

where

$$\begin{aligned}\mathcal{Z}(n) &= \int_{x_{Tt}}^1 z_t^{n-1}D_\pi^q(z_t)\int_0^{\sqrt{s}/2}\Sigma_q(\hat{p}_T) \\ &\quad\times\int_0^{\pi}\hat{p}_n G(\hat{p}_n(\vec{r}_{zt}))\cdot D_\pi^q\!\left(\frac{p_{Ta}}{\hat{p}_{Ta}(\vec{r}_{zt})}\right) \\ &\quad\times\frac{1}{\hat{p}_{Ta}^2(\vec{r}_{zt})}\,d\phi d\hat{p}_T dz_t\end{aligned}$$

and $\vec{r}_{zt} = (p_{Tt}/z_t, \phi, \hat{p}_T, k_T)$. The $\hat{x}_h(k_T)|_{p_{Tt},p_{Ta}}$ is evaluated as

$$\hat{x}_h(k_T)|_{p_{Tt},p_{Ta}} = \left.\frac{\langle\hat{p}_{Ta}\rangle}{\langle\hat{p}_{Tt}\rangle}\right|_{p_{Tt},p_{Ta}} = \frac{\mathcal{X}_a(1)}{\mathcal{X}_a(0)}\,\frac{\mathcal{X}_t(0)}{\mathcal{X}_t(1)}, \tag{48}$$

where

$$\begin{aligned}\mathcal{X}_t(n) &= \int_{p_{Tt}}^{\sqrt{s}/2}\hat{p}_{Tt}^{n-1}D_\pi^q\!\left(\frac{p_{Tt}}{\hat{p}_{Tt}}\right)\int_0^{\sqrt{s}/2}\Sigma_q(\hat{p}_T) \\ &\quad\times\int_0^{\pi}\hat{p}_n(\vec{r}_t)G(\hat{p}_n(\vec{r}_t))\cdot D_\pi^q\!\left(\frac{p_{Ta}}{\hat{p}_{Ta}(\vec{r}_t)}\right) \\ &\quad\times\frac{1}{\hat{p}_{Ta}^2(\vec{r}_t)}\,d\phi d\hat{p}_T\hat{p}_{Tt} \\ \mathcal{X}_a(n) &= \int_{p_{Ta}}^{\sqrt{s}/2}\hat{p}_{Ta}^{n-1}D_\pi^q\!\left(\frac{p_{Ta}}{\hat{p}_{Ta}}\right)\int_0^{\sqrt{s}/2}\Sigma_q(\hat{p}_T) \\ &\quad\times\int_0^{\pi}\hat{p}_n(\vec{r}_a)G(\hat{p}_n(\vec{r}_a))\cdot D_\pi^q\!\left(\frac{p_{Tt}}{\hat{p}_{Tt}(\vec{r}_a)}\right) \\ &\quad\times\frac{1}{\hat{p}_{Tt}^2(\vec{r}_a)}\,d\phi d\hat{p}_T\hat{p}_{Ta}.\end{aligned}$$

We have tested the above formulae on PYTHIA simulation. We have generated events with $\sqrt{\langle k_T^2 \rangle} = 3$ GeV/c and evaluated the partons' momenta unbalance variation with p_{Tt} for fixed $3 < p_{Ta} < 4$ GeV/c bin. The results from the PYTHIA simulation (solid points on Fig. 24) are compared to calculation based on Eq. (48) (solid line on Fig. 24). The magnitude of momentum unbalance saturates at $p_{Tt} \approx 10$ GeV/c around $\sqrt{\langle k_{Tx}^2 \rangle}$ and then starts to decrease. The maximum value depends on the k_T magnitude and on the asymmetry between p_{Tt} and p_{Ta}. Eventually, the unbalance should vanish at high p_{Tt} as a consequence of $\Sigma_q(\hat{p}_T)$ flattening.

The comparison of $\langle z_t \rangle$ and $\langle z_a \rangle$ found in PYTHIA and derived according to Eq. (47) is shown in Fig. 25. The overall agreement between the PYTHIA simulations and the calculation is excellent. The small deviations may be attributed to the fact that in the PYTHIA simulation, 1 GeV/c-wide bins were used for trigger and associated particle identification, whereas the calculation was performed for fixed values of p_{Tt} and p_{Ta}.

The last missing piece of information needed before solving Eq. (22) is the fragmentation function D_π^q and unsmeared $\Sigma_q(\hat{p}_T)$. The description of how this knowledge was extracted from the data is a subject of the next section.

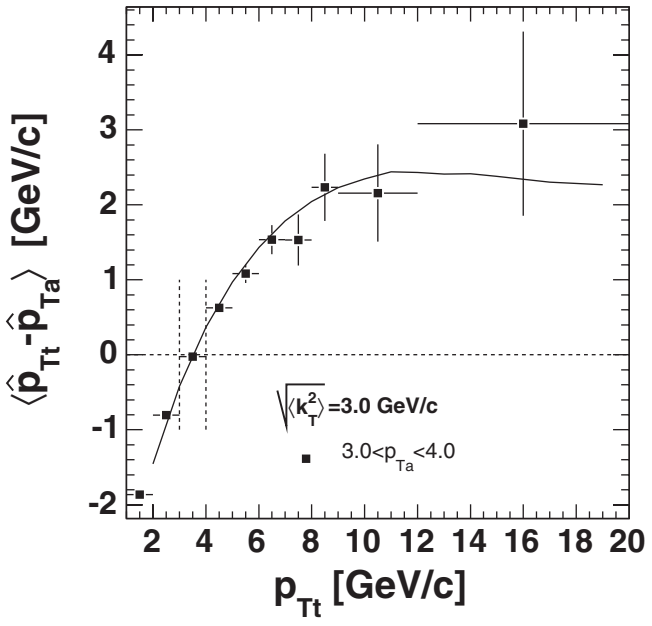

FIG. 24. PYTHIA simulated average momentum unbalance for the associated particles in $3.0 < p_{Ta} < 4.0$ GeV/c bin and calculated according Eq. (48). The two vertical dashed line indicates the range where p_{Tt} and p_{Ta} bins are equal and the parton momenta unbalance vanishes (fixed correlations).

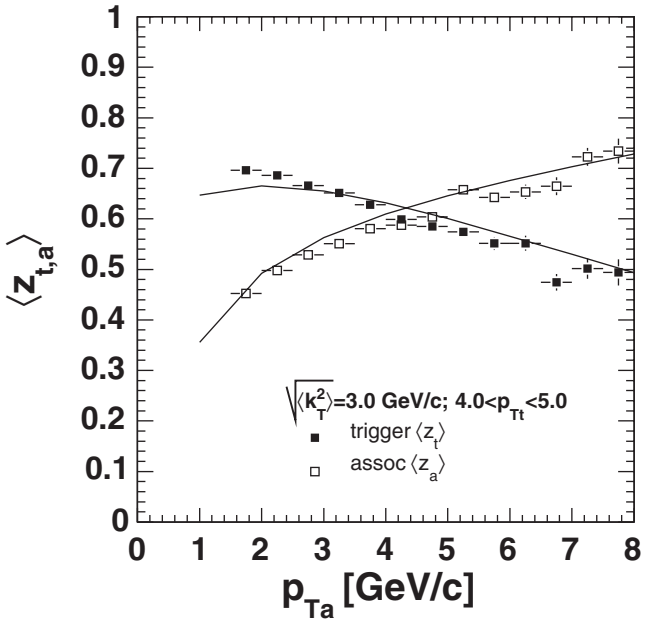

FIG. 25. Average z of a trigger and associated particle as a function of p_{Ta} from PYTHIA and according Eq. (47).

VII. CORRECTED $\langle k_T \rangle$ RESULTS

The $\hat{x}_h^{-1} \langle z_t \rangle \sqrt{\langle k_T^2 \rangle}$ extracted according to Eq. (22) for various p_{Tt} and p_{Ta} are shown in Fig. 16 and 17. In order to extract $\sqrt{\langle k_T^2 \rangle}$ values we have solved

$$x_h^{-1} \sqrt{\langle p_{out}^2 \rangle - \langle j_{Ty}^2 \rangle (x_h^2 + 1)} - \hat{x}_h^{-1} \langle z_t \rangle \sqrt{\langle k_T^2 \rangle} = 0 \quad (49)$$

for $\sqrt{\langle k_T^2 \rangle}$ where the $\langle z_t \rangle$ and $\hat{x}_h = \langle \hat{p}_{Ta} \rangle / \langle \hat{p}_{Tt} \rangle$ are evaluated according Eq. (47) and (48) respectively. These two quantities depend on $\sqrt{\langle k_T^2 \rangle}$ so we solved Eq. (49) iteratively by varying a $\sqrt{\langle k_T^2 \rangle}$ value and in every step the $\langle z_t \rangle$ and $\hat{x}_h$ were recalculated. To do so we need to know the unsmeared final state parton spectrum $\Sigma_q(\hat{p}_T)$ and the fragmentation function. For the latter we used the LEP data (see Fig. 22) where the fragmentation functions of gluon and quark jets were measured in e^+e^- collision at $\sqrt{s} = 180$ GeV. We have chosen

$$D_\pi^q \propto z^{-\alpha}(1 - z)^\beta (1 + z)^{-\gamma} \quad (50)$$

form used e.g. in [52] and extracted α, β, and γ parameters from the fit to distributions shown in Fig. 22 and Table VIII.

For a given set of parameters α, β, and γ the power of the unsmeared final state parton spectra $\Sigma_q(\hat{p}_T)$ was evaluated from the fit formula Eq. (27) to the single inclusive π^0 invariant cross section [43]. Here we used the simplified k_T smearing

$$f'_q(\hat{p}_{\mathrm{Tt}}) = \frac{1}{\hat{p}_{\mathrm{Tt}}}\Sigma'_q(\hat{p}_{\mathrm{Tt}}) = \frac{1}{\hat{p}_{\mathrm{T}}}\Sigma_q(\hat{p}_{\mathrm{T}}) \otimes \exp\frac{-(\hat{p}_{\mathrm{T}} - \hat{p}_{\mathrm{Tt}})^2}{\langle k_{\mathrm{Tx}}^2\rangle}$$

and for the fixed value of $\sqrt{\langle k_{\mathrm{T}}^2\rangle} = \sqrt{2}\sqrt{\langle k_{\mathrm{Tx}}^2\rangle} = 2.5$ GeV/c the power n of $\Sigma q(\hat{p}_{\mathrm{T}})$ distribution was determined.

The measurement of the fragmentation functions at LEP was done separately for quark and gluon jets and the slopes of these two $D(z)$ distributions are different. Quark jets produce a significantly harder spectrum than gluon jets (see Fig. 22). Since the relative abundance of quark and gluon jets at $\sqrt{s} = 200$ GeV is not known, for the final results we assumed that the numbers of quark and gluon jets are equal; the final $D(z)$ uses the averaged parameter values between quark and gluon and the difference was used as a measure of the systematic uncertainty.

Resulting $\sqrt{\langle k_{\mathrm{T}}^2\rangle}$ values for $3 < p_{\mathrm{Tt}} < 4$ GeV/c and $5 < p_{\mathrm{Tt}} < 10$ GeV/c as a function of p_{Ta} are shown in Fig. 26 and Table IX. The solid and dashed lines bracket the systematic error due to the unknown ratio of quark and gluon jets. These data points correspond to the uncorrected $\hat{x}_{\mathrm{h}}^{-1}\langle z_{\mathrm{t}}\rangle\sqrt{\langle k_{\mathrm{T}}^2\rangle}$ values shown in Fig. 16. The $\sqrt{\langle k_{\mathrm{T}}^2\rangle}$ values for varying p_{Tt} corresponding to the data of Fig. 17 are shown in Fig. 27 and Table X. The solid lines bracket the systematic error due to the unknown ratio of quark and gluon jets. It is evident that unfolded $\sqrt{\langle k_{\mathrm{T}}^2\rangle}$ values reveal, within the error bars, no dependence neither on p_{Ta} nor on p_{Tt}.

We compared the $\sqrt{\langle k_{\mathrm{T}}^2\rangle}$ data obtained in this analysis to $\sqrt{\langle k_{\mathrm{T}}^2\rangle}$ values found by the CCOR Collaboration at $\sqrt{s} = 62.4$ GeV [1] (empty triangles on Fig. 27). Although the trend with p_{Tt} seems to be similar the overall magnitude at $\sqrt{s} = 200$ GeV is significantly higher.

The $\langle z_{\mathrm{t}}\rangle$ and $\hat{x}_{\mathrm{h}}$ values from the iterative solution of Eq. (49) as a function of the π^0 trigger momenta p_{Tt} and associated momenta p_{Ta} are shown in Fig. 28 and 29 and Tables XI and XII. There is an opposite trend; whereas the $\langle z_{\mathrm{t}}\rangle$ rises with p_{Tt} it is falling with p_{Ta}. It is an interesting consequence of two effects: competition between steeply falling final state parton spectra and rising fragmentation function with parton momentum. Secondly, the detection of trigger particle biases the $\vec{k}_{\mathrm{T}}$ vector in the direction of the trigger jet as discussed in Sec. VI B.

TABLE VIII. Extracted values of $D(z)$ parameters according Eq. (50) from the fit to the LEP data (see Fig. 22) and power n of the unsmeared final state parton spectra $\Sigma_q(\hat{p}_{\mathrm{T}})$ extracted from the fit to the single inclusive π^0 invariant cross section [43] for corresponding fragmentation function and fixed value of $\sqrt{\langle k_{\mathrm{T}}^2\rangle} = 2.5$ GeV/c.

	Gluon	Quark	(gluon + quark)/2
α	0.16	0.49	0.32
β	0.88	0.57	0.72
γ	13.29	8.00	10.65
n	7.53	7.28	7.40

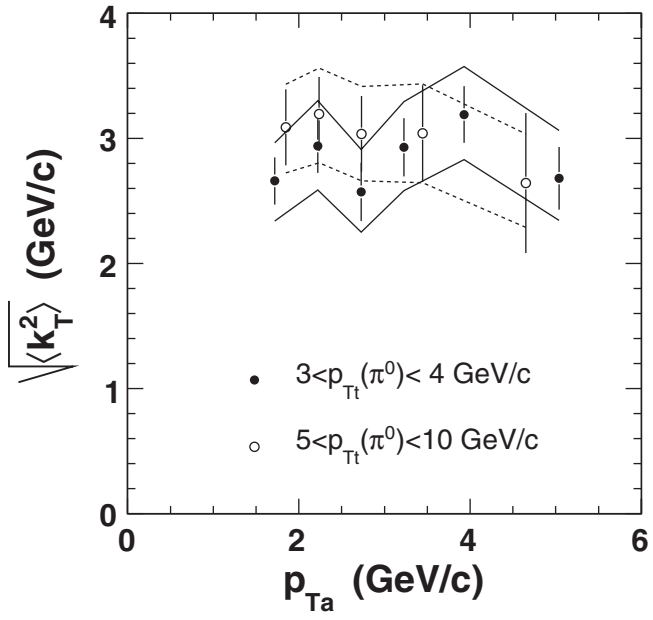

FIG. 26. $\sqrt{\langle k_{\mathrm{T}}^2\rangle}$ values corresponding to Fig. 16 as a solution to Eq. (49) for trigger π^0 in $3 < p_{\mathrm{Tt}} < 4$ GeV/c (solid symbols) and $5 < p_{\mathrm{Tt}} < 10$ GeV/c (open symbols) range. The solid and dashed lines bracket the systematic uncertainty due to the unknown ratio of quark and gluon jets, for the solid and open symbols, respectively.

The p_{Tt} averaged value of $\sqrt{\langle k_{\mathrm{T}}^2\rangle}$ (Fig. 27) is compared to the average parton-pair momentum, $\langle \hat{p}_{\mathrm{n}}\rangle = \langle p_{\mathrm{T}}\rangle$pair, presented in [33] (see Fig. 30). The value of $\langle p_{\mathrm{T}}\rangle$ pair is determined as a sum of the two partons' $\langle k_{\mathrm{T}}\rangle$. In the present

8.34	2.53 ± 0.62	3.11 ± 0.60 ± 0.33

analysis the $\sqrt{\langle k_T^2\rangle}$ is determined and thus the value of $\langle p_T\rangle$ *pair* is evaluated as $\langle p_T\rangle_{pair} = \sqrt{2}\times\langle k_T\rangle = \sqrt{\pi/2}\times\sqrt{\langle k_T^2\rangle}$.

The present value of $\langle p_T\rangle$ *pair*

$$\langle p_T\rangle_{pair} = 3.36 \pm 0.09(\text{stat}) \pm 0.43(\text{sys})\ \text{GeV/c}$$

appears to be in a good agreement with the lower energy dijet and dilepton measurements or the higher energy measurement in diphoton production [54]. A UA2 measurement of $\langle p_T\rangle$ of Z^0 production at $\sqrt{s} \sim 600$ GeV gives 8.6 ± 1.5 GeV/c [55,56].

VIII. SUMMARY

We have made the first measurement of jet j_T and k_T for $p + p$ collisions at $\sqrt{s} = 200$ GeV using the method of two-particle correlations. Analysis of the angular widths of the near-side peak in the correlation function has determined that the jet-fragmentation transverse momentum j_T is constant with trigger particle p_{Tt} and the extracted value $\sqrt{\langle j_T^2\rangle} = 585 \pm 6(\text{stat}) \pm 15(\text{sys})$ MeV/c is comparable with previous lower $\sqrt{s}$ measurements. The width of the

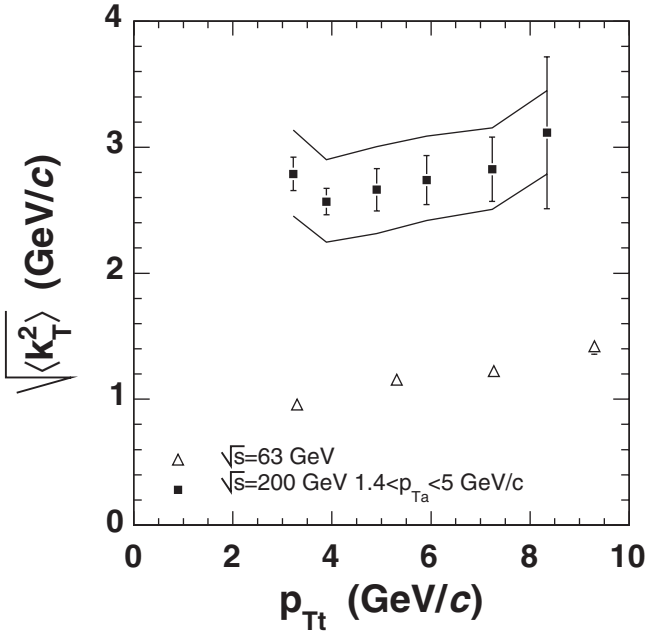

FIG. 27. $\sqrt{\langle k_T^2\rangle}$ values corresponding to Fig. 17 as a solution to Eq. (49) for associated particles in $1.4 < p_{Ta} < 5$ GeV/c region (solid symbols). The solid lines bracket the systematic error due to the unknown ratio of quark and gluon jets. The CCOR measurement at $\sqrt{s} = 62.4$ GeV [1] (empty triangles).

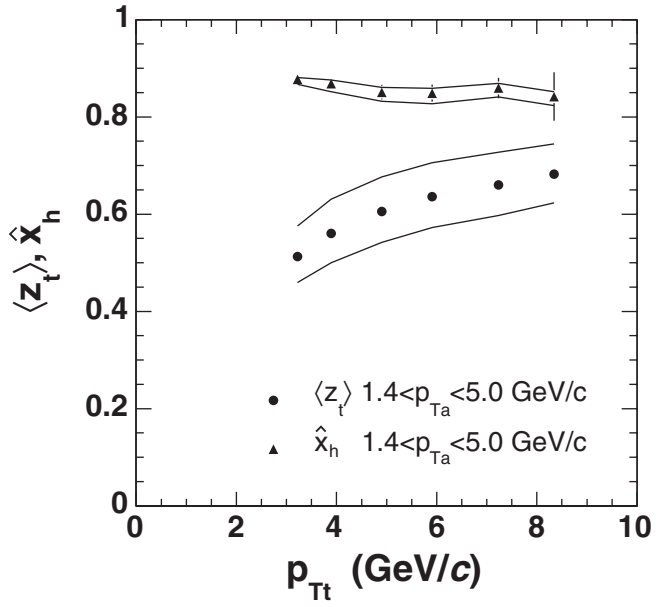

FIG. 28. $\langle z_t\rangle$ and $\hat{x}_h$ as a function of p_{Tt} for the $1.4 < p_{Ta} < 5.0$ GeV/c associated region. The data values are shown in Table XI.

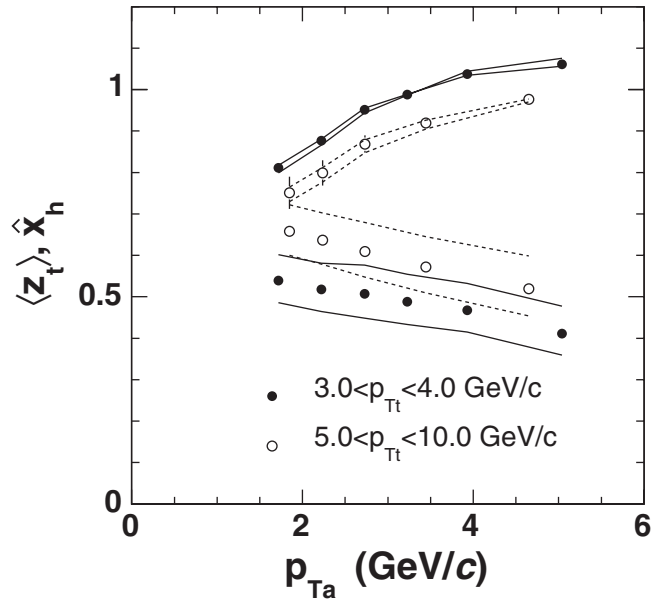

FIG. 29. The values of $\hat{x}_h$(upper two curves) and $\langle z_t\rangle$ (lower two curves) as a function of p_{Ta} are shown as solutions of Eq. (48) for $3 < p_{Tt} < 4$ GeV/c and $5 < p_{Tt} < 10$ GeV/c. Equation (20) defines $\langle z_t\rangle$ and $\hat{x}_h$. The data values are shown in Table XII.

TABLE XI. The $\langle z_t \rangle$ and $\hat{x}_h$ values with p_{Tt} shown in Fig. 28.

p_{Tt} (GeV/c)	$\langle z_t \rangle$	$\hat{x}_h$
3.22	$0.51 \pm 4 \times 10^{-3} \pm 0.06$	0.88 ± 0.01
3.89	$0.56 \pm 2 \times 10^{-3} \pm 0.07$	0.87 ± 0.01

3.44	$0.57 \pm 2 \times 10^{-3} \pm 0.07$	0.92 ± 0.02
4.65	$0.52 \pm 5 \times 10^{-3} \pm 0.08$	0.98 ± 0.01

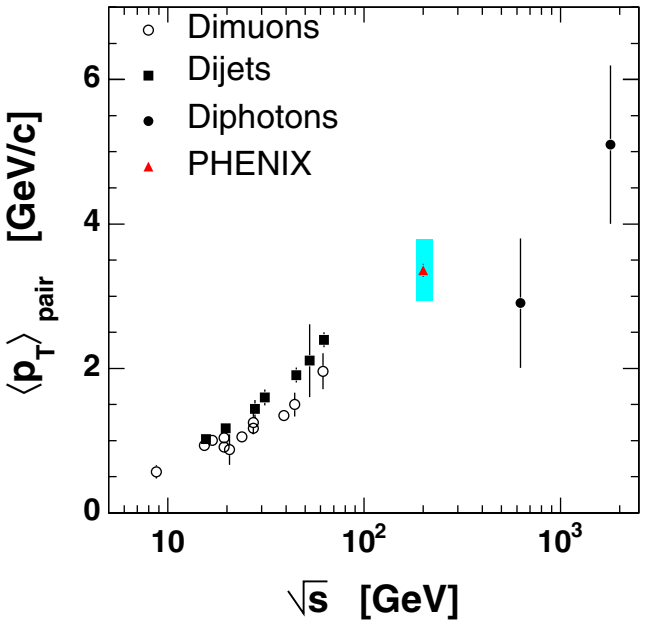

FIG. 30 (color online). Compilation of mean pair p_T measurements [33] and comparisons to the $\langle p_T \rangle$ pair measured in this analysis.

away-side peak is shown to be a measure of the convolution of j_T with the jet momentum fraction z and the partonic transverse momentum k_T. $\langle z_t \rangle$ is determined through a combined analysis of the measured π^0 inclusive and associated spectra using the jet-fragmentation functions from e^+e^- measurements. The average of $\langle z_t \rangle$ from the gluon and quark fragmentation functions is used and the difference is taken as the measure of the systematic error. The final extracted values of k_T are then determined to be also independent of the transverse momentum of the trigger π^0, in the range measured, with values of $\sqrt{\langle k_T^2 \rangle} = 2.68 \pm 0.07(\text{stat}) \pm 0.34(\text{sys})$ GeV/c.

APPENDIX A: FIRST AND SECOND MOMENTS OF NORMALLY DISTRIBUTED QUANTITIES

Let x be a 1D variable with normal (Gaussian) distribution and $r = \sqrt{x^2 + y^2}$ is a 2D variable with x and y of

normal distribution then the following relations can be easily derived.

$$\begin{array}{llll} \langle x\rangle & = & 0 & \langle r\rangle = \sqrt{\frac{\pi}{2}}\sigma_1 \\ \langle |x|\rangle & = & \sqrt{\frac{2}{\pi}}\sigma_1 & \langle |r|\rangle = \langle r\rangle \\ \langle x\rangle^2 & = & \sigma_1^2 & \langle r\rangle^2 = 2\sigma_1^2 \equiv \sigma_2^2 \end{array}$$

Both $\vec{j}_T$ and $\vec{k}_T$ are two-dimensional vectors. We assume Gaussian distributed x and y components and thus the mean value $\langle k_{Tx}\rangle$ and $\langle k_{Ty}\rangle$ is equal to zero. The nonzero moments of 2D Gaussian distribution are e.g. the root mean squares $\sqrt{\langle j_T^2\rangle}$, $\sqrt{\langle k_T^2\rangle}$ or the mean absolute values of the $\vec{j}_T$, $\vec{k}_T$ projections into the perpendicular plane to the jet axes $\langle |j_{Ty}|\rangle$ and $\langle |k_{Ty}|\rangle$. Note that there are a trivial correspondences

$$\sqrt{\langle k_T^2\rangle} = \frac{2}{\sqrt{\pi}}\langle k_T\rangle = \sqrt{\pi}\langle |k_{Ty}|\rangle. \quad (51)$$

APPENDIX B: THE CORRECT WAY TO ANALYZE THE AZIMUTHAL CORRELATION FUNCTION

Construction and fitting of the two-particle azimuthal correlation function is discussed in Sec. IV. Traditionally the correlation function is fitted by two Gaussian functions—one for intrajet correlation (near peak) and one for the interjet correlations (away-side peak). From the extracted variances of the Gaussian functions the j_T and p_{out} magnitudes are extracted.

There is, however, a fundamental problem with this approach. The p_{out}-vector defined in Eq. (17) is equal to $p_{Ta}\sin\Delta\phi$ event by event. However, we measure the width of the correlation peak and this corresponds to $\sqrt{\langle\Delta\phi^2\rangle} = \sigma_A$. The relation $\sqrt{\langle p_{out}^2\rangle} \approx p_{Ta}\sin\sigma_A$ is not a good approximation for $\sigma_A > 0.4$ rad (see Fig. 31). The assumption that the away-side correlation has a Gaussian shape is also good only for small values of σ_A (see Fig. 31).

One way of relating $\sqrt{\langle p_{out}^2\rangle}$ and σ_A was proposed e.g. by Peter Levai [48] and used in several other analyzes. Since $\sqrt{\langle p_{out}^2\rangle} = p_{Ta}\sqrt{\langle\sin^2\Delta\phi\rangle}$ one possibility how to relate p_{out} and σ_A is to expand

$$\langle\sin^2\Delta\phi\rangle = \left\langle \Delta\phi^2 - \frac{1}{3}\Delta\phi^4 + \frac{2}{45}\Delta\phi^6 \ldots \right\rangle$$
$$= \sigma_A^2 - \sigma_A^4 + \frac{2}{3}\sigma_A^6 \ldots,$$

where we assumed a Gaussian distribution of $\Delta\phi$. The comparison of $p_{Ta}\cdot(\sigma_A^2 - \sigma_A^4 + \frac{2}{3}\sigma_A^6\ldots)$ with the true p_{out} magnitude (simple monte carlo) for various σ_A values is shown in Fig. 31. It is obvious that there is only a little

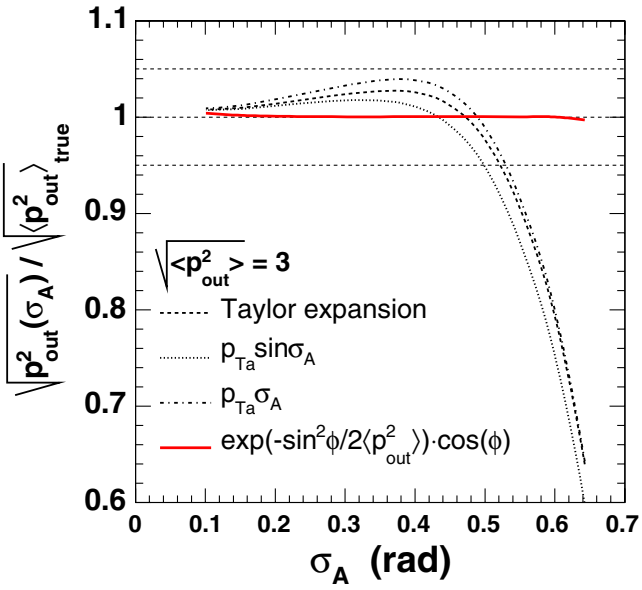

FIG. 31 (color online). The relative error on p_{out} determination from the azimuthal correlation function based on the Taylor expansion of $\langle\sin\Delta\phi^2\rangle$ (dashed line), with an assumption of $\sqrt{\langle p_{out}^2\rangle} = p_{Ta}\sin\sigma_A$ (dotted line) and $\sqrt{\langle p_{out}^2\rangle} = p_{Ta}\sigma_A$ (dotted-dashed line). The solid red line corresponds to $\sqrt{\langle p_{out}^2\rangle}$ from Eq. (23).

difference between $\sqrt{\langle p_{out}^2\rangle} = p_{Ta}\sin\sigma_A$, $\sqrt{\langle p_{out}^2\rangle} = p_{Ta}\sigma_A$ and the Taylor series. In the region where $\sigma_A > 0.4$ rad, all approximations seems to be equally bad.

However, p_{out}, the only quantity with a truly Gaussian distribution (if we neglect the radiative corrections responsible for non-Gaussian tails in the p_{out} distribution which are anyway not relevant for the k_T analysis) can be directly extracted from the correlation function. With the assumption of Gaussian distribution in p_{out}, we can write the away-side $\Delta\phi$-distribution (normalized to unity) as

$$\left.\frac{dN_{away}}{d\Delta\phi}\right|_{\pi/2}^{3\pi/2} = \frac{dN}{dp_{out}}\frac{dp_{out}}{d\Delta\phi} = \frac{-p_{Ta}\cos\Delta\phi}{\sqrt{2\pi\langle p_{out}^2\rangle}\,\mathrm{Erf}\left(\frac{\sqrt{2}p_{Ta}}{\sqrt{\langle p_{out}^2\rangle}}\right)} \times \exp\left(-\frac{p_{Ta}^2\sin^2\Delta\phi}{2\langle p_{out}^2\rangle}\right).$$

This is the correct way of extracting a dimensional quantity from the azimuthal correlation function in the case of narrow associated bin. Similar line of arguments can be drawn also in the case of near peak. However, given the narrowness of the near-angle peak, the simple Gaussian approximation is good enough.

(Received 17 March 2006; published 8 June 2006)

Deuteron-gold (d + Au) collisions at the Relativistic Heavy Ion Collider provide ideal platforms for testing QCD theories in dense nuclear matter at high energy. In particular, models suggesting strong saturation effects for partons carrying small nucleon momentum fraction (x) predict modifications to jet production at forward rapidity (deuteron-going direction) in d + Au collisions. We report on two-particle azimuthal angle correlations between charged hadrons at forward/backward (deuteron/gold going direction) rapidity and charged hadrons at midrapidity in d + Au and p + p collisions at $\sqrt{s_{NN}} = 200$ GeV. Jet structures observed in the correlations are quantified in terms of the conditional yield and angular

width of away-side partners. The kinematic region studied here samples partons in the gold nucleus with $x \sim 0.1$ to ~ 0.01. Within this range, we find no x dependence of the jet structure in d + Au collisions.

DOI: 10.1103/PhysRevLett.96.222301 PACS numbers: 25.75.Dw, 25.75.Gz

Observations in d + Au collisions at $\sqrt{s_{NN}} = 200$ GeV at the Relativistic Heavy Ion Collider (RHIC) reveal a significant suppression of hadron production at forward rapidity (deuteron-going direction) relative to $p + p$ collisions scaled up by the equivalent number of nucleon-nucleon collisions (N_{coll}) [1–3]. This suppression is observed for hadrons with momentum transverse to the beam direction in the range $p_T \approx 1.5$–4 GeV/c. In contrast, measurements at midrapidity [4–7] and backward rapidity [1–3] show a modest enhancement relative to N_{coll} scaling in the same p_T range. Particle production at forward rapidity is sensitive to partons in the gold nucleus which carry a small nucleon momentum fraction (small Bjorken x). The suppression has generated significant theoretical interest including different calculational frameworks for understanding the data [8–11].

One such framework, the color glass condensate (CGC), attempts to describe the data in terms of gluon saturation [8]. At small x the probability of emitting an extra gluon is large and the number of gluons grows in a limited transverse area. When the transverse density becomes large, partons start to overlap and gluon-gluon fusion processes start to dominate the parton evolution in the hadronic wave functions. Thus the gluon density saturates. Since the nonlinear growth of the gluon density depends on the transverse size of the system, gluon saturation effects are expected to set in at higher x for heavy nuclei than for free nucleons.

In the leading order pQCD framework, a quark or gluon jet with large transverse momentum produced in a hard-scattering process (high momentum transfer or large Q^2) must be momentum balanced by another quark or gluon jet in the opposite direction but with almost the same p_T. Thus the azimuthal angle correlation between particles from the pair of jets (referred to as dijets) is characterized by two peak structures separated by 180°. In CGC calculations, the momentum to balance a jet may come from a large multiplicity of gluons in the saturation regime, and thus no single partner jet may appear on the opposite side [12]. This effect is analogous to the nuclear Mössbauer effect, and is often referred to as the appearance of monojets. Alternative calculations, describing the suppression of single hadrons at forward rapidity in d + Au reactions in terms of leading twist pQCD effects, predict no such monojet feature [13].

We want to probe this high gluon density regime in d + Au collisions with relatively high p_T particles at forward rapidity. Such particles are likely to result from hard-scattering collisions involving small x partons in the gold nucleus. At small x the gluon density increases rapidly with Q^2 and saturation effects may be relevant for $x \approx 0.01$ at modest p_T. CGC calculations [12] predict significant suppression of the conditional yield and widening of away-side jet azimuthal correlations between rapidity-separated hadron pairs when one of those hadrons is at forward rapidity.

In this Letter we report on measurements of two-particle azimuthal angle correlations between unidentified charged hadrons in $p + p$ and d + Au collisions at $\sqrt{s_{NN}} =$ 200 GeV. In our analysis, the two particles are referred to as the *trigger* and *associated* particles. The trigger particle is at forward ($1.4 < \eta < 2.0$) or backward ($-2.0 < \eta < -1.4$) rapidity and the associated particle is at midrapidity, $|\eta| < 0.35$. The particles are separated by an average pseudorapidity gap $\langle \Delta\eta \rangle \sim 1.5$. The criteria for trigger particles, associated particles, and event selection are described elsewhere [3,14]. The two-particle azimuthal angle correlation technique has been used extensively by RHIC experiments and is described in detail elsewhere [14–18]. In this technique the azimuthal correlation function is formed from the angular difference, $\Delta\phi = \phi^{\text{assoc}} - \phi^{\text{trig}}$, between each trigger and associated particle pair. Two jet peaks are normally observed in such correlation functions: the near-side peak ($\Delta\phi \sim 0$) in which the two particles come from the same jet, and the away-side peak ($\Delta\phi \sim \pi$) in which they come from back-to-back jets. In addition to these peaks the correlation functions also have a $\Delta\phi$ independent combinatoric background contribution due to trigger-associated pairs from different jets or from non-jet processes.

We can construct separate correlation functions that are sensitive to partons in the gold nucleus with different x ranges. By choosing trigger particles with $1.0 < p_T < 5.0$ GeV/c at forward (backward) rapidity and associated particles with $0.5 < p_T < 2.5$ GeV/c at midrapidity, we sample partons in gold nuclei with $x \sim 0.01(0.1)$. We do not expect our data at $x \sim 0.1$ to be sensitive to saturation effects, but they may at $x \sim 0.01$ [19]. The comparison in d + Au reactions between these two cases, as well as with the $p + p$ case, may give insights into possible saturation effects on jet production and other mechanisms for forward rapidity single-particle suppression. It should be noted that the prediction of monojets in [12] assumes one particle at $\eta = 3.8$ and one at midrapidity, thus demonstrating sensitivity at smaller x ($\sim 10^{-4}$) than presented in this analysis.

Data for this analysis were collected by PHENIX [20] in 2003. For d + Au collisions, we divide the data into two centrality (impact parameter) classes based on the number of hits in the backward-rapidity PHENIX beam-beam counter (BBC, $-3.9 < \eta < -3.0$). Central (peripheral)

collisions comprise 0%–40% (40%–88%) of the minimum bias cross section. Using a Glauber model [3] and a simulation of the BBC, we determine $\langle N_{\rm coll}\rangle = 13.0 \pm 0.9(4.7 \pm 0.4)$ for central (peripheral) collisions.

Trigger particles are unidentified charged hadrons measured in the PHENIX muon spectrometers [20]. We only select particles from $1.4 < |\eta| < 2.0$ to obtain homogenous acceptance from $1 < p_T < 5$ GeV/c and to reduce beam correlated backgrounds. We identify hadrons, as opposed to muons, in the muon spectrometers by comparing their momentum and penetration depth [3]. It is notable that our trigger hadrons have a modified composition (pion/kaon/proton ratio) relative to that at the collision vertex due to species-dependent nuclear interaction cross sections. Detailed simulations show that kaons make up 65%–90% of positively charged trigger particles and pions make up 70%–90% of negatively charged trigger particles. The sizes of the quoted ranges of particle composition are due to uncertainties on the input particle compositions in simulation and due to variations, correlated with polar angle and therefore rapidity, in the length of absorber material that particles traverse. The baryon contribution to our trigger particle sample is negligible. We find the two-particle azimuthal angle correlations for positively and negatively charged trigger particles to be consistent and therefore combined the results. Associated particles are unidentified charged hadrons measured in the PHENIX central spectrometers [20] which cover $|\eta| < 0.35$ and in this analysis have $0.5 < p_T < 2.5$ GeV/c. Standard track selection criteria [14] are applied.

For comparison we have also included measurements where trigger particles and associated particles are both measured in the PHENIX central spectrometers at midrapidity. The d + Au points for this comparison are from [14] and the $p + p$ point is an extension in p_T of the analysis that was published in [16].

We define the azimuthal angle correlation function as $\mathrm{CF} = \frac{dN(\Delta\phi)/d(\Delta\phi)}{\mathrm{acc}(\Delta\phi)}$, where $dN(\Delta\phi)/d(\Delta\phi)$ is the measured two-particle distribution and $\mathrm{acc}(\Delta\phi)$ is the two-particle acceptance obtained by mixing trigger particles and associated particles from different events within the same centrality and collision vertex category. This correction is necessary because the PHENIX central arm detector is not azimuthally symmetric and the pair acceptance varies as a function of $\Delta\phi$.

Figure 1 shows the correlation functions for trigger particles with $p_T = 2$–5 GeV/c and associated particles with $p_T = 0.5$–1.0 GeV/c. A clear peak is seen near $\Delta\phi = \pi$ on all plots corresponding to the away-side jet. It is notable that there is no peak near $\Delta\phi = 0$, as expected, because the rapidity gap between the two particles is larger than the width of the near-side jet. Although the rapidity of away-side particles is not necessarily the same as the rapidity of the away-side jet, PYTHIA [21] studies show that the distribution of final state particles around the jet axis is symmetric in $\Delta\eta$ and $\Delta\phi$ and the jet cone width is less than 1 unit of rapidity, which is smaller than the rapidity gap.

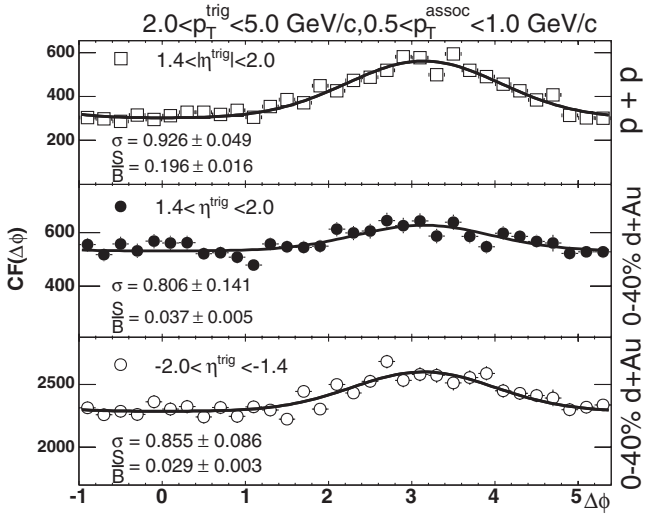

FIG. 1. Azimuthal angle correlation functions. Gaussian widths from the fits and the signal to background ratio integrated over $\pi - 1 < \Delta\phi < \pi + 1$ are shown. Note that the y axis is zero suppressed on the middle and bottom panels.

After constructing the correlation functions in various bins in $p_T^{\rm assoc}$, $p_T^{\rm trig}$, and $\eta^{\rm trig}$ we used two methods to determine the unnormalized number of trigger-associated particle pairs, $N_{\rm pair}$, above a constant background. In the first method, we define $N_{\rm pair} = \sum_{\Delta\phi=\pi-1}^{\pi+1} \mathrm{CF}(\Delta\phi) - \sum_{\Delta\phi=-1}^{+1} \mathrm{CF}(\Delta\phi)$, where the first term is the integral of the correlation function (CF) in the area of the correlation peak ($\pi - 1 < \Delta\phi < \pi + 1$) and the second term is the integral away from the peak ($-1 < \Delta\phi < 1$). In the second method we fit the correlation function with a Gaussian distribution centered at $\Delta\phi = \pi$ plus a constant background. The values of $N_{\rm pair}$ obtained by both methods are found to be consistent and the small differences are included in our systematic errors. The solid lines in Fig. 1 show the resulting fits. Gaussian width parameters (σ) and the integrated signal to background ratios ($\frac{S}{B}$) over the signal region ($\pi - 1 < \Delta\phi < \pi + 1$) are quoted.

The conditional yield (CY) (per trigger particle) is defined to be $\mathrm{CY} = \frac{N_{\rm pair}/\varepsilon_{\rm assoc}}{N_{\rm trig}}$, where $\varepsilon_{\rm assoc}$ ($\sim 0.15 \pm 0.015$) is the efficiency times acceptance for associated particles and $N_{\rm trig}$ is the number of trigger particles used to generate the correlation function. $\varepsilon_{\rm assoc}$ is obtained for each colliding system, centrality class, and p_T bin by a GEANT based simulation of the PHENIX detector [14].

It is interesting to plot the conditional yields as a function of $\eta^{\rm trig}$. Changing $\eta^{\rm trig}$ from -2.0 to 2.0 effectively changes the range of Bjorken x of sampled partons in gold nuclei from $0.1^{+0.06}_{-0.04}$ to $0.01^{+0.02}_{-0.007}$. Figure 2 shows the

results. The first observation is that there is no difference beyond statistical fluctuations in the conditional yields for $p + p$, $d + \mathrm{Au}$ peripheral, or $d + \mathrm{Au}$ central collisions at any trigger particle pseudorapidity.

We further quantify any nuclear modification in the conditional yield by defining a ratio $I_{d\mathrm{Au}} = \frac{\mathrm{CY}|_{d+\mathrm{Au}}}{\mathrm{CY}|_{p+p}}$. The technique of comparing conditional yields per trigger to investigate the source of single-particle nuclear modifications in the trigger particle region of phase space is well established at RHIC [14–16]. The fact that single-particle yields are strongly modified in the trigger particle p_T range makes $I_{d\mathrm{Au}}$ particularly interesting since it may shed light on the nature of the single-particle suppression. For our rapidity-separated pairs two different models [12,13], which posit different mechanisms to be responsible for the single-particle suppression, predict very different results for the evolution of the correlation function vs centrality and x.

Figure 3 shows the ratio $I_{d\mathrm{Au}}$ vs p_T^{assoc} for different p_T^{trig}, η^{trig} and $d + \mathrm{Au}$ centrality bins. Shaded bands on each data point show point-to-point independent systematic errors due to differences in N_{pair} obtained from the two methods described above. There is also a point-to-point correlated $\sim 2\%$ systematic uncertainty in the centrality dependence of $\varepsilon_{\mathrm{assoc}}$ determined by embedding Monte Carlo tracks into real events. The size of this uncertainty is comparable to the width of the $I_{d\mathrm{Au}} = 1$ line.

For trigger particles at both forward rapidity (sampling low-x partons in the gold nucleus) and backward rapidity (sampling high-x partons in the gold nucleus), the measured $I_{d\mathrm{Au}}$ is consistent with one. There may even be some evidence of slight enhancement for the case with trigger particles at forward rapidity in central $d + \mathrm{Au}$ collisions. We note that if monojets were a major contributor to the trigger particle sample in our x range, we would have expected a decrease in the conditional yield for $d + \mathrm{Au}$ central collisions with the trigger particle at forward rapidity.

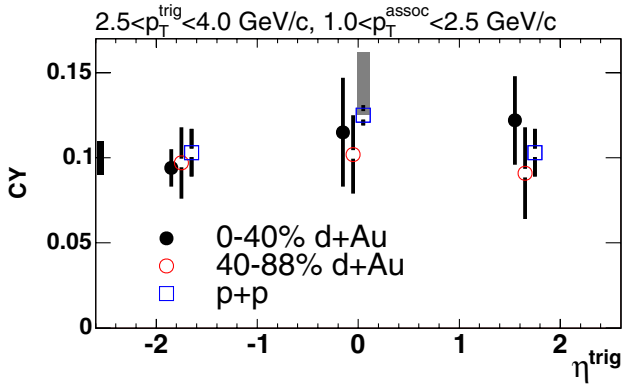

FIG. 2 (color online). Conditional yields are shown as a function of trigger particle pseudorapidity. Data points at midrapidity for $d + \mathrm{Au}$ collisions are from [14]. To increase visibility, we artificially shift data points belonging to the same η^{trig} bin. The errors on each point are statistical. The black bar around 0.1 on the y axis indicates a 10% common systematic error for all the data points due to uncertainties in $\varepsilon_{\mathrm{assoc}}$. There is an additional $+0.037$ systematic error on the midrapidity $p + p$ point from jet yield extraction, which is shown as the gray bar on that point (similar analysis as [16]).

Our measurement is inconsistent with any large nuclear suppression (i.e., monojets) of the jet structure in this kinematic range, but it is in agreement with leading twist pQCD calculations that predict suppression of single-particle yields at forward rapidity, with little modification of the conditional yield [13]. However, we note that in these modest p_T ranges, there may be contributions from both "hard" (large Q^2) processes and "soft" coherent (small Q^2) processes. In $d + \mathrm{Au}$ collisions soft particle production is shifted backwards in rapidity [22]. Thus, the fraction of hadrons at forward rapidity from hard processes may be increased in central $d + \mathrm{Au}$ reactions. This may offer an explanation for the modest enhancement seen in the conditional yield for this case and could also mask a small monojet signal.

We have also compared the Gaussian widths of the correlation peaks in $d + \mathrm{Au}$ collisions vs $p + p$ collisions. Ratios of the $d + \mathrm{Au}$ to $p + p$ widths are plotted in Fig. 4 vs p_T^{assoc}. There may be a hint of a slight p_T^{assoc} dependence in the ratio, but overall there is no significant difference in the width in $d + \mathrm{Au}$ collisions for different η^{trig}.

In conclusion, we measured two-particle azimuthal correlations with trigger particles at forward, backward, and midrapidity and correlated them with associated particles at midrapidity in $d + \mathrm{Au}$ and $p + p$ collisions. Associated particle conditional yields in central $d + \mathrm{Au}$ collisions are consistent with those in $p + p$ collisions and are consistent over the range $|\eta^{\mathrm{trig}}| < 2.0$. We have also compared the widths of the away-side jet peaks in $d + \mathrm{Au}$ and in $p + p$ collisions, and find no evidence for η^{trig}-dependent modification within our statistical errors. Overall the results

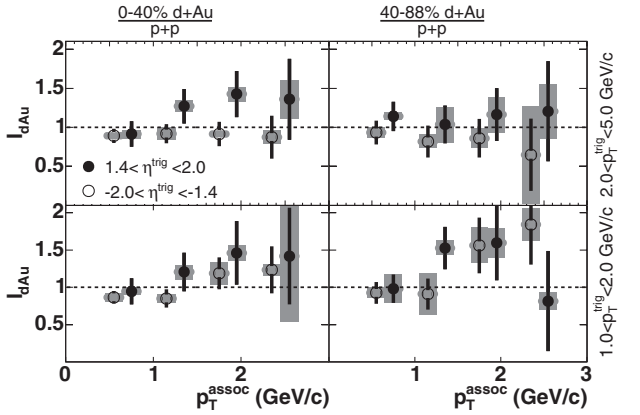

FIG. 3. $I_{d\mathrm{Au}}$ vs p_T^{assoc} for different centrality, p_T^{trig} and η^{trig} bins. To increase visibility, we artificially shift data points belonging to the same p_T^{assoc} bin.

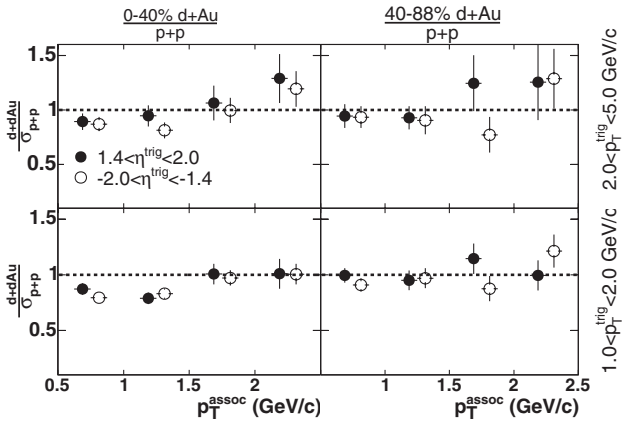

FIG. 4. The ratio of correlation peak widths between d + Au and $p + p$ collisions. Only statistical errors are shown. To increase visibility, we artificially shift the data points belonging to the same p_T^{assoc} bin.

presented here do not support models that predict strong modifications on jet production in the kinematic range covered by this analysis. However, we also note that the backwards rapidity shift of soft particle production may reduce the amplitude of such modifications.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 8 March 2006; published 16 August 2006)

PHENIX has measured the centrality dependence of midrapidity pion, kaon, and proton transverse momentum distributions in $d + \mathrm{Au}$ and $p + p$ collisions at $\sqrt{s_{NN}} = 200$ GeV. The $p + p$ data provide a reference for nuclear effects in $d + \mathrm{Au}$ and previously measured $\mathrm{Au} + \mathrm{Au}$ collisions. Hadron production is enhanced in $d + \mathrm{Au}$, relative to independent nucleon-nucleon scattering, as was observed in lower energy collisions. The nuclear modification factor for (anti)protons is larger than that for pions. The difference increases with centrality but is not sufficient to account for the abundance of baryon production observed in central $\mathrm{Au} + \mathrm{Au}$ collisions at the BNL Relativistic Heavy Ion Collider (RHIC). The centrality dependence in $d + \mathrm{Au}$ shows that the nuclear modification factor increases gradually with the number of collisions encountered by each participant nucleon. We also present comparisons with lower energy data as well as with parton recombination and other theoretical models of nuclear effects on particle production.

I. INTRODUCTION

Since the early 1970s, it has been well established [1–3] that energetic particle production in proton-nucleus ($p + A$) collisions increases faster than the number of binary nucleon-nucleon collisions. This effect, called the "Cronin effect," is a manifestation of the fact that particle production and propagation is influenced by the nucleus. If the A dependence of the invariant cross section I of particle i in $p + A$ collisions is parametrized as

$$I_i(p_T, A) = I_i(p_T, 1)A^{\alpha_i(p_T)}, \quad (1)$$

then it has been observed that α_i is greater than unity above some transverse momentum value, typically 1–1.5 GeV/c, denoting significant enhancement of particle production in $p + A$ collisions. The enhancement depends on the momentum and the type of particle produced, with protons and antiprotons exhibiting a much larger enhancement than pions and kaons at $p_T > 2$–3 GeV/c. At $\sqrt{s_{NN}} = 27.4$ GeV, the enhancement peaks at around $p_T = 4.5$ GeV/c, with $\alpha_{K^+} \simeq \alpha_{\pi^+} = 1.109 \pm 0.007$, while, at the same momentum, the protons can be described by an α factor of $\alpha_p - \alpha_{\pi^+} = 0.231 \pm 0.013$ [2].

Although the observables in Eq. (1) have been clearly related to the nuclear medium, the cause of the Cronin enhancement and its species dependence are not yet completely understood, and further experimental study is warranted in its own right. Furthermore, in the search for the quark gluon plasma at the BNL Relativistic Heavy Ion Collider (RHIC), the Cronin effect is extremely important, as novel effects observed in central Au + Au collisions require good control of the initial state conditions. At RHIC energies, it was discovered that hadron production at high transverse momentum ($p_T \geqslant 2$ GeV/c) is suppressed in central Au + Au collisions [4] compared to nucleon-nucleon collisions. Such suppression may be interpreted as a consequence of the energy loss suffered by the hard-scattered partons as they propagate through the hot, dense medium. However, since the Cronin effect acts in the opposite direction, enhancing the hadron yields, it has to be taken into account when the parton energy loss is determined from the data.

Another unexpected discovery at RHIC energies is that the yields of p and $\bar{p}$ at intermediate p_T ($1.5 < p_T < 5$ GeV/c) in central Au + Au collisions [5–7] are comparable to the yield of pions, in striking contrast to the proton to pion (p/π) ratios of $\sim$0.1–0.3 measured in $p + p$ collisions [8]. Novel mechanisms of particle production in the environment of dense matter, such as recombination of boosted quarks [9] or contributions from baryon junctions [10], which can become dominant in the presence of pion suppression, were proposed to explain the data. Since it has been observed that at lower energies Cronin enhancement is stronger for protons than for pions [2], this effect has to be considered at RHIC energies before new physics is invoked.

The effects from the initial state are best studied by performing a control experiment in which no hot and dense matter is produced. Deuteron + gold collisions at $\sqrt{s_{NN}} = 200$ GeV serve this purpose. Since there is no hot and dense final state medium, the initial state conditions become accessible to the experiment. In addition to Cronin enhancement, known initial state effects also include nuclear shadowing and gluon saturation [11]. The Cronin enhancement is usually attributed to momentum broadening due to multiple initial state soft [12] or semihard [13–16] scattering. Such models typically do not predict the particle species dependence observed in the data. Recently, Hwa and collaborators provided an alternative explanation due to final state interactions. The particle species dependent enhancement is attributed to recombination of shower quarks with those from the medium, where no distinction is made if hot or cold nuclear matter is produced [17]. Identified hadron production measured as a function of centrality brings important experimental data relevant to the long-outstanding problem of the baryon Cronin effect. The dependence of the enhancement upon the thickness of the medium, or the number of collisions suffered by each participating nucleon, can help differentiate among the different scattering models, and the species dependence helps to separate initial from final state effects in $d + $Au.

The paper is arranged as follows. Section II describes the experiment, data analysis, and systematic uncertainties. Section III presents hadron spectra, yields, and the resulting nuclear modification factors. Discussion of the centrality, energy, and species dependence of the nuclear modification factors and implications for understanding of the Cronin effect are in Sec. IV. Section V presents conclusions.

II. EXPERIMENT AND DATA ANALYSIS

A. Data sets and trigger

Data presented here include collisions at $\sqrt{s_{NN}} = 200$ GeV of Au + Au taken in the 2002 run of RHIC and of $d + $Au and $p + p$ collisions collected in 2003. In the following, we discuss our analysis of the $p + p$ and $d + $Au data; details of the Au + Au analysis and the Au + Au results are found in [7]. Events with vertex position along the beam axis within $|z| < 30$ cm were triggered by the beam-beam counters (BBCs) located at $|\eta| = 3.0$–3.9 [18]. The minimum bias trigger accepts 88.5($\pm$4)% of all $d + $Au collisions that satisfy the vertex condition, and 51.6($\pm$9.8)% of $p + p$ collisions. A total of 42 and 25 million minimum bias events were analyzed for $d + $Au and $p + p$ collisions, respectively.

In $p + p$ collisions, PHENIX determines the differential invariant cross section via

$$E\frac{d^3\sigma}{dp^3} = \frac{\sigma_{\rm BBC}}{N_{\rm BBC}^{\rm total}}\frac{1}{2\pi}\frac{1}{p_T}C_{\rm eff}^{\rm geo}(p_T)\,C_{\rm bias}^{\rm BBC}\frac{d^2N}{dp_T dy}. \quad (2)$$

The BBC cross section $\sigma_{\rm BBC}$ was determined via the van der Meer scan technique [19]. In this $p + p$ data set, $\sigma_{\rm BBC} = 23.0 \pm 2.2(9.6\%)$ mb. $N_{\rm BBC}^{\rm total}$ is the total number of BBC triggers analyzed. The factor $C_{\rm eff}^{\rm geo}(p_T)$ denotes the efficiency and geometrical acceptance correction, calculated

TABLE I. Mean number of binary collisions, participating nucleons from the Au nucleus, number of collisions per participating deuteron nucleon, and trigger bias corrections for the d + Au centrality bins.

	00%–20%	20%–40%	40%–60%	60%–88%
$\langle N_{\rm coll}\rangle$	15.4 ± 1.0	10.6 ± 0.7	7.0 ± 0.6	3.1 ± 0.3
$\langle N_{\rm part}\rangle$	15.6 ± 0.9	11.1 ± 0.6	7.7 ± 0.4	4.2 ± 0.3
$\langle \nu = N_{\rm coll}/N^{d}_{\rm part}\rangle$	7.5 ± 0.5	5.6 ± 0.4	4.0 ± 0.3	2.2 ± 0.2
Trigger bias correction	0.95 ± 0.3	0.99 ± 0.007	1.03 ± 0.009	1.04 ± 0.027

with a detailed GEANT Monte Carlo simulation [20] of the PHENIX detector. $C^{\rm geo}_{\rm eff}(p_T)$ normalizes the cross section in one unit of rapidity and full azimuthal coverage. The $C^{\rm BBC}_{\rm bias}$ factor corrects for the fact that the forward BBCs measure only a fraction of the inelastic $p + p$ cross section. This subset of events on which the BBC triggers contains only a fraction of the inclusive particle yield at midrapidity. For charged hadrons, this fraction was determined using triggers on the beam crossing clock; the fraction was found to be 0.80 ± 0.02, independent of p_T. The $C^{\rm BBC}_{\rm bias}$ term is, in our nomenclature, the inverse of this fraction.

In d + Au collisions, PHENIX measures the inelastic yield per BBC triggered event.[1] The collision centrality is selected in d + Au using the south (Au-going side) BBC (BBCS). We assume that the BBCS signal is proportional to the number of participating nucleons ($N^{\rm Au}_{\rm part}$) in the Au nucleus, and that the hits in the BBCS are uncorrelated to each other. We use a Glauber model [22] and simulation of the BBC to define four centrality classes in d + Au collisions, as discussed in detail in [23]. The deuteron nucleus is modeled after a wave function derived by Hulthèn [24]

$$\phi_{\rm d}(\mathbf{r}_{pn}) = \left(\frac{\alpha\beta(\alpha+\beta)}{2\pi(\alpha-\beta)^2}\right)^{\frac{1}{2}} \frac{(e^{-\alpha \mathbf{r}_{pn}} - e^{-\beta \mathbf{r}_{pn}})}{\mathbf{r}_{pn}}, \qquad (3)$$

where $\alpha = 0.228\,{\rm fm}^{-1}$; $\beta = 1.18\,{\rm fm}^{-1}$; and $\mathbf{r}_{pn}$ refers to the separation between the proton and the neutron. The Au nucleus is modeled using a Woods-Saxon density distribution

$$\rho(r) = \frac{\rho_0}{1 + \exp\left(\frac{r-c}{a}\right)}, \qquad (4)$$

where $a = 0.54$ fm and $c = 1.12\,A^{1/3} - 0.86\,A^{-1/3} = 6.40$ fm, a value which agrees well with the measured charge radius of $R = 6.38$ fm for gold.

Using the above parameters and taking into account the BBC efficiency, the mean number of binary collisions along with the mean number of participating nucleons from the Au nucleus that correspond to each centrality bin are shown in Table I. For the minimum bias d + Au collisions, $\langle N_{\rm coll}\rangle = 8.5 \pm 0.4$ and $\langle N_{\rm part}\rangle = 9.1 \pm 0.4$.

As for $p + p$ collisions, there is a BBC trigger bias, but it is much smaller in d + Au. In addition, a second bias occurs in d + Au centrality selected collisions. This second bias arises from the fact that events containing high-p_T hadrons from hard scatterings may have larger multiplicity, and consequently they produce a larger signal in the BBCS. Such events would be considered more central than events without a hard scattering. This effect gives an opposite bias from the first trigger bias effect in the most peripheral bin as events can be shifted out of this bin but not into it. We correct for both biases in d + Au collisions using simulations and a Glauber model. The combined corrections for these effects range from 0% to 5%, depending on the centrality category, and are shown in Table I. Systematic uncertainties on these corrections are less than 4%.

B. Tracking and particle identification

Charged particles are reconstructed using a drift chamber (DC) and two layers of multiwire proportional chambers with pad readout (PC1, PC3) [18]. Pattern recognition is based on a combinatorial Hough transform in the track bend plane, while the polar angle is determined by PC1 and the location of the collision vertex along the beam direction [25]. The track reconstruction efficiency is approximately 98%.

Particle momenta are measured with a resolution $\delta p/p = 0.7\% \oplus 1.1\%\, p$ (GeV/c). The momentum scale is known to 0.7%. Particle identification is based on particle mass calculated from the measured momentum and the velocity obtained from the time-of-flight and path length along the trajectory. The measurement uses the portion of the spectrometer containing the high-resolution time-of-flight (TOF) detector, which covers pseudorapidity $-0.35 \leqslant \eta \leqslant 0.35$ and $\Delta\phi = \pi/8$ in azimuthal angle. The timing uses the BBC for the global start and the stop signals from the TOF scintillators located at a radial distance of 5.06 m. Tracks are required to match a hit on the TOF within ± 3 standard deviations, σ, of the track projection to the TOF radial location. The particle yields are corrected for losses due to this matching cut.

Figure 1 illustrates the performance of the hadron identification system. The system resolution is $\sigma \approx 130$ ps for both d + Au and $p + p$; the start time resolution is limited by the low hit multiplicity in the BBC. The TOF resolution achieved allows for a clear separation of π/K and K/p up to $p_T = 2$ and $p_T = 3.6$ GeV/c, respectively. A 2σ cut in mass squared is used to separate the different hadron species, as shown in Fig. 2 for hadrons in the p_T range 1.2–1.6 GeV/c. A clear separation between pions and kaons is seen. The particle yields are corrected for losses due to the 2σ cut. A simple cut on mass would leave the pion spectrum above 2 GeV/c in p_T with an admixture of kaons. This is avoided by calculating a pion and kaon probability for each particle,

[1] To convert the reported inelastic yield to differential cross section, one must multiply by the BBC trigger cross section of $\sigma^{\rm tot}_{\rm MB}(d{\rm Au})\epsilon^{\rm BBC}_{\rm MB}(d{\rm Au}) = 1.99 \pm 0.10$ b [21].

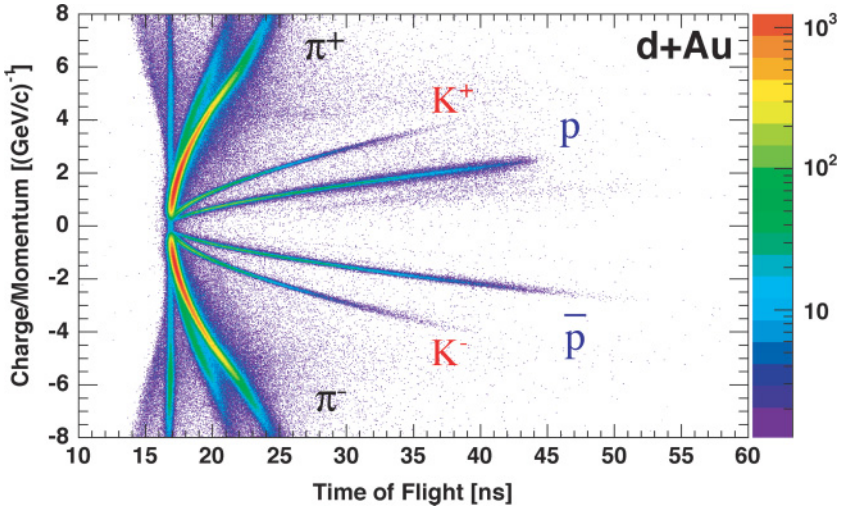

FIG. 1. (Color online) Time of flight vs charge/momentum for particles in minimum bias $d + \mathrm{Au}$ collisions. Bands corresponding to the different hadrons are labeled. Electron and muon bands are also visible, though not labeled.

utilizing the measured pion and kaon centroid and width in mass squared. For $2.0 \leqslant p_T \leqslant 2.7$ GeV/c, particles within the 2σ particle identification (PID) cut for pions that also fall inside the 2σ kaon band are vetoed from the pion spectrum. The resulting loss in efficiency is corrected by applying the same procedure in the Monte Carlo simulations. This procedure has been verified using 1σ PID cuts, which allows full pion-kaon separation to 2.7 GeV/c.

Corrections to the charged-particle spectrum for geometrical acceptance, decays in flight, reconstruction efficiency, energy loss in detector material, and momentum resolution are determined using a single-particle GEANT Monte Carlo simulation.

The proton and antiproton spectra are corrected for feed down from weak decays via a Monte Carlo simulation using as input experimental data on Λ production. The total number of protons produced in the collisions can be written as $p + 0.64(\Lambda + \Sigma^0 + \Xi^0 + \Xi^- + \Omega^-) + 0.52\Sigma^+$, where p denotes the primordial number of protons produced, the other symbols denote the primordial number of those particles produced in the collision, and 0.64 and 0.52 are the branching ratios for $\Lambda \to p\pi^-$ and $\Sigma^+ \to p\pi^0$, respectively. The hyperons listed together with Λ decay to Λ with approximately 100% branching ratio, and so yield protons with the $\Lambda \to p\pi$ branching ratio. We estimate the proton and antiproton spectra from weak decays and subtract them from the measured yields, using experimental data from UA5 [26] from nonsingle diffractive $\sqrt{s} = 200$ GeV $p + \bar{p}$ collisions, and preliminary Λ and $\overline{\Lambda}$ spectra from STAR in $p + p$ and $d + \mathrm{Au}$ collisions at the same energy [27–30]. The shape of the Σ^0, Ξ^0, and Ξ^- spectra are constructed from the Λ spectrum by m_T scaling (i.e., under the assumption that these hadrons are all produced with roughly the same spectrum in transverse mass [30]). The relative normalization of Λ, Σ^0, Ξ^0, and Ξ^- from UA5 [26] is used for both $p + p$ and $d + \mathrm{Au}$ collisions. This is justified by the similarity of the Cronin effect for different baryons. The contribution of Ω^- is negligible, and is not included in the correction. The Monte Carlo simulation decays these baryons and propagates the products through the PHENIX magnetic field and central arm detectors, accounting also for the change of momentum distributions between parent and daughter particles due to decay kinematics. The resulting proton and antiproton spectra are then subtracted from the measured inclusive spectra. The fractional contribution from

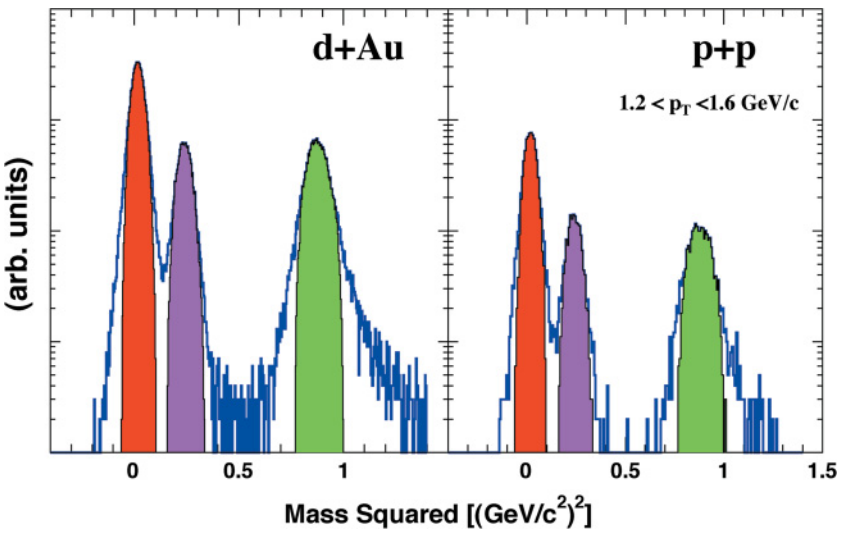

FIG. 2. (Color online) Mass squared distribution for positively charged tracks with $1.2 \leqslant p_T \leqslant 1.6$ GeV/c, using the high-resolution TOF measurement. Solid regions indicate the mass squared ranges for accepted pions, kaons, and protons, respectively, from left to right.

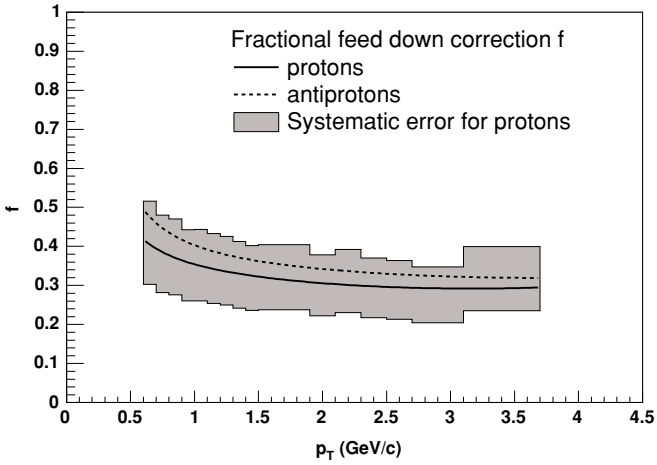

FIG. 3. Fractional contributions of protons f (solid line) and antiprotons (dashed line), as a function of p_T, from weak decays in all measured protons and antiprotons. Systematic error band (26%) for the protons is shown and discussed in the text. The same systematic error applies for the antiprotons.

feed-down protons from weak decays to the total measured proton spectrum, f, is approximately 30% at moderate and high p_T growing slowly for lower p_T and reaching 40% at $p_T = 0.6$ GeV/c. f is shown as a function of p_T in Fig. 3, along with the corresponding fractional contribution for the antiprotons.

C. Systematic uncertainties

Systematic uncertainties on the hadron spectra are estimated as in Ref. [7]. Various sets of p_T spectra and ratios of different particle types were made by varying the cut parameters such as the fiducial cut to check acceptance corrections, track association (i.e., matching) windows, and PID cuts, from those used in the analysis. For each of these spectra and ratios, the same changes in cuts were made in the Monte Carlo analysis. The uncertainties were evaluated by comparing fully corrected spectra and ratios from different cuts. The resulting uncertainties from each cut are given in Table II and added in quadrature to yield overall systematic uncertainties.

Additional systematic uncertainties on the hadron spectra arise from time variations in the TOF timing (slat-by-slat and run-by-run variations), the small remaining contamination by other species after matching and PID cuts, uncertainty in the corrections for track reconstruction efficiency, and uncertainty on particle energy loss in the detector material. These uncertainties, which do not depend measurably on the hadron momentum, are listed in Table II. The sizable uncertainty in the matching cut is due to the non-Gaussian tails on the z-coordinate matching distributions. The track matching in this direction is limited by a relatively poor vertex resolution determined by the BBC in $p + p$ and $d +$ Au collisions due to the small multiplicities. The quoted 3%–4% uncertainty in the reconstruction efficiency correction represents the maximum local discrepancy between efficiencies measured with strict and loose track quality cuts.

TABLE II. Systematic errors in percent on particle yields in $d +$ Au and $p + p$ collisions. These values are independent of p_T.

	$d +$ Au	$p + p$
Geometric acceptance correction	4	4
Track matching	9	8
Timing variations	5	5
Reconstruction efficiency correction	3	4
Energy loss correction	1	2
Trigger bias	–	4

Uncertainties due to particle identification cuts are momentum dependent. For protons and antiprotons, the identification uncertainty is 8% at low p_T and decreases to 3% at high p_T. Kaons at low momentum have 10% PID uncertainty, decreasing to 3% at high p_T. For pions, the uncertainty increases from 4% to 10% with increasing p_T. Kaon and proton uncertainties decrease with increasing p_T because energy loss and decay corrections become smaller. The pion uncertainties are dominated by the particle identification performance, which worsens with increasing p_T.

The systematic error on the feed-down proton spectrum is 26%, primarily due to uncertainty in the measured Λ spectra and particle composition. The resulting systematic error on the final prompt proton and antiproton spectra is of the order of 10% in both $p + p$ and $d +$ Au. The systematic error on the proton to pion ratio is 12%, including the uncertainty on $\overline{\Lambda}/\Lambda$.

Systematic uncertainties on the $d +$ Au nuclear modification factors mostly cancel as the $p + p$ and $d +$ Au data were collected immediately following one another, and detector performance was very similar. The overall systematic error in the nuclear modification factor is due to uncertainties in the reconstruction efficiencies, fiducial volumes, and small run-by-run variations. It is approximately 10%, independent of particle species and p_T. An additional $d +$ Au scale uncertainty is shown as boxes around 1.0 in the figures; this is the quadrature sum of uncertainties on the $p + p$ cross section of 9.6% and the number of binary collisions in the each centrality bin (presented in Table I).

The systematic error on the Au + Au nuclear modification factors is derived by propagating the systematic errors on $p + p$ and Au + Au data [7] to the final ratio. The average systematic error for pions is approximately 15%, while for protons and antiprotons it is on the order of 19%. The normalization uncertainty, as in $d +$ Au, is the quadrature sum of uncertainties on the $p + p$ cross section and the error on the number of binary collisions in the corresponding Au + Au centrality bin from Ref. [7]. We note that for the most central Au + Au bin (0%–5%), $N_{\rm coll} = 1065.4$ and the uncertainty is ± 105.3; in the most peripheral bin (60%–92%), $N_{\rm coll} = 14.5 \pm 4.0$.

III. RESULTS

A. Hadron spectra

The fully corrected p_T distributions of π, K, p, and $\bar{p}$ for the four $d +$ Au centrality bins and for $p + p$ collisions are

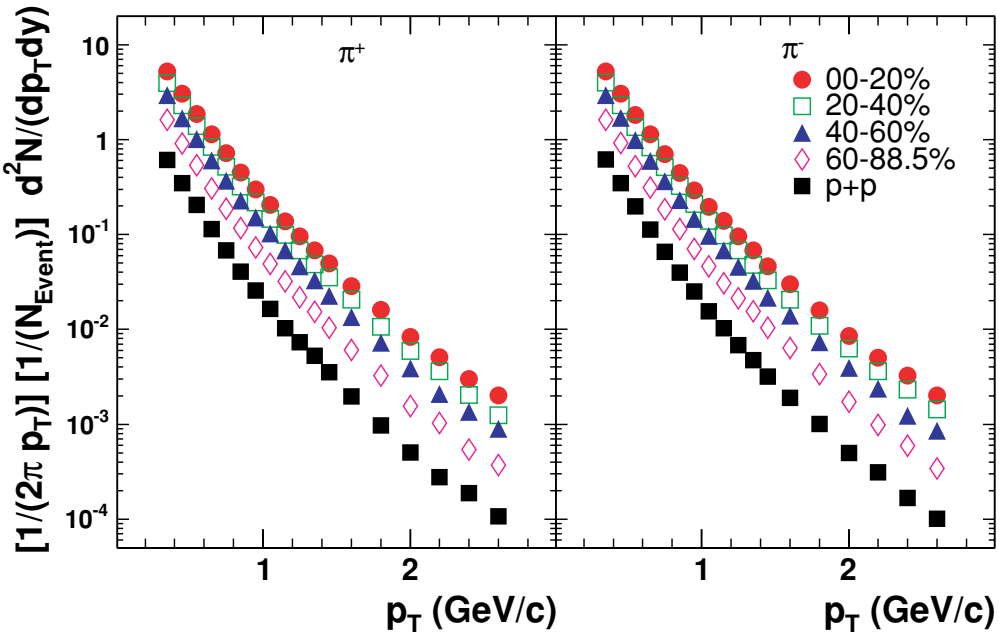

FIG. 4. (Color online) Invariant yields at midrapidity for positive and negative pions as a function of p_T for various centrality classes in $d + \text{Au}$ and $p + p$ collisions. The error bars show statistical uncertainties only and are typically smaller than the data points.

shown in Figs. 4, 5, and 6, respectively. Pions show a power law spectral shape, while kaons and protons are exponential.

To probe the hadron production mechanism, it is instructive to compare particle and antiparticle spectra. Figures 7, 8, and 9 show the ratios of antiparticle to particle production as a function of p_T in $p + p$, $d + \text{Au}$, and (for comparison) central $\text{Au} + \text{Au}$ collisions from [7] for π, K, and p, respectively. For all three hadron species, the ratios are flat with p_T in the PHENIX p_T range. The values agree within uncertainties with measurements by the STAR Collaboration [31]. The $d + \text{Au}$ yield ratios are in good agreement with $p + p$ collisions, and the ratios remain the same even in central $\text{Au} + \text{Au}$ collisions. The production ratio of antiparticle to particle is $0.99 \pm 0.01(\text{stat}) \pm 0.06(\text{syst})$ for pions and $0.92 \pm 0.01(\text{stat}) \pm 0.07(\text{syst})$ for kaons in both minimum bias $d + \text{Au}$ and $p + p$ collisions. The antiproton to proton ratio is measured to be $0.70 \pm 0.01(\text{stat}) \pm 0.08(\text{syst})$ in minimum bias $d + \text{Au}$ collisions and $0.71 \pm 0.01(\text{stat}) \pm 0.08(\text{syst})$ in $p + p$ collisions. All ratios are consistent within errors with values reported by PHOBOS [32] and BRAHMS [33].

B. Nuclear modification factors

The measurement of identified hadrons in both $d + \text{Au}$ and $p + p$ collisions allows study of the centrality dependence of the nuclear modification factor in $d + \text{Au}$. A standard way to quantify nuclear medium effects on high-p_T particle production in nucleus-nucleus collisions is provided by the

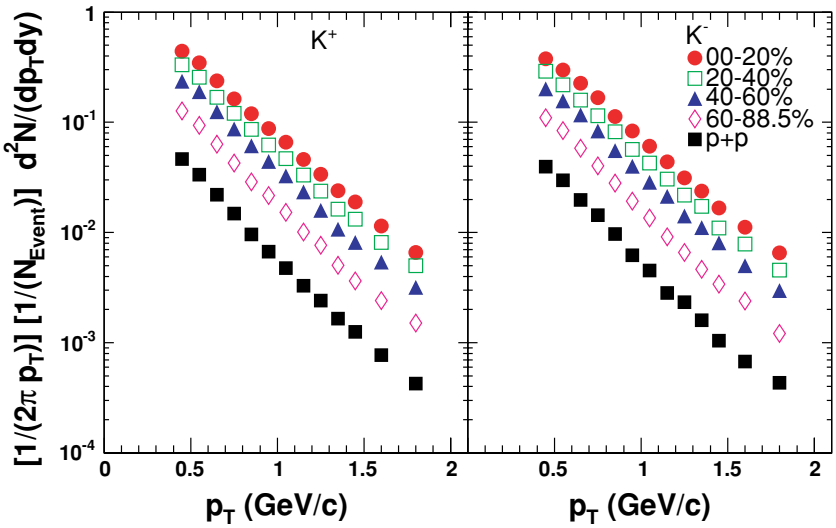

FIG. 5. (Color online) Same as Fig. 4, but for kaons.

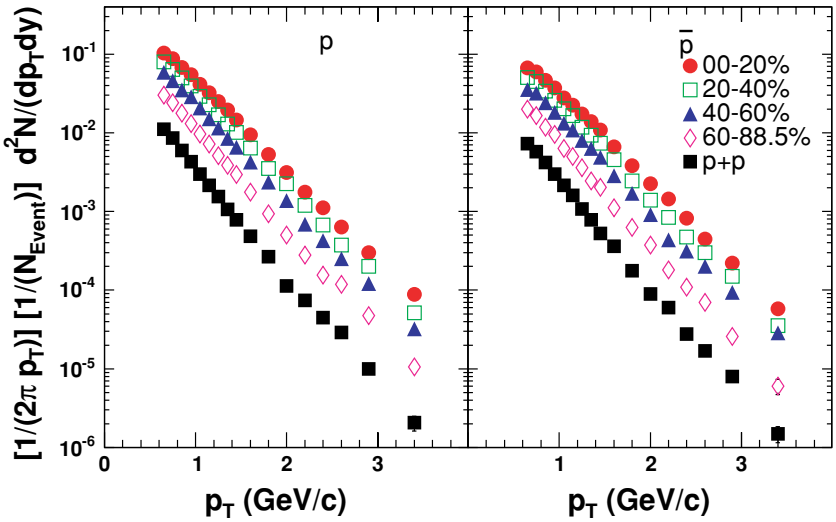

FIG. 6. (Color online) Same as Fig. 4, but for protons and antiprotons.

nuclear modification factor. This is the ratio of the $d + \mathrm{Au}$ invariant yields to the binary collision scaled $p + p$ invariant yields, that is,

$$R_{d\mathrm{Au}}(p_T) = \frac{\left(1/N_{d\mathrm{Au}}^{\mathrm{evt}}\right) d^2N_{d\mathrm{Au}}/dy\,dp_T}{T_{d\mathrm{Au}}\, d^2\sigma_{\mathrm{inel}}^{pp}/dy\,dp_T}, \qquad (5)$$

where $T_{d\mathrm{Au}} = \langle N_{\mathrm{coll}}\rangle/\sigma_{\mathrm{inel}}^{pp}$ describes the nuclear geometry, and $d^2\sigma_{\mathrm{inel}}^{pp}/dy dp_T$ for $p + p$ collisions is derived from the measured $p + p$ cross section. $\langle N_{\mathrm{coll}}\rangle$ is the average number of inelastic nucleon-nucleon collisions determined from simulation using the Glauber model as input, as described in Sec. II A. $N_{d\mathrm{Au}}^{\mathrm{evt}}$ is the number of $d + \mathrm{Au}$ events in the relevant centrality class.

Figure 10 shows $R_{d\mathrm{Au}}$ for pions, kaons, and protons for minimum bias $d + \mathrm{Au}$ collisions. We observe a nuclear enhancement in the production of hadrons with $p_T \gtrsim 1.5$–2 GeV/c in $d + \mathrm{Au}$ collisions, compared to that in $p + p$. As was already suggested when comparing the enhancement for inclusive charged hadrons with that of neutral pions [34], there is a species dependence in the Cronin effect. The Cronin effect for charged pions is small, as was observed for neutral pions. The nuclear enhancement for protons and antiprotons is considerably larger. The kaon measurement has a more limited kinematic range, but the $R_{d\mathrm{Au}}$ agrees with that of the pions at comparable p_T.

Figure 11 shows $R_{d\mathrm{Au}}$ for pions, kaons, and protons in the four $d + \mathrm{Au}$ centrality bins. Peripheral $d + \mathrm{Au}$ collisions ($\langle N_{\mathrm{coll}}\rangle = 3.1 \pm 0.3$) do not show any modification of high-momentum hadron production, compared to that in $p + p$ collisions. At $p_T \leqslant 1$ GeV/c, the nuclear modification factor falls below 1.0. This is to be expected as soft particle production scales with the number of participating nucleons, not with the number of binary nucleon-nucleon collisions. More central collisions show increasing nuclear enhancement in both high-p_T pion and proton production.

The bands in Fig. 11 show a calculation of the Cronin effect for pions by Accardi and Gyulassy, using a pQCD model of multiple semihard collisions and taking geometrical shadowing into account [13]. The agreement above 1 GeV/c, where the calculation should be reliable, is very good for all four centrality bins. This agreement illustrates that the multiple

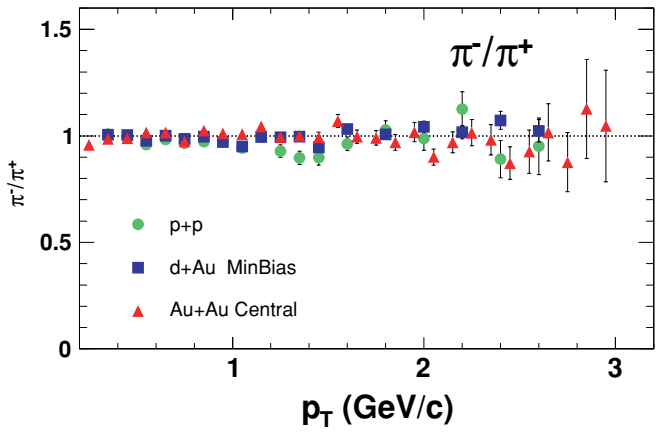

FIG. 7. (Color online) Ratio of midrapidity spectra for π^- to π^+ in $d + \mathrm{Au}$, $p + p$, and central $\mathrm{Au} + \mathrm{Au}$ collisions. Error bars show statistical uncertainties only.

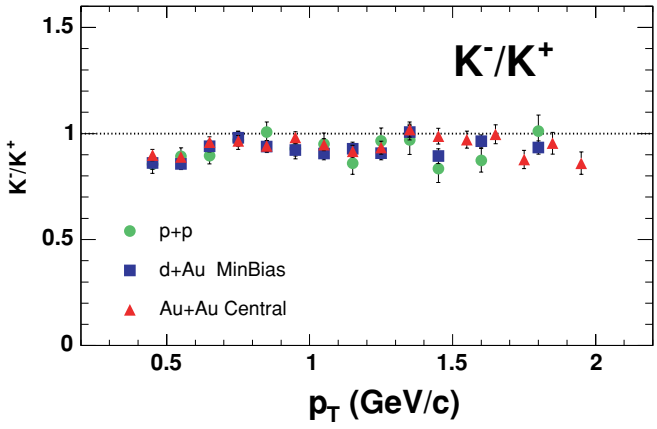

FIG. 8. (Color online) Same as Fig. 7, but for K^- to K^+.

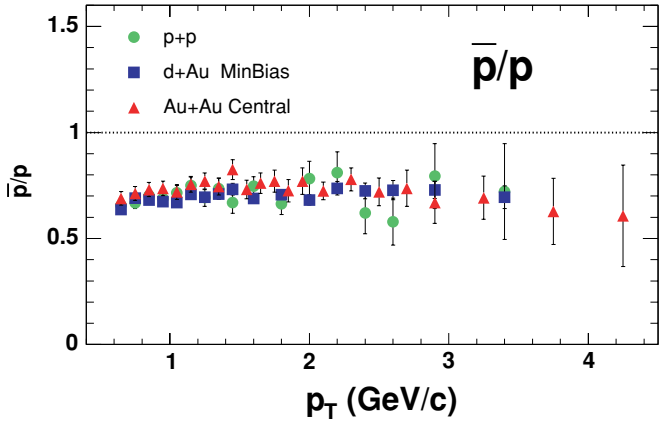

FIG. 9. (Color online) Same as Fig. 7, but antiprotons to protons.

partonic scattering and nuclear shadowing alone can explain the observed Cronin effect and leaves very little room for gluon saturation effects in the nuclear initial state at midrapidity at RHIC energies [13].

C. Centrality dependence

We further probe the effect of cold nuclear matter upon hadron production using the number of collisions suffered by each projectile nucleon for the four centrality bins. Figure 12 compares the centrality dependence of $R_{d\mathrm{Au}}$ for pions and protons in two momentum bins. The modification factors are plotted as a function of $\nu = N_{\mathrm{coll}}/N^{d}_{\mathrm{part}}$, the number of collisions per participating deuteron nucleon. The lower momentum bin, $0.6 \leqslant p_T \leqslant 1.0\ \mathrm{GeV}/c$, is chosen in the region

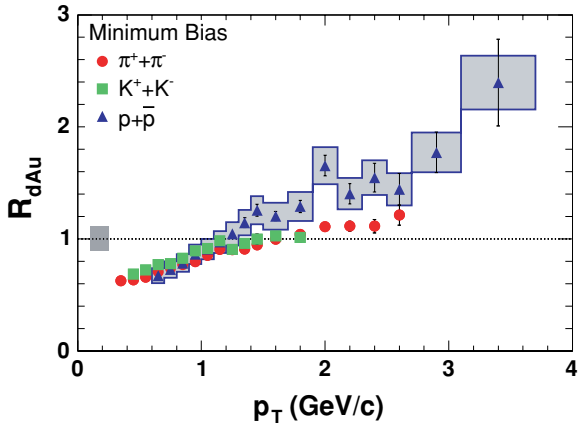

FIG. 10. (Color online) Nuclear modification factor $R_{d\mathrm{Au}}$ for pions, kaons, and protons in $d + \mathrm{Au}$ collisions for minimum bias events. The error bars represent the statistical errors. The box around 1.0 shows uncertainties in the $p + p$ absolute cross section and in the calculation of N_{coll}. For the proton and antiproton $R_{d\mathrm{Au}}$, the ~10% systematic uncertainty is also presented as boxes around the points. The systematic uncertainty on the pion and kaon $R_{d\mathrm{Au}}$ is similar but not shown in the picture for clarity.

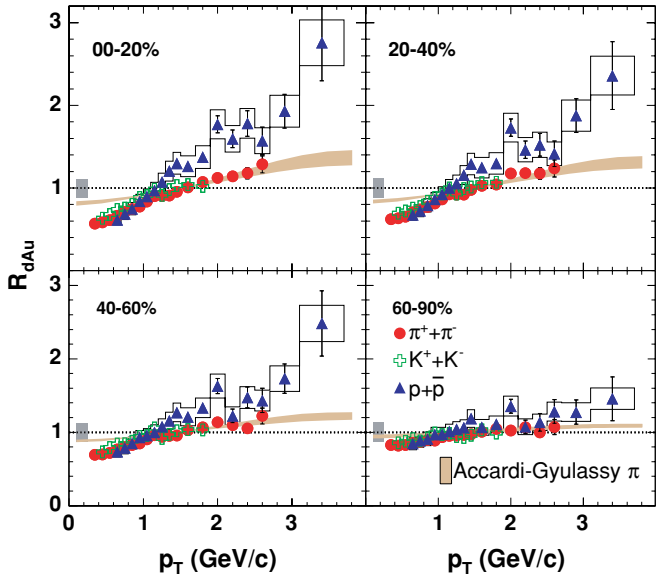

FIG. 11. (Color online) Nuclear modification factor $R_{d\mathrm{Au}}$ for pions, kaons, and protons in $d + \mathrm{Au}$ collisions in four centrality bins. The error bars represent the statistical errors. Boxes around 1.0 show uncertainties in the $p + p$ absolute cross section and in the calculation of N_{coll}. For the proton and antiproton $R_{d\mathrm{Au}}$, the ~10% systematic uncertainty is also presented as boxes around the points. The systematic uncertainty on the pion and kaon $R_{d\mathrm{Au}}$ is similar but not shown in the picture for clarity. Solid bands show the calculation of the nuclear modification factors for pions by Accardi and Gyulassy [13].

where $R_{d\mathrm{Au}}$ is less than 1.0, and hadron yields scale very nearly with the number of nucleons participating in the collision, rather than with the number of binary collisions. As expected,

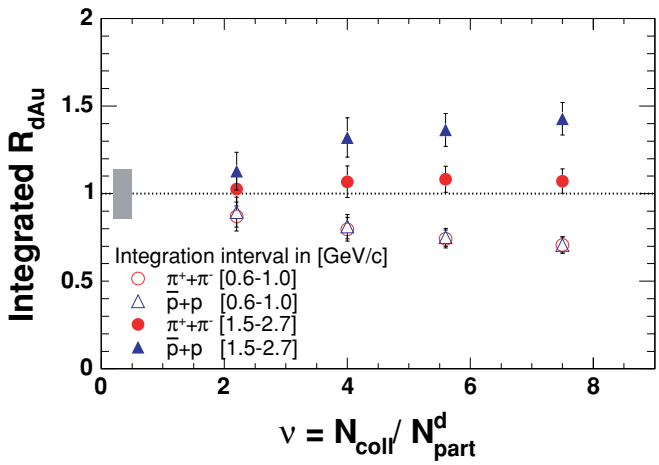

FIG. 12. (Color online) Integrated $R_{d\mathrm{Au}}$ for pions and protons in two momentum bins as a function of the number of collisions suffered by the deuteron participant ν. Error bars indicate the quadrature sum of statistical errors and uncertainties on the number of collisions bin by bin. The solid box on the left shows the magnitude of the centrality independent uncertainties.

$R_{d\mathrm{Au}}$ decreases with ν in this p_T range, with negligible difference between pions and protons. In the higher p_T bin, $R_{d\mathrm{Au}}$ increases with the number of collisions, with a notably larger rate of increase for baryons than for mesons. Though the $R_{d\mathrm{Au}}$ values for higher p_T hadrons appear to flatten with increasing centrality, the uncertainties are too large to allow a definitive conclusion about saturation with the number of collisions encountered by each participant nucleon [14].

D. Cronin effect for baryons

Figure 13 shows the ratio of the nuclear modification factors observed for protons and antiprotons to that for pions in the most central and most peripheral $d+\mathrm{Au}$ collisions. The enhancement for protons is stronger, by approximately 30–50% in the most central collisions; this was also reported by STAR [31,35]. The increasing difference between baryons and mesons for more central collisions indicates that the baryon production mechanism appears to depend upon the surrounding nuclear medium already found in $d+\mathrm{Au}$ collisions. We note, however, that the species dependence of the Cronin effect in $d+\mathrm{Au}$ collisions is much smaller than the factor of $\approx$3 enhancement of protons in central Au + Au collisions, as can be seen by comparing the nuclear modification factors for pions and protons in central Au + Au collisions shown below in Sec. IV A.

By converting the nuclear modification factors to beam per-nucleon cross section ratios and vice versa, it is possible to compare them to measurements of the Cronin effect at other energies. Figure 14 shows nuclear modification factors from this work compared to those derived from α factors measured at lower energies [2], in a manner similar to that used in [3] to calculate per-nucleon cross section ratios. To make the transition to nuclear modification factors from per-nucleon cross section ratios we assume that $\sigma_{d+\mathrm{Au}} = 2\sigma_{p+A}$ and that $\sigma_{p+d} = 2\,\sigma_{p+p}$ at the low energy of interest, which is a very reasonable approximation for all particle species [2].

The observed species dependence of the enhancement is similar to that measured in lower energy collisions [3]. The

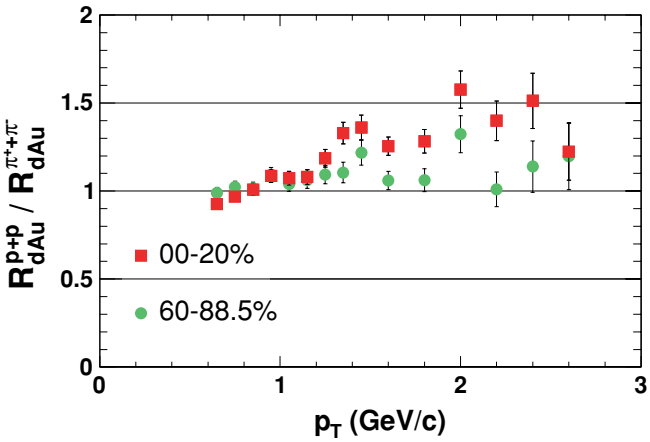

FIG. 13. (Color online) Ratio of the proton over the pion nuclear modification in $d+\mathrm{Au}$ collisions, for central and peripheral events. Error bars indicate statistical errors only.

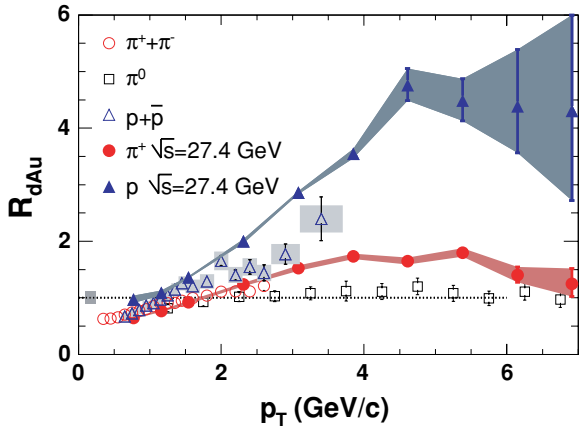

FIG. 14. (Color online) Nuclear modification factors for charged pions, neutral pions [34], and protons and antiprotons from minimum bias $d+\mathrm{Au}$ from this work (open symbols) compared to nuclear modification factors calculated from the per-beam nucleon cross sections reported for $\sqrt{s} = 27.4$ GeV $p+A$ collisions [2] (closed symbols and continuous bands).

magnitude of the enhancement for pions at $p_T > 3$ GeV/c is larger at $\sqrt{s} = 27.4$ GeV than at 200 GeV. Protons and antiprotons are also more enhanced at the lower beam energy: a factor of 3.5 at $p_T \approx 4$ GeV, as compared with a factor of 2 at $\sqrt{s} = 200$ GeV. This energy dependence of the Cronin effect for pions has been interpreted as evidence for a different production mechanism for high-p_T hadrons at RHIC energies compared to lower energies [36]. In this model, high-p_T hadrons are produced incoherently on different nucleons at low energy, while in higher energy collisions the production amplitudes can interfere because the process of gluon radiation is long compared to the binary collision time. Coherent radiation from different nucleons is subject to Landau-Pomeranchuk suppression. However, the difference between the baryon and meson Cronin effects is not predicted by this model.

IV. DISCUSSION

Traditional explanations of the Cronin effect all involve multiple scattering of incoming partons that lead to an enhancement at intermediate p_T [12]. Various theoretical models of multiple scattering predict somewhat different dependence upon the number of scattering centers. The observed centrality or ν dependence for pions is well reproduced by semihard initial state scattering [13] as shown in Fig. 11; see also [14–16]. The models include initial state multiple scattering as well as geometrical shadowing. However, none of these models would predict a species-dependent Cronin effect, as initial state parton scattering precedes fragmentation into the different hadronic species. The markedly larger Cronin effect for protons and antiprotons requires processes in addition to initial state multiple scattering in baryon production at moderate transverse momenta.

Recently, Hwa and Yang [17] demonstrated an alternative explanation of the Cronin effect, attributed to the recombination of shower quarks with those from the medium in

d + Au collisions. Such models do predict a larger Cronin effect for protons than for pions, which may be justified by the rather short formation times of $p_T = 2$–4 GeV/c protons. According to the uncertainty principle, the formation time in the rest frame of the hadron can be related to the hadron size R_h. In the laboratory frame, the formation time of a hadron with mass m_h and energy E_h is given by $\tau_f \approx R_h \frac{E_h}{m_h}$. For a $p_T = 2.5$ GeV/c pion, the formation time is 9–18 fm/c (for $R_h = 0.5$–1.0 fm), well outside the collision region. However, for $p_T = 2.5$ GeV/c protons, the corresponding formation time is only 2.7 fm/c, suggesting that the hadronization process may well begin in or near the nuclear medium.

A. Comparison to Au + Au collisions

The proton to pion ratio from minimum bias $p + p$ and minimum bias d + Au are compared to each other and to central and peripheral Au + Au collisions in Fig. 15. As noted above, protons and antiprotons are feed-down corrected in each system.

The p/π ratio in d + Au is very similar to that in peripheral Au + Au collisions and lies slightly above the $p + p$ ratio. The p/π ratio in central Au + Au collisions, however, is much larger. The difference between the ratio in d + Au and central Au + Au clearly indicates that baryon yield enhancement is not simply an effect of sampling a large nucleus in the initial state. The large enhancement requires the presence of a substantial volume of nuclear medium.

Figures 16–18 compare the nuclear modification factors for pions, kaons and (anti)protons in Au + Au and d + Au collisions. The $p + p$ data from this work allow, for the first time, the calculation of nuclear modification factors in Au + Au by PHENIX. The Au + Au data are taken from [7]. It should be noted that common fluctuations between $R_{d\mathrm{Au}}$ and R_{AuAu} in Figs. 17 and 18 arise because the $p + p$ denominators are common.

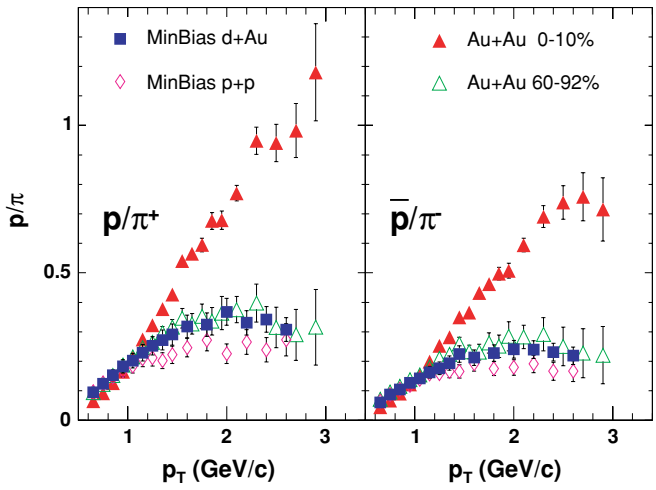

FIG. 15. (Color online) Ratio of feed-down-corrected protons to π^+ and antiprotons to π^- in minimum bias $p + p$ and d + Au compared to peripheral and central Au + Au collisions. Statistical error bars are shown.

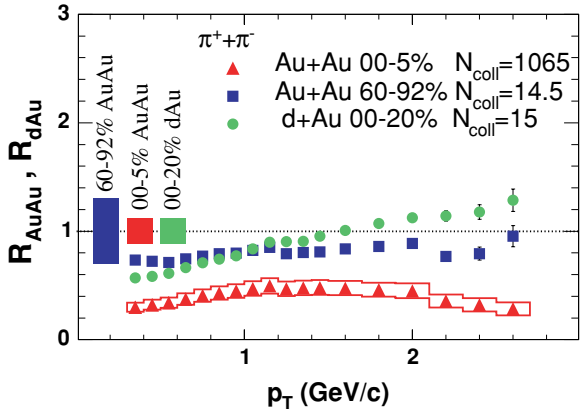

FIG. 16. (Color online) Nuclear modification factors for pions, comparing central and peripheral Au + Au collisions to central d + Au. Note that the number of binary nucleon-nucleon collisions in peripheral Au + Au and in central d + Au are very similar. Solid bars on the left indicate normalization uncertainties in the $p + p$ absolute cross section and in the calculation of N_{coll} for the three systems. Error bars indicate statistical errors only; for the most central Au + Au case, the systematic errors discussed in the text are shown as boxes around the points.

Central and peripheral Au + Au collisions are compared to central d + Au collisions, which have a similar number of binary collisions as the peripheral Au + Au sample. Pions show a much lower R_{AuAu} at high p_T in central than in peripheral Au + Au collisions, as expected from the large energy loss suffered by the partons in central collisions. The nuclear modification factor rises faster with p_T in d + Au than in peripheral Au + Au, despite the comparable number of binary collisions. As Au + Au involves a second Au nucleus, shadowing effects can be expected to be larger, reducing the observed Cronin effect.

The proton and antiproton nuclear modification factors show a quite different trend. The Cronin effect, larger than 1.0 at higher p_T values, is independent of centrality in Au + Au collisions. This feature was already observed as binary collision scaling of proton and antiproton production in the central/peripheral collision yield ratios [6]. The Cronin effect in d + Au is at least as large as that in peripheral

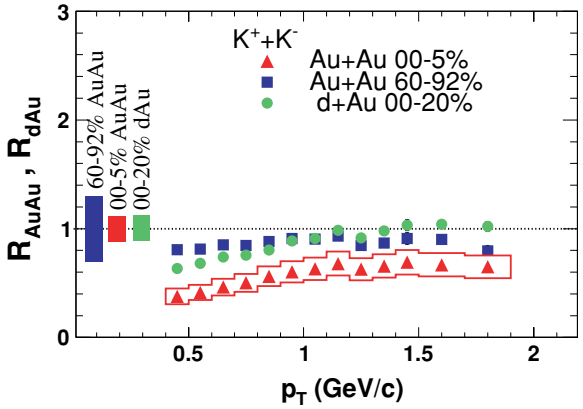

FIG. 17. (Color online) Same as Fig. 16, but for kaons.

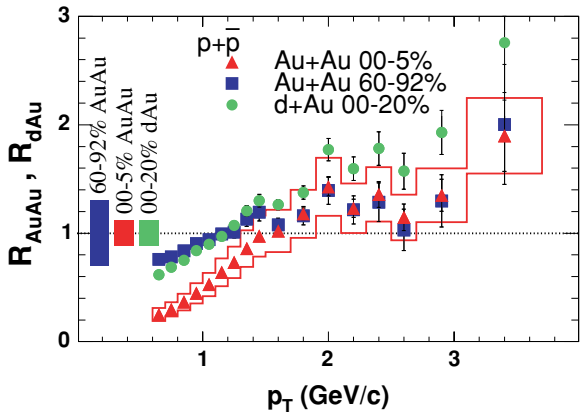

FIG. 18. (Color online) Same as Fig. 16, but for protons and antiprotons.

Au + Au. The difference indicates that baryon production must involve a complex interplay of processes in addition to initial state nucleon-nucleon collisions.

V. CONCLUSION

We have presented the centrality and species dependence of identified particle spectra in d + Au collisions, including the dependence of the nuclear modification factor upon the number of collisions per participant nucleon. We also presented the first measurement of R_{AuAu} for pions, kaons, protons, and antiprotons in Au + Au collisions.

The Cronin effect for charged pions is small, but nonzero. The proton to pion ratio in d + Au is similar to that in peripheral Au + Au, while the corresponding ratio in $p + p$ is somewhat lower. The nuclear modification factor in d + Au for protons shows a larger Cronin effect than that for pions, and the difference increases with collision centrality. This difference was seen, but never fully understood, in lower energy collisions; but it is not large enough to account for the abundance of protons in central Au + Au collisions. The difference between pions and protons does, however, indicate that the Cronin effect is not simply due to multiple scattering of the incoming partons. R_{AuAu} for protons and antiprotons confirms previous observations that the production of high-p_T baryons in Au + Au scales with the number of binary nucleon-nucleon collisions, but the baryon yield per collision in Au + Au exceeds that in $p + p$.

ACKNOWLEDGMENTS

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions. (Received 1 February 2006; published 25 May 2006)

We present an improved measurement of the double helicity asymmetry for π^0 production in polarized proton-proton scattering at $\sqrt{s} = 200$ GeV employing the PHENIX detector at the Relativistic Heavy Ion Collider (RHIC). The improvements to our previous measurement come from two main factors: Inclusion of a new data set from the 2004 RHIC run with higher beam polarizations than the earlier run and a recalibration of the beam polarization measurements for the earlier run, which resulted in reduced uncertainties and increased beam polarizations. The results are compared to a Next to Leading Order (NLO) perturbative Quantum Chromodynamics (pQCD) calculation with a range of polarized gluon distributions.

DOI: 10.1103/PhysRevD.73.091102 PACS numbers: 13.85.Ni, 13.88.+e, 21.10.Hw, 25.40.Ep

From polarized lepton-nucleon deep inelastic scattering (DIS) experiments it is known that only ~25% of the proton spin can be attributed to the spins of the quarks and antiquarks [1]. The rest of the proton spin is assumed to be carried by the gluons and orbital angular momentum.

The double helicity asymmetry of inclusive π^0 production in polarized $p + p$ collisions, $A_{LL}^{\pi^0}$, is directly sensitive to the polarized gluon distribution function in the proton through gluon-gluon and gluon-quark subprocesses [2]. Results on $A_{LL}^{\pi^0}$ from polarized $p + p$ collisions at $\sqrt{s} =$ 200 GeV using the PHENIX detector at the Relativistic Heavy Ion Collider (RHIC) were published earlier [3]. The unpolarized cross section for π^0 production is described well by next-to-leading-order perturbative QCD (NLO pQCD) calculations within the theoretical scale uncertainty [4]. The double spin asymmetry can hence be reliably interpreted in terms of the polarized gluon and polarized quark distributions in the nucleon.

$A_{LL}^{\pi^0}$ is the difference between π^0 production cross sections for like helicity and unlike helicity proton collisions, divided by the sum. Experimentally, $A_{LL}^{\pi^0}$ is obtained from the difference in production rates for polarized collisions of like and unlike helicities, divided by the sum, and normalized by the product of the polarizations of each beam.

The published $A_{LL}^{\pi^0}$ data [3] were collected in the 2003 RHIC run (Run-3) when the average polarization of the beams in RHIC was 0.35 and 0.30 for the ''blue'' and ''yellow'' ring, respectively. Recalibration of the proton-carbon CNI polarimeter [5], based on a polarized atomic hydrogen gas jet at RHIC [6], changed the absolute scale of beam polarizations by 22%. In addition, this recalibration reduced the uncertainty in the polarization measurement for each beam from ~34% to ~18% (and for a product of two beam polarizations from 65% to 28%). An important, but less significant, change in Run-3 data as published occurred when we found a polarization pattern error in 10% of the data files of Run-3, and this was corrected.

In 2004, one week of RHIC operation was dedicated to the study and improvement of the beam polarization in RHIC. The PHENIX detector took data during this time. The results of this run (Run-4) are presented here combined with the data from the previous year.

The statistical uncertainty of a double spin asymmetry is inversely proportional to the square root of the figure of merit defined by $\mathcal{L}P_B^2P_Y^2$, where the P_B and P_Y are the beam polarization values of the blue and yellow RHIC beams, respectively, and $\mathcal{L}$ is the integrated luminosity collected by the experiment. Table I shows the average beam polarization values, the integrated luminosities and the figures of merit of the two runs. The Run-3 figure of merit in [3] was 1.2 nb^{-1}.

The stable spin direction in RHIC is vertical, and spin rotators are used to provide longitudinal polarization at PHENIX [7]. For the Run-3 and Run-4 data sets, the longitudinal fraction of the beam polarization was >0.98 and >0.99, respectively. Details of the Run-4 analysis method including the handling of detector efficiency, relative luminosity, determination of the longitudinal fraction of the beam polarization in the PHENIX interaction region, and the background subtraction are described in our Run-3 publication [3].

Table II and Fig. 1 show the results of the Run-3 reanalysis and the Run-4 analysis. Bunch-to-bunch and fill-to-fill systematic uncertainties for the asymmetry measurements are negligible. Also indicated for each data set are the total scale uncertainties due to the uncertainty in beam polarization, which consists of two terms: an 18% scale

TABLE I. Comparison of the data sets from 2003 (Run-3) and 2004 (Run-4) RHIC runs.

Run	$\langle P_B \rangle$	$\langle P_Y \rangle$	$\mathcal{L}$ (nb^{-1})	$\mathcal{L}\langle P_B P_Y \rangle^2$ (nb^{-1})
Run-3	0.35	0.30	220	2.6
Run-4	0.45	0.44	75	2.9

TABLE II. $A_{LL}^{\pi^0}$ for four p_T bins. The total point-to-point uncertainties are shown. Scale uncertainties of 28%, 24% and 18% for Run-3, Run-4 and combined runs are not included. For the combined results, uncorrelated systematic uncertainties for Run-3 and Run-4 have been included as point-to-point uncertainties, and are shown in parenthesis.

p_T ($\langle p_T \rangle$) (GeV/c)	Run-3 (10^{-2})	Run-4 (10^{-2})	Run-3+Run-4 (10^{-2})
1–2 (1.59)	-0.97 ± 0.85	-0.35 ± 0.72	$-0.60 \pm 0.56(0.10)$
2–3 (2.39)	-0.92 ± 0.90	0.56 ± 0.82	$-0.10 \pm 0.61(0.10)$
3–4 (3.37)	-0.90 ± 1.88	0.03 ± 1.79	$-0.41 \pm 1.30(0.09)$
4–5 (4.38)	-1.37 ± 4.19	7.90 ± 4.04	3.23 ± 2.98 (0.65)

uncertainty (9% for each beam), due to the proton-carbon CNI polarimeter calibration, common for each data set; and an uncorrelated uncertainty (21% in Run-3 and 16% in Run-4). The additional p_T-independent systematic uncertainty related to the relative luminosity measurement between colliding bunches with the same and opposite helicities was estimated to be below 1.5×10^{-3}.

Table II and Fig. 2 show the combined asymmetries for Run-3 and Run-4 data. The point-to-point uncertainties include the uncorrelated polarization uncertainties described above. Figure 2 also presents two NLO pQCD calculations using different assumptions for the polarized gluon distribution. One uses the best global fit to the inclusive DIS data (GRSV-std) and the other uses a polarized gluon distribution equal to the unpolarized distribution at the input scale of $Q^2 = 0.4$ GeV^2 (GRSV-max) [2,8].

Following the discussion in [3], we compared our results with theoretical curves, calculating confidence levels (C.L.) for all p_T points (> 1 GeV/c) and for the three highest p_T points (> 2 GeV/c). The data are consistent with GRSV-std with a C.L. = 61–63% (73–74%) for the range in polarization uncertainty of the measurement, considering all four points (the three highest p_T points). The results are less consistent with the large gluon polarization, with C.L. = 0.04–2% (0.3–5%) for GRSV-max [2,8]. These confidence levels do not include the theoretical uncertainty from the choice of scales or of the parton distribution functions or fragmentation function.

In summary, we present results for $A_{LL}^{\pi^0}$ that are improved over our previous publication [3]. Both the statistical and systematic uncertainties are reduced by more than a factor of 2. The new results probe the polarized gluon distribution in the proton with improved resolving power. We conclude that the observed asymmetry is small and not consistent with a maximal gluon polarization.

We thank the RHIC Polarimeter Group and the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We acknowledge support from

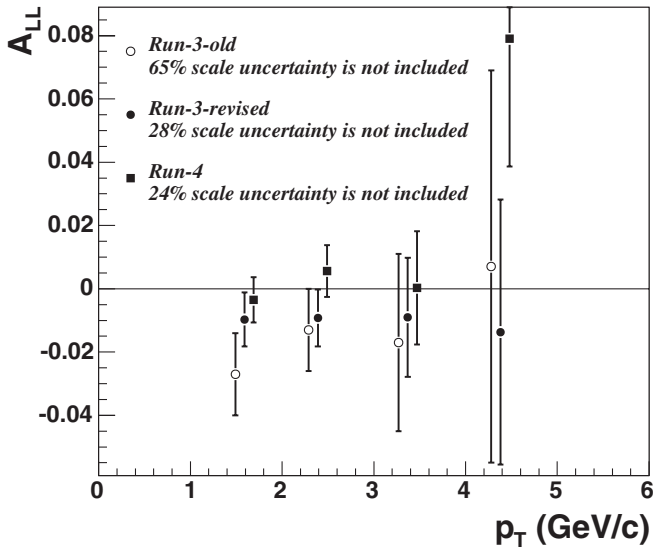

FIG. 1. Run-3 and Run-4 results on $A_{LL}^{\pi^0}$ versus mean p_T in each bin. Run-3-old results from [3] are also shown for comparison. For clarity, Run-3-old and Run-4 points are shifted by -0.1 GeV/c and $+0.1$ GeV/c, respectively.

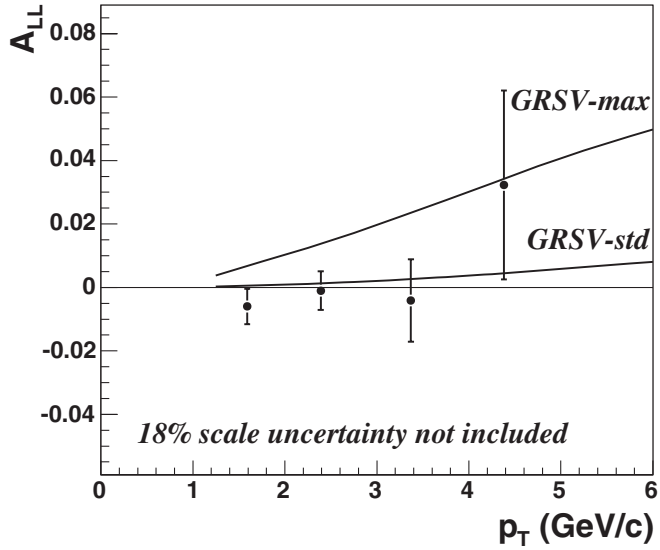

FIG. 2. Run-3+Run-4 combined results on $A_{LL}^{\pi^0}$ versus mean p_T in each bin. Two theoretical calculations based on NLO pQCD are also shown for comparison with the data (see text and [2,8] for details).

(Received 26 January 2006; published 22 May 2006)

Inclusive transverse momentum spectra of η mesons have been measured within $p_T = 2$–10 GeV/c at midrapidity by the PHENIX experiment in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. In central Au + Au the η yields are significantly suppressed compared to peripheral Au + Au, d + Au, and $p + p$ yields scaled by the corresponding number of nucleon-nucleon collisions. The magnitude, centrality, and p_T dependence of the suppression is common, within errors, for η and π^0. The ratio of η to π^0 spectra at high p_T amounts to $0.40 < R_{\eta/\pi^0} < 0.48$ for the three systems, in agreement with the world average measured in hadronic and nuclear reactions and, at large scaled momentum, in e^+e^- collisions.

DOI: 10.1103/PhysRevLett.96.202301 PACS numbers: 25.75.Dw

The major motivation for the study of high energy nucleus-nucleus ($A + A$) collisions is the opportunity to probe strongly interacting matter at extremely high energy densities. Of particular interest are energy densities well above the expected transition from normal hadronic matter to a deconfined system of quarks and gluons. Lattice quantum chromodynamics (QCD) calculations [1] predict that this transition will occur at a temperature of $T \approx 170$ MeV $\approx 10^{12}$ K. The formation of a quark-gluon plasma (QGP) in $A + A$ reactions should manifest itself in a variety of experimental signatures [2].

At center-of-mass energies reached by the Relativistic Heavy Ion Collider (RHIC), arguably the most exciting experimental results so far are connected with the predicted "jet quenching" phenomenon [3–5] due to energy loss of hard-scattered partons as they traverse the dense medium formed in the reaction. Since (leading) hadrons with $p_T > 4$ GeV/c at RHIC carry a large fraction of the momentum of the parent quark or gluon [$\langle z \rangle = p_{\mathrm{hadron}}/p_{\mathrm{parton}} \approx 0.5$–$0.7$ [6,7]], parton energy loss results in a significantly suppressed production of high-p_T hadrons [4]. The inclusive spectra of high-p_T neutral pions [8,9] and charged hadrons [10,11] in Au + Au at $\sqrt{s_{NN}} = 200$ GeV are indeed suppressed by as much as a factor of 5 compared to the corresponding yields in $p + p$ [12] and $d +$ Au [13,14], scaled by the number of incoherent nucleon-nucleon (NN) collisions. The centrality [15], p_T [16–18] and center-of-mass energy [19] dependences of the observed quenching are consistent with theoretical calculations of QCD energy loss due to multiple gluon emission in a dense medium. Assuming a thermalized parton system, the magnitude of the suppression for central Au + Au at $\sqrt{s_{NN}} = 200$ GeV implies initial energy densities above 15 GeV/fm^3, $\sim$100 times larger than normal nuclear matter [20].

The equal amount of suppression for π^0 and $h^{\pm}$ observed above $p_T \approx 5$ GeV/c for the same Au + Au centrality seems to indicate that the mechanism of quenching is independent of the identity of the high-p_T light-quark hadron. This is expected if the suppression takes place at the parton level *prior* to its fragmentation into a given hadron. Indeed, in this case the high-p_T deficit depends only on the energy lost in the medium by the parent (u, d, s) quark or gluon and not on the nature of the final leading hadron which will be produced with the same *universal* probabilities (fragmentation functions) which govern hadron production in the vacuum in more elementary systems. The partons involved in high-p_T hadroproduction considered in this work have typical momenta $\gtrsim 5$ GeV/c, 10 times larger than the "bulk" average momenta $\langle p_T \rangle \approx 0.55$ GeV/c of the system [21]. Such energetic partons are then supposed to traverse (and lose energy in) the medium and hadronize in the *vacuum* a few tens of fm/c later [15]. The equal suppression of $h^{\pm}$ and π^0 does not by itself provide a conclusive argument for parton energy loss *before* fragmentation in the vacuum because above $p_T \approx 5$ GeV/c, unidentified charged hadron yields are dominated by $\pi^{\pm}$ [11]. Measurement of the yields of an additional light-quark species like the η meson at large enough p_T allows a confirmation of the independence of the quenching with respect to the nature of the produced hadron, and tests the consistency of the data with medium-induced *partonic* energy loss prior to vacuum hadronization. Besides its interest as a *signal* in its own right, the η meson constitutes, after the π^0, the second most important source of decay $e^{\pm}$ and γ. Reliable knowledge of their production cross sections is thus required in order to eliminate the *background* of secondary $e^{\pm}$ and γ in single electron [22], dielectron [23], and direct γ [24] measurements.

This Letter presents measurements of the η meson by the PHENIX experiment [25] in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV during the second RHIC run (2001–2002) and compares them to η from $p + p$ and $d +$ Au [26] and to π^0 [8,9] and direct γ [24] from Au + Au, all measured in the same experiment at the same $\sqrt{s_{NN}}$. The η measurement reaches the second largest p_T for identified hadrons at RHIC, after the π^0. The analysis reported here uses beam-beam counters (BBC, $3.0 < |\eta| < 3.9$) plus the zero degree calorimeters (ZDC) for trigger and global event characterization. For each collision, the reaction centrality is obtained by cuts in the correlated distribution of the charge detected in the BBC and the energy measured in the ZDC [27]. A Glauber Monte Carlo model combined with a simulation of BBC and ZDC responses is used to determine the corresponding nuclear overlap function $\langle T_{AA} \rangle$ for each centrality [8]. The η mesons are reconstructed at midrapidity in the lead-scintillator (PbSc) electromagnetic calorimeter [28] via their $\gamma\gamma$ decay mode (BR = 39.43%). The PbSc consists of 15 552 individual lead-scintillator sandwich modules (5.54 cm $\times$ 5.54 cm $\times$ 37.5 cm, 18 X_0), grouped in six sectors located at a radial distance of 5.1 m from the beam line, covering a total solid angle of $\Delta\eta \approx 0.7$ and $\Delta\phi \approx 3\pi/4$ rad. The energy calibration of the PbSc modules is obtained from the beam-test values and confirmed with the measured position of the π^0 mass peak, the energy deposited by minimum ionizing particles traversing the calorimeter, as well as with the expected $E_{\mathrm{PbSc}}/p_{\mathrm{tracking}} \sim 1$ value for $e^{\pm}$ identified by the Ring-Imaging Čerenkov detector. The systematic error on the absolute energy scale is less than 1.5%, which translates into a maximum 8% uncertainty in the final η yields.

For this analysis a minimum bias (MB) trigger sample of 34×10^6 events, also used for the previously published π^0 analysis [8], is combined with a Level-2 trigger event sample for centralities 0%–60%, equivalent to an additional 30×10^6 minimum bias events. The Level-2 trigger sample is obtained with a software trigger on highly energetic particles (3.5 GeV threshold). The resulting trigger reaches a 50% (100%) efficiency for η above $p_T = 5(7)$ GeV/c. The normalization of the Level-2 data sample

relative to the MB data sample is accurate to 2%. Both sets of events are required to have a vertex position $|z| < 30$ cm along the beam axis. Photon candidates are identified in the PbSc by applying particle identification (PID) cuts based on the time-of-flight and shower profile [8,26]. The systematic uncertainty on the yields related to the applied PID cuts is ~8%. The η yields are determined by an invariant mass analysis of photon pairs with asymmetries $|E_{\gamma 1} - E_{\gamma 2}|/(E_{\gamma 1} + E_{\gamma 2}) < 0.5$. The combinatorial background is obtained by combining uncorrelated photon pairs from different events with similar centrality and vertex, and by normalizing the distribution in a region below ($m_{\rm inv} = 400$–450 MeV$/c^2$) and above ($m_{\rm inv} = 750$–1000 MeV$/c^2$) the η mass peak. The resulting distribution is fit to a Gaussian plus an exponential to account for the residual background not described by the mixed-event background (inset of Fig. 1). The open (solid) symbols depict the η signal after mixed (plus residual) background subtraction. To estimate the uncertainty in the subtraction procedure, different pair asymmetries and an alternative linear parametrization of the residual background are used. The signal-to-background ratio in peripheral (central) collisions is approximately 1.3 (1.5) for the highest p_T and 0.05 (0.002) for the lowest p_T.

The raw spectra are normalized to one unit of rapidity and full azimuth. This purely geometrical acceptance factor amounts to ~4 at large p_T. The spectra are further corrected for the detector response (energy resolution, dead areas), the reconstruction efficiency (analysis cuts), and occupancy effects (cluster overlaps). These corrections are quantified by embedding simulated single η from a full PHENIX GEANT [29] simulation into real events, and analyzing the merged events with the same analysis cuts used to obtain the real yields. The total η yield efficiency correction is ~3 and rises $\lesssim 20\%$ with centrality. The losses are dominated by fiducial and asymmetry cuts. The nominal energy resolution is adjusted in the simulation by adding a p_T-independent energy smearing of 3% for each PbSc tower. The shape, position, and width of the η peak measured for all p_T's and centralities are well reproduced by the embedded data.

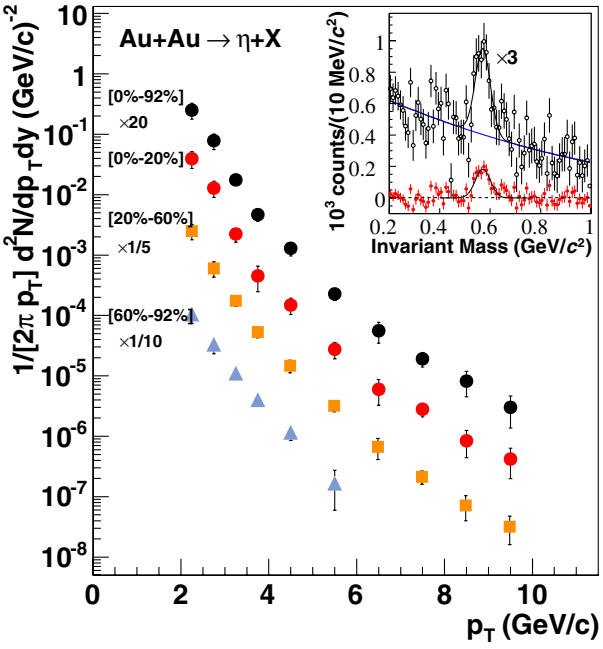

FIG. 1 (color online). Invariant η yields as a function of transverse momentum for 3 centralities and MB Au + Au at $\sqrt{s_{NN}} = 200$ GeV scaled by the factors indicated in the plot. Inset: invariant mass distribution of γ pairs with $p_T = 4$–5 GeV$/c$ measured in MB Au + Au, after mixed-event (black open circles) plus residual (red solid circles) background subtraction.

The main sources of systematic errors in the measurement are the uncertainties in the yield extraction (10%–30%), the yield correction (10%), and the energy scale (a maximum of 8%). The final combined systematic errors on the spectra are at the level of 10%–30% (point-to-point) and 10%–20% (p_T-correlated) depending on the p_T and centrality bin [26]. A correction in the yield to account for the true mean value of each p_T bin is applied to the steeply falling spectra. The fully corrected p_T distributions are shown in Fig. 1 for MB and 3 centrality bins (0%–20%, 20%–60%, and 60%–92%) scaled for clarity by the factors indicated. The error bars are the quadratic sum of statistical and systematic errors.

Medium effects in $A + A$ collisions are quantitatively determined using the *nuclear modification factor* given as the ratio of the measured $A + A$ invariant yield over the $p + p$ cross section scaled by the Glauber nuclear overlap function $\langle T_{AA} \rangle$ in the centrality bin under consideration:

$$R_{AA}(p_T) = \frac{d^2N_{AA}/dp_T dy}{\langle T_{AA} \rangle d^2\sigma_{pp}/dp_T dy}. \quad (1)$$

Deviations from $R_{AA}(p_T) = 1$ quantify the degree of departure of the hard $A + A$ yields from an incoherent superposition of NN collisions. Figure 2 compares the nuclear modification factor for η in central (0%–20%), semicentral (20%–60%), and peripheral (60%–92%) Au + Au reactions using the reference $d^2\sigma_{pp}/dp_T dy$ spectrum measured in $p + p$ collisions [26]. As observed for high-p_T π^0 [8,9], the η yields are consistent with the expectation of independent NN scatterings in peripheral reactions ($R_{AA} \approx 1$) but are increasingly reduced for smaller centralities. The p_T dependence of R_{AA} is flat above 4 GeV$/c$ as seen also for the π^0.

Figure 3 compares the $R_{AA}(p_T)$ measured in Au + Au at $\sqrt{s_{NN}} = 200$ GeV for η (0%–20% centrality), π^0 [8,9], and γ [24] (0%–10% centralities). Whereas direct γ are unsuppressed compared to the T_{AA}-scaled reference given here by a next-to-leading-order (NLO) calculation [24,30] that reproduces the PHENIX $p + p$ photon data well [31], π^0 and η are suppressed by a similar factor of ~5 compared to the corresponding $p + p$ cross sections [9,26]. Within the current uncertainties, light-quark mesons at

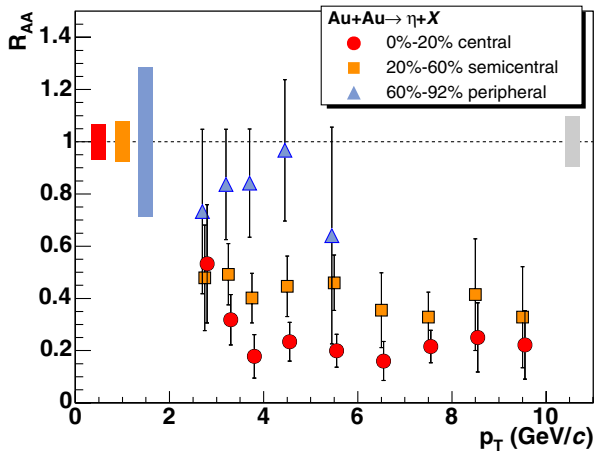

FIG. 2 (color online). Nuclear modification factors for η in Au + Au centralities: 0%–20%, 20%–60%, 60%–92%. The error bars show point-to-point uncertainties. The absolute normalization error bands at $R_{AA} = 1$ show the uncertainties in $\langle T_{AA} \rangle$ for decreasing centralities. The error box on the right indicates the 9.7% $p + p$ cross-section uncertainty [14].

RHIC show a flat suppression in the range $p_T = 4$–14 GeV/c, independent of their mass (note that the η is 4 times heavier than the π^0). The results are in agreement with expectations of in-medium non-Abelian energy loss of the parent parton prior to its fragmentation in the vacuum. The initial gluon densities needed to quench the high-p_T hadrons by such an amount are of the order of $dN^g/dy = 1100$ (solid curve in Fig. 3) [16].

An additional way to determine possible differences in the suppression pattern of π^0 and η is to study the centrality dependence of the η/π^0 ratio in Au + Au collisions and compare it with the ratio in more elementary systems (e^+e^-, $p + p$, d + Au). The η/π^0 ratio in hadron-hadron, hadron-nucleus, and nucleus-nucleus collisions is seen to increase rapidly with p_T and flatten out above $p_T \approx 2.5$ GeV/c at an asymptotically constant $R_{\eta/\pi^0} \approx 0.5$ for all systems [26]. Likewise, in e^+e^- at the Z pole ($\sqrt{s} = 91.2$ GeV) one also finds $R_{\eta/\pi^0} \approx 0.5$ for η and π^0 at large scaled momenta $x_p = p_{\text{hadron}}/p_{\text{beam}} \gtrsim 0.3$–$0.7$ [26] consistent with the range of fractional momenta $\langle z \rangle$ relevant for high-p_T production discussed here. It is interesting to test if this ratio is modified in any way by final- and/or initial-state medium effects in Au + Au collisions at RHIC.

Figure 4 shows $R_{\eta/\pi^0}(p_T)$ for three Au + Au centrality selections and for $p + p$ and d + Au collisions [26]. A fit to a constant for $p_T > 2$ GeV/c gives $R_{\eta/\pi^0}^{\text{AuAu0\%–20\%}} = 0.40 \pm 0.04$, $R_{\eta/\pi^0}^{d\text{AuMB}} = 0.47 \pm 0.03$, and $R_{\eta/\pi^0}^{pp} = 0.48 \pm 0.03$, where the quoted errors are the quadratic sum of statistical and systematic uncertainties. The Au + Au ratio is consistent within $\sim 1\sigma$ with both the essentially identical d + Au and $p + p$ ratios. The R_{η/π^0} ratio shows thus no apparent collision system, centrality, or p_T dependence. The dotted curve is the predicted PYTHIA [32] result for the $p + p$ ratio at $\sqrt{s} = 200$ GeV which is also coincident with the world data measured in the same momentum range in hadronic, nuclear, and e^+e^- collisions in a wide range of energies ($\sqrt{s} \approx 3$–1800 GeV) [26].

In summary, the transverse momentum spectra of η mesons have been measured at midrapidity in the range $p_T = 2$–10 GeV/c in Au + Au at $\sqrt{s_{NN}} = 200$ GeV. The invariant yields per nucleon-nucleon collision are increasingly depleted with centrality in comparison to $p + p$ results at the same center-of-mass energy. The maximum

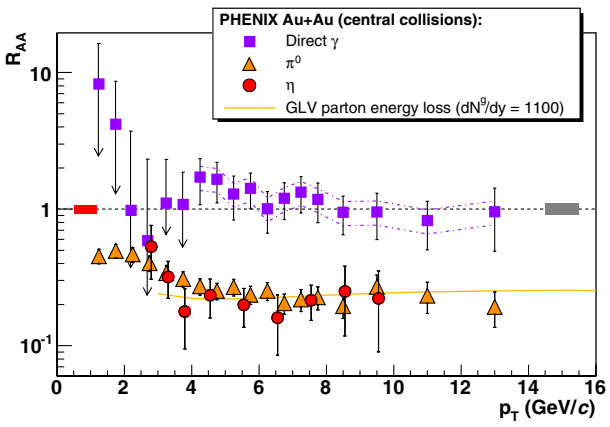

FIG. 3 (color online). $R_{AA}(p_T)$ measured in central Au + Au at $\sqrt{s_{NN}} = 200$ GeV for η, π^0 [8,9], and direct γ [24]. The error bars include all point-to-point errors. The error bands at $R_{AA} = 1$ have the same meaning as in Fig. 2. The baseline $p + p \rightarrow \gamma + X$ reference used is a NLO calculation [24,30], that reproduces our own data well [31], with theoretical uncertainties indicated by the dash-dotted lines around the points. The solid yellow curve is a parton energy loss prediction for a medium with density $dN^g/dy = 1100$ [16].

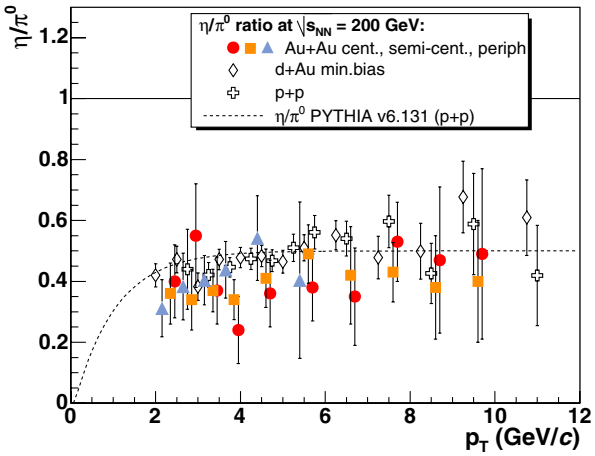

FIG. 4 (color online). η/π^0 ratio in Au + Au (centralities: 0%–20%, 20%–60%, 60%–92%) compared to the ratio in $p + p$ and d + Au [26] at $\sqrt{s_{NN}} = 200$ GeV. The error bars include all point-to-point errors that do not cancel in the ratio of yields. The dashed curve is the PYTHIA [32] prediction for $p + p$ at $\sqrt{s} = 200$ GeV consistent with the asymptotic $R_{\eta/\pi^0} \approx 0.5$ measured in hadronic and e^+e^- collisions in a wide range of c.m. energies [26].

suppression factor is ~5 in central Au + Au. The magnitude, p_T, and centrality dependences of the suppression are the same for η and π^0 suggesting that the production of light neutral mesons at large p_T in nuclear collisions at RHIC is affected by the medium in the same way. The measured η/π^0 ratio is flat with p_T and amounts to $R_{\eta/\pi^0} = 0.40 \pm 0.04$. This value is consistent with the world value at high p_T in hadronic and nuclear reactions and, at high x_p, in e^+e^- collisions. We conclude that all these observations are in agreement with a scenario where the parent parton first loses energy in the produced dense medium and then fragments into a leading meson in the vacuum according to the same probabilities that govern high-p_T hadroproduction in more elementary systems ($p + p$, e^+e^-).

Direct photons in 200 GeV $p+p$, d+Au, and Au+Au from PHENIX

S. Bathe[a*] for the PHENIX Collaboration[†]

[a]University of California at Riverside

Direct photons were measured with the PHENIX experiment in $p+p$, d+Au, and Au+Au at $\sqrt{s_{NN}} = 200$ GeV. To tackle the p_T region below 5 GeV/c, direct photons were measured through their internal conversion into e^+e^- in Au+Au collisions.

1. Introduction

Direct photons are a unique probe of the hot and dense matter created at RHIC: they allow access to the initial, thermalized state of the collision. Their measurement, however, is challenging. One has to cope with a large background from hadronic decays.

Direct photon measurements in $p+p$ constrain the hard-scattering contribution in Au+Au. A comparison to d+Au allows to quantify contributions from initial-state effects. In heavy ion collisions, thermal direct photons constrain the temperature of the collision system in its hottest phase while hard direct photons serve as a crucial baseline for the interpretation of the high-p_T hadron suppression observed earlier [1].

2. Direct Photon Analysis Via Low-Mass Electron Pairs

The conventional direct photon measurement with the EMCal has been described elsewhere [2,3]. In the following we will focus on the measurement through internal conversion of direct photons into e^+e^-. Compared to the conventional measurement, this technique improves both the signal-to-background ratio and the energy resolution at intermediate p_T where thermal production is expected to contribute substantially [4]. The measurement relies on a combination of excellent mass resolution at low invariant mass, m_{ee}, and a low conversion probability due to little material in the aperture. It has been carried out in heavy ion experiments for the first time [5,6].

The full 2004 data set of about 900 M minimum bias events was analyzed. Events and centrality were selected as described in [7]. Electrons in the central arms were identified by matching charged particle tracks to clusters in the EMCal and to rings in a ring imaging Čerenkov (RICH) detector.

To illustrate the underlying idea we consider the π^0 Dalitz decay where one decay photons is a virtual photon that further decays into an e^+-e^- pair. The invariant-mass distribution of the virtual photon is given by [8]

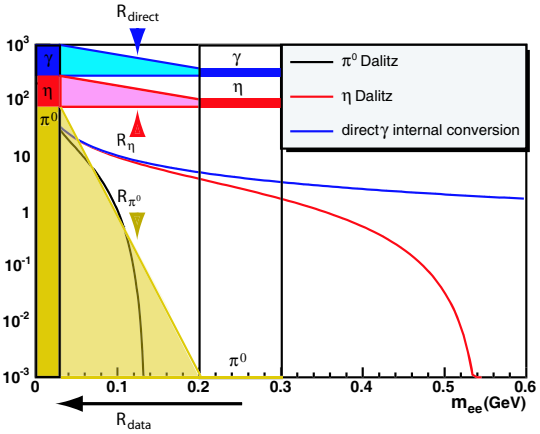

Figure 1. Invariant-mass distribution of virtual photons from the π^0 and η Dalitz decays as well as from direct photons according to Eq. 1. It is illustrated how the various contributions decrease to a fraction R when going to higher invariant mass with the π^0 contribution exhausting.

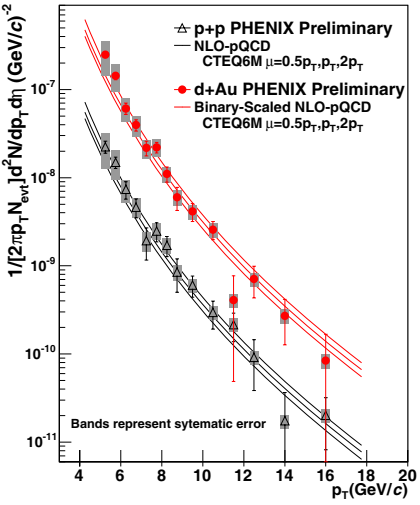

Figure 2. Preliminary direct photon invariant yield as a function of p_T for $p+p$ [3] and minimum-bias d+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The solid curves are pQCD predictions [9] for three different scales that represent the uncertainty on the calculation.

$$\frac{1}{N_\gamma}\frac{dN_{ee}}{dm_{ee}} = \frac{2\alpha}{3\pi}\sqrt{1-\frac{4m_e^2}{m_{ee}^2}}\left(1+\frac{2m_e^2}{m_{ee}^2}\right)\frac{1}{m_{ee}} \mid F(m_{ee}^2) \mid^2 \left(1-\frac{m_{ee}^2}{M^2}\right)^3 , \qquad (1)$$

and depicted in Fig. 1. In general, any source of real photons produces virtual photons with very low invariant mass. The rate and mass distribution of those virtual photons is given by the same formula[3]. For direct photons the phase space is not limited when $m_{ee} << p_T^{photon}$.

To obtain a clean invariant-mass distribution of e^+-e^- pairs, pairs originating from photon conversions in the beam pipe or detector material are rejected by an analysis cut. The combinatorial background is removed by the mixed-events technique. In this measurement decay photons can mostly be eliminated by measuring the yield of e^+-e^- pairs in an invariant-mass region where pairs from the π^0 Dalitz decay are largely suppressed due to their limited phase space. In order to convert the measured virtual photons into real photons, the obtained yield has to be related to the yield in an region where the phase space is unrestricted, so that $\gamma^\star_{direct}/\gamma^\star_{incl.} = \gamma_{direct}/\gamma_{incl.}$. The term $\gamma^\star_{direct}/\gamma^\star_{incl.}$ can be calculated from the ratio of total yields in the two intervals, $R_{\rm data} = N(90\text{-}300\ {\rm MeV})/N(0\text{-}30\ {\rm MeV})$,

[3]Since the virtual photons decay in the medium, this relation might be slightly modified. This would not affect the significance of the observed excess of direct photons, only its translation into an absolute yield of real direct photons.

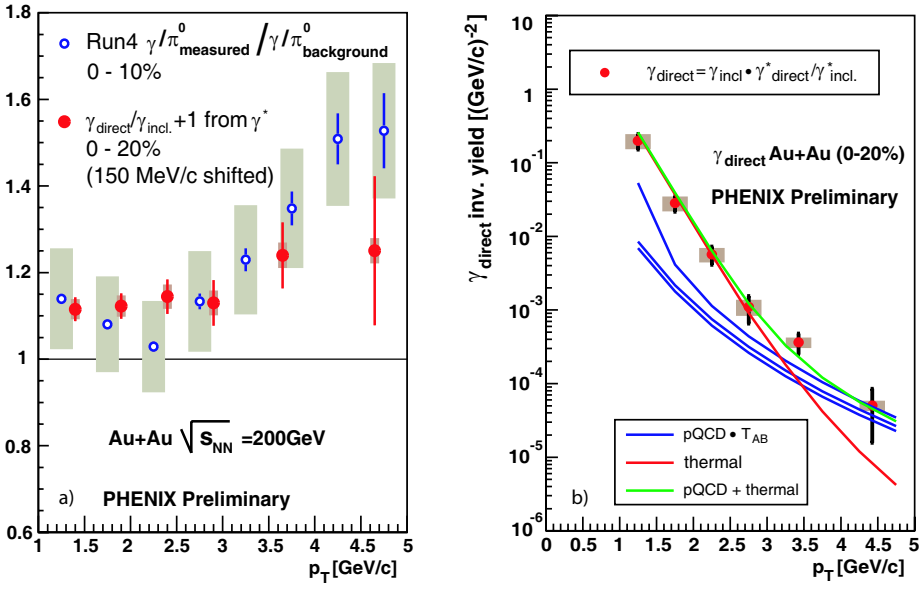

Figure 3. a) Direct photon excess for the conventional and the internal-conversion measurement in central Au+Au. b) Direct photon spectrum from the latter compared to pQCD [9], thermal-photon [11], and the sum of both calculations.

which is known from the measurement, and the ratios, $R_i, i = \{\gamma_{\rm direct}, \pi^0, \eta, {\rm other}\}$, for the various contributions, which can precisely be calculated from Eq. 1 (cf. Fig.1). Decay photons from a cocktail of hadrons are considered here. Finally, the yield of real inclusive photons known from the EMCal measurement [2] is needed to obtain the yield of real direct photons.

Since only the ratio of decay photon yields in the two invariant-mass intervals is needed, the uncertainty on the η-to-π^0 ratio of about 20 % [10] is the main source of uncertainty, translating into an uncertainty of 20 % on the measured direct photon yield. Other sources are the EMCal-measured inclusive photon yield (10 %) and the e^+-e^--pair acceptance (5 %). The total systematic uncertainty is 25 %.

3. Results

The preliminary direct photon spectra from the conventional measurement for $p + p$ [3] and minimum-bias d+Au at $\sqrt{s_{NN}} = 200$ GeV is shown in Fig. 2. For the whole p_T range of 5 to 16 GeV/c the observed yield is consistent with a next-to-leading-order perturbative-QCD (NLO pQCD) calculation [9] for both $p+p$ and d+Au. This supports the validity of the pQCD calculation as a reference for hard direct photon production in Au+Au. As shown by PHENIX in the 2002 run [2], at high p_T direct photon production is consistent with the pQCD expectation also in Au+Au. In the following we will focus on the region at intermediate p_T.

In a preliminary analysis with the conventional method, a small but stable subset of the 2004 data was selected to revisit the intermediate-p_T region, where no significant result had been previously obtained for $p_T \lesssim 3$ GeV/c. The new result is shown in Fig. 3 a) in terms of the double ratio $(\gamma/\pi^0|_{meas.})/(\gamma/\pi^0|_{bckgrd.})$. This ratio indicates a direct photon excess as an enhancement above 1. There is still no significant excess below 3 GeV/c. Further work is ongoing to increase the significance.

The preliminary result from the measurement of virtual photons is presented in the same figure in terms of $\gamma_{direct}/\gamma_{incl.} + 1$, which also indicates a direct photon excess as an enhancement above 1. (Note that the two quantities aren't exactly equivalent.). The result shows a significant direct photon excess of about 10 % for $1 < p_T < 5$ GeV/c and the 20 % most central Au+Au collisions. It is consistent with the EMCal measurement. In Fig. 3 b) the direct photon invariant yield from the virtual photon measurement is shown and compared to various theoretical calculations. With large significance, a direct photon spectrum was obtained for $1 < p_T < 5$ GeV/c. The spectrum lies significantly above a T_{AB}-scaled pQCD calculation [9] for $p_T \lesssim 3$ GeV/c. A 2+1 hydrodynamical model [11] for thermal-photon emission with an average initial temperature of $T_0^{ave} = 360$ MeV ($T_0^{max} = 570$ MeV) and a formation time of $\tau_0 = 0.15$ fm/c underpredicts the data for $p_T \gtrsim 3$ GeV/c. The data can be described when both sources are combined. The obtained temperature is only meaningful if the observed excess is of thermal origin. To confirm the result, an analysis of $p + p$ and d+Au using the same technique is needed. If the excess in Au+Au is mainly from thermal photons the reference data will show a much smaller effect.

4. Summary

Direct photons were measured with the PHENIX experiment in $p + p$, d+Au, and Au+Au at $\sqrt{s_{NN}} = 200$ GeV. At high p_T ($\gtrsim 5$ GeV/c), the measured yield in all systems is consistent with a NLO pQCD calculation. To tackle the p_T region below 5 GeV/c, direct photons were measured through their internal conversion into e^+e^- in Au+Au collisions. With this powerful technique a significant measurement for $1 < p_T < 5$GeV/c was achieved, lying significantly above the NLO pQCD expectation, but consistent with calculations when thermal photon emission is taken into account.

Measurement of direct photons in $\sqrt{s_{NN}} = 200\,\mathbf{GeV}$ $p+p$ and Au+Au collisions with the PHENIX Experiment at RHIC

Stefan Bathe for the PHENIX Collaboration

University of California, Riverside, CA, USA

E-mail: bathe@bnl.gov

Abstract. The measurement of direct photons in $\sqrt{s_{NN}} = 200\,\mathrm{GeV}$ p+p and Au+Au collisions is presented. The signal is compared to NLO pQCD calculations, which, in case of Au+Au, are scaled with the number of underlying nucleon-nucleon collisions. The agreement of the calculation with the data in both cases confirms the scaling of hard processes with the number of nucleon-nucleon collisions and supports the explanation of the earlier-observed pion suppression as a final-state effect.

1. Introduction

Direct photons are a unique probe of the hot and dense matter created at RHIC: they allow access to the initial, thermalized state of the nuclear collision. Their measurement, however, is challenging. One has to cope with a large background from hadronic decays.

While several definitions of direct photons are used, we pragmatically attribute this term to all photons that are not decay photons. The main direct photon production processes are quark-antiquark annihilation and quark-gluon Compton scattering [1]. In addition, direct photons are produced through fragmentation of hard partons. These are also called bremsstrahlung photons.

Direct photon measurements in p+p collisions provide a superb test of pQCD. They probe the gluon distribution function. At RHIC they can also probe the spin gluon distribution function [2] in the polarized-proton program. In contrast to hadron measurements, their interpretation does not suffer much from uncertainties on the fragmentation function. Furthermore, they provide a constraint on the hard-scattering contribution to direct photon production in Au+Au collisions.

In heavy ion collisions, thermal direct photons allow, in principle, measurement of the temperature of the collision system in its hottest phase. Also, hard direct photons serve as a crucial baseline for the interpretation of the earlier observed high-p_T hadron suppression [3]. Interactions of hard partons with the medium provide an additional source of direct photons, either through annihilation and Compton scattering [4] or through medium-induced bremsstrahlung [5].

With its high-resolution, highly-segmented electromagnetic calorimeter PHENIX [6] has an excellent capability to measure photons. PHENIX has made precision measurements of neutral pions and η mesons up to transverse momenta of 15 GeV/c. With this crucial measurement of the direct photon background, PHENIX has extracted direct photons in $p+p$ and Au+Au collisions at $\sqrt{s_{NN}} = 200\,\mathrm{GeV}$.

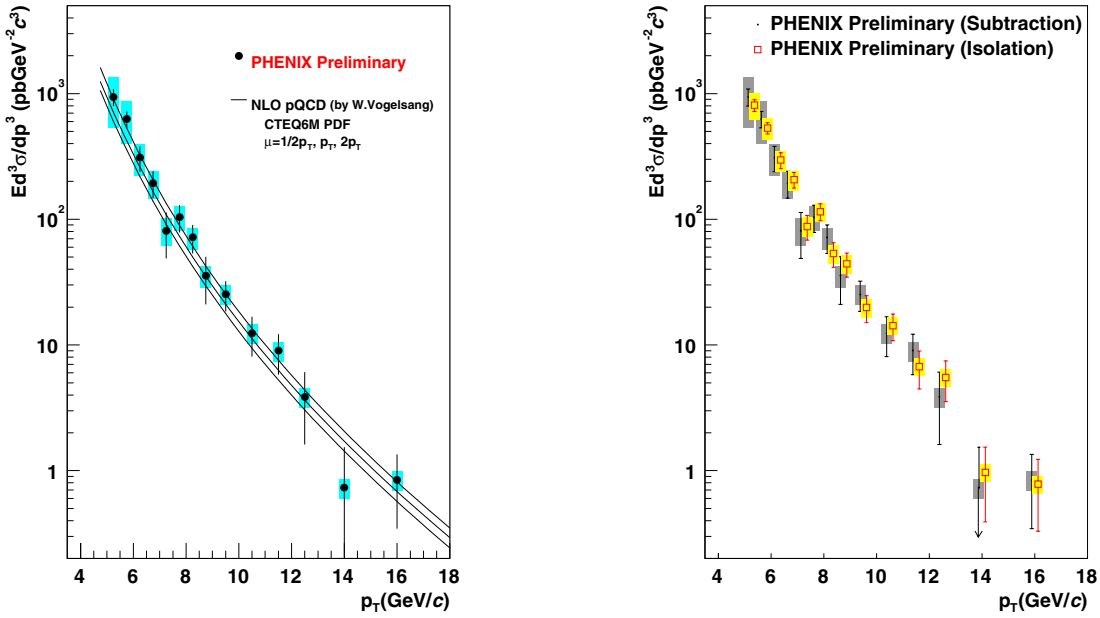

Figure 1. PHENIX preliminary direct photon invariant cross section [7] in $p+p$ collisions at $\sqrt{s}$ = 200 GeV . The left panel shows the result obtained with even-by-event subtraction of decay photons. The curves represent a NLO pQCD calculation for three different scales. The right panel compares this result to the result obtained by an isolation cut.

2. Direct Photon Analysis

The first step in the direct photon analysis in Au+Au is to get a clean inclusive photon sample. To achieve this, non-photon backgrounds, as from charged particles, have to be subtracted. The next step is to measure the p_T spectrum of π^0's and η's. From these spectra, the number of decay photons is determined in a Monte Carlo calculation, which also considers contributions from other hadronic decays. Finally, the decay photon spectrum is subtracted from the inclusive photon spectrum to obtain the direct photon spectrum. This method makes no attempt to identify direct photons on an event-by-event basis. Therefore it is called the subtraction method or statistical method. Further details can be found in [8].

In p+p collisions, where the multiplicity and the occupancy on the detector are small, it is possible to tag and subtract decay photons event by event. In addition, an isolation cut, *i. e.* a cut on the maximum energy allowed in a cone around a direct photon, allows further suppression of decay photons on an event-by-event basis. As an additional feature the isolation cut helps to identify fragmentation photons. Further details on the $p+p$ analysis can be found in [7].

For the measurement of direct photon production in $p+p$ collisions, an integrated luminosity of 266 nbarn^{-1} sampled in the 2003 RHIC $p+p$ run was analyzed. The Au+Au result is based on the 2002 run with an integrated luminosity of 24 μbarn^{-1}. Photons were detected by the electromagnetic calorimeter (EMCal), which is located in the two central arms of the PHENIX detector, each covering $2 * 90°$ in azimuth and a pseudorapidity (η) range of ± 0.35. For the $p+p$ measurement, only one arm was used. The energy calibration was checked by the position and width of the π^0 invariant-mass peak. The fraction of charged-particle contamination was determined with the central-arm tracking detectors which are located in front of the EMCal.

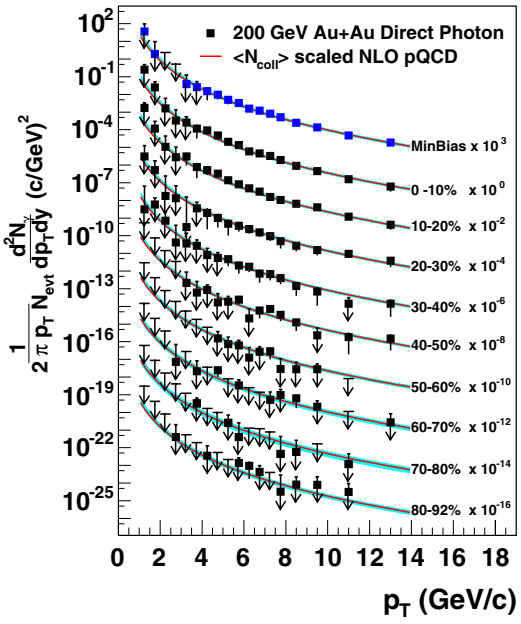

Figure 2. Direct photon invariant yields [8] as a function of p_T for 9 centrality selections and minimum bias Au+Au collisions at $\sqrt{s_{NN}}$ = 200 GeV. The error bars indicate the total error. Arrows indicate measurements consistent with zero yield with the tail of the arrow indicating the 90% confidence level upper limit. The solid curves are pQCD predictions.

3. Direct Photon Cross Section in $p+p$ Collisions

Figure 1 shows the PHENIX preliminary direct photon cross section measured in $\sqrt{s} = 200\,\mathrm{GeV}$ $p+p$ collisions as a function of p_T [7]. The left panel shows the result obtained with event-by-event tagging and subtraction of decay photons. The curves represent a NLO pQCD calculation for three different scales [9]. The calculation agrees well with the measurement. The right panel of Fig. 1 compares this result to the result obtained by an isolation cut. No significant reduction of the direct photon yield by the isolation cut is observed. This suggests that either the contribution from fragmentation photons is small or that the efficiency of the isolation cut to discount fragmentation photons is low. These preliminary results substantially increase the statistical significance and the p_T reach of the published result from the 2002 run [10].

4. Direct Photon Yield in Au+Au Collisions

The direct photon spectra measured in $\sqrt{s_{NN}} = 200\,\mathrm{GeV}$ Au+Au collisions [8] are shown in Fig. 2 for different centrality selections. They are compared to NLO pQCD calculations [9] scaled by the corresponding number of binary nucleon collisions. It can be seen that the pQCD calculations provide a good description of the measured direct photon spectra.

A common way to study possible medium effects in AA collisions is the *nuclear modification factor* R_{AA}, *i. e.* the ratio of the AA invariant yields to the NN-collision-scaled $p+p$ invariant yields [3]. The centrality dependence of R_{AA} for the integrated yield in $p_T > 6$ GeV/c for direct photons (closed circles) is now compared to that of π^0's (open circles) in Fig. 3. The direct photon $p+p$ yield is taken as the NLO pQCD calculation [9] as in the previous figure, while the π^0 $p+p$ yield is taken from the measured π^0 yield [11]. The R_{AA} trend confirms the observation from above in more detail: the direct photon production in Au+Au is consistent with the binary-scaled $p+p$ pQCD calculation. This is in sharp contrast [3] to the centrality dependence of the π^0 R_{AA}, indicating that the observed large suppression of high-p_T hadron production in central Au+Au collisions is dominantly a final-state effect due to parton energy loss in the dense produced medium, rather than an initial-state effect.

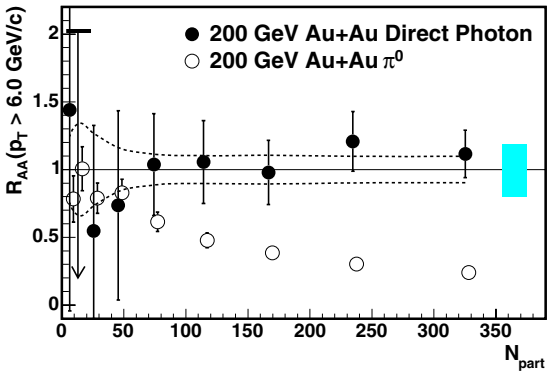

Figure 3. $R_{AA}(p_T > 6\text{GeV}/c)$ as a function of centrality (N_{part}) for direct photons (closed circles) and π^0's (open circles) [8]. The error bars indicate the total error excluding the error on $\langle N_{coll} \rangle$ shown by the dashed lines and the scale uncertainty of the NLO calculation shown by the shaded region at the right.

5. Summary

Direct photon production has been measured in $p + p$ and Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. In $p + p$, NLO pQCD calculations agree well with the measurement. The equally good agreement between measurement and binary scaled pQCD calculations in Au+Au suggests that nuclear modifications at mid-rapidity are small. The result provides strong confirmation that the observed large suppression of high p_T hadron production in central Au+Au collisions is dominantly a final-state effect.

(Received 17 October 2005; published 26 January 2006)

The PHENIX experiment has measured midrapidity ($|\eta| < 0.35$) transverse momentum spectra ($0.4 < p_T < 5.0$ GeV/c) of electrons as a function of centrality in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Contributions from photon conversions and from light hadron decays, mainly Dalitz decays of π^0 and η mesons, were removed. The resulting nonphotonic electron spectra are primarily due to the semileptonic decays of hadrons carrying heavy quarks. Nuclear modification factors were determined by comparison to nonphotonic electrons in $p + p$ collisions. A significant suppression of electrons at high p_T is observed in central Au + Au collisions, indicating substantial energy loss of heavy quarks.

DOI: 10.1103/PhysRevLett.96.032301 PACS numbers: 25.75.Dw

It is well established that neutral pions and charged hadrons are strongly suppressed at high transverse momentum (p_T) in high energy Au + Au collisions [1–5]. The suppression, which is absent in d + Au collisions at midrapidity, implies that hard scattered partons traversing the medium created in Au + Au collisions experience considerable energy loss. Although high p_T suppression is expected for charm quarks as well, their interaction with the medium has been predicted to be smaller than for light quarks, i.e., they should lose a lower fraction of their energy, as their large mass decreases the phase space available for gluon radiation, which is known as the ''dead cone'' effect [6]. If the medium is indeed less opaque to charm quarks, they will also participate less in the collective expansion of the medium, leading to a smaller elliptic flow strength v_2 [7] for particles carrying charm quarks compared to those solely composed of light quarks. Such medium effects should be even less pronounced for bottom than for charm quarks.

The interaction of heavy quarks with the medium can be studied experimentally through systematic measurements of the p_T spectra of open heavy flavor, i.e., hadrons composed of a heavy and a light quark. While the full reconstruction of D meson decays at the Relativistic Heavy Ion Collider (RHIC) is reported for d + Au collisions [8], indirect measurements of open heavy flavor via semileptonic decays are available for $p + p$ and d + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [8–10] as well as for Au + Au collisions at 130 and 200 GeV [11,12]. In $p + p$ collisions, the extracted electron p_T spectrum from heavy flavor decays is in reasonable agreement with perturbative quantum chromodynamics (pQCD) calculations in next-to-leading order. However, the data leave room for contributions from further production mechanisms in which the heavy quarks are not created in the initial hard parton scattering, e.g., via jet fragmentation [9]. In d + Au collisions, no indications for strong cold nuclear matter effects were found [8,10]. For Au + Au collisions of different centrality, the total electron yield from heavy flavor decays was observed to scale with the nuclear overlap integral $\langle T_{AA} \rangle$ as expected for pointlike pQCD processes [12]. However, these electrons show an azimuthal anisotropy with respect to the reaction plane [13], consistent with the notion of charm quark flow in Au + Au collisions. It has been pointed out that if the charm quarks flow along with the bulk of the medium, this is evidence for thermalization of charm. In this situation, the medium modifications of the charm spectrum should be substantial [14].

In this Letter, we report on the p_T spectra of nonphotonic electrons, $(e^+ + e^-)/2$, measured at midrapidity ($|\eta| < 0.35$) up to $p_T = 5$ GeV/c by the PHENIX experiment in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The photonic electron background was removed by a *cocktail* subtraction, in contrast to the *converter* subtraction used in [12], where a subset of the current data sample was analyzed. The converter method is better suited for a determination of the total yield of heavy flavor electrons, while the cocktail subtraction used here provides a precision measurement of the spectral shape [15]. The nuclear modification is then determined by comparing the spectra to those in $p + p$ collisions [9].

The data used in this analysis were collected by the PHENIX detector [16] during the 2001 run of RHIC. A coincidence of the beam-beam counters (BBC) and the zero degree calorimeters (ZDC) provided the minimum bias trigger ($92.2^{+2.5}_{-3.0}\%$ of the Au + Au inelastic cross section). The centrality was determined by the correlation between the multiplicity measured by the BBC and the energy of spectator neutrons measured by the ZDC. After restricting the vertex range to $|z| < 20$ cm to eliminate background originating from the central magnet, a data sample of 25×10^6 minimum bias events was analyzed.

For the electron analysis, charged particle tracks were reconstructed with the drift chamber and the first layer of pad chambers of the PHENIX east-arm spectrometer ($|\eta| < 0.35$, $\Delta\phi = \pi/2$), as discussed in detail elsewhere [12]. Tracks were confirmed by matching hits in the electromagnetic calorimeter (EMC) within 2σ in position. Electron candidates had at least three associated hits in the ring imaging Čerenkov detector (RICH). After an additional cut on the correlation between the momentum p and the energy E deposited in the EMC [$-2\sigma < (E - p)/p < 3\sigma$], the only background remaining in the electron sample was due to accidental coincidences between RICH hits and hadron tracks. This background was estimated ($\approx$15% at low p_T in central collisions, decreasing towards high p_T and for peripheral events) and subtracted statistically by an event-mixing method.

The raw electron spectra were corrected as a function of p_T for geometrical acceptance and reconstruction efficiency [12]. The multiplicity dependent efficiency loss was estimated by embedding simulated electrons into real events. This loss increased from 5% to 26% from peripheral to central collisions without a significant p_T dependence in the range relevant here. The 1σ systematic uncertainty of all corrections is 11.8%, after correction for the effect of finite bin width in p_T. The fully corrected inclusive electron spectrum is shown in Fig. 1(a) for minimum bias collisions.

The spectra of electrons from heavy flavor decays were determined by subtracting cocktails of background contributions from other sources from the inclusive data. The most important background is the π^0 Dalitz decay which was calculated individually for each centrality class with a hadron decay generator using parametrizations of measured π^0 [2] and $\pi^\pm$ [17] spectra as input. The spectral shapes of other light hadrons h were obtained from the pion spectra, assuming a universal spectrum in $m_T = \sqrt{p_T^2 + m_h^2}$. Within this approach the ratios h/π^0 are constant at high p_T with the values [11]: $\eta/\pi^0 = 0.45 \pm 0.10$, $\rho/\pi^0 = 1.0 \pm 0.3$, $\omega/\pi^0 = 1.0 \pm 0.3$, $\eta'/\pi^0 = 0.25 \pm 0.08$, and $\phi/\pi^0 = 0.40 \pm 0.12$. Only the η contribution

is of any practical relevance, and the chosen parametrization is in good agreement with the measured η meson spectra [18]. Another major electron source is the conversion of photons, mainly from $\pi^0 \to \gamma\gamma$ decays, in material in the acceptance ($\approx 1\%\ X/X_0$). The spectra of electrons from conversions and Dalitz decays are very similar. In a GEANT simulation [19] of π^0 decays, the ratio of conversion electrons to Dalitz electrons was determined to be 1.25 ± 0.10, essentially p_T independent. Contributions from photon conversions from other sources were taken into account as well. Electrons from kaon decays (K_{e3}), determined in a GEANT simulation based on measured kaon spectra [17], and electrons from external as well as internal conversions of direct photons [20,21] were included.

All background sources are compared with the inclusive data in Fig. 1(a). Further background from $J/\psi \to e^+e^-$ decays and from Drell-Yan pairs [22] is negligible. A possible low mass dilepton enhancement through $\pi + \pi \to \rho \to e^+e^-$, as reported in Pb + Pb collisions at lower $\sqrt{s_{NN}}$ [23], would constitute another background source

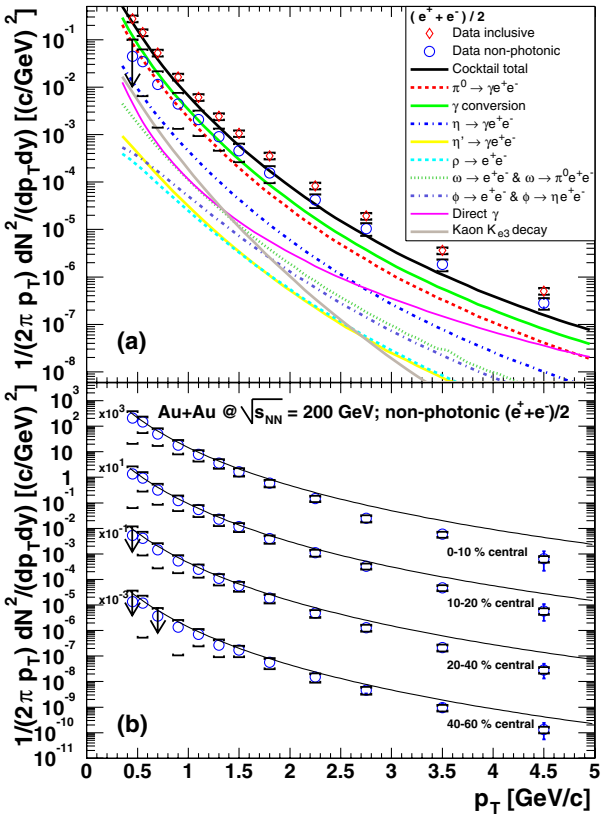

FIG. 1 (color online). (a) Inclusive and nonphotonic electron invariant yields in minimum bias Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV, compared with contributions from all background electron sources included in the cocktail. (b) Invariant yields of electrons from heavy flavor decays for different Au + Au centrality classes, scaled by powers of ten for clarity, together with the best fit to the $p + p$ reference scaled with the appropriate nuclear overlap integrals $\langle T_{AA} \rangle$. The error bars (brackets) correspond to statistical (systematic) uncertainties.

which is neglected here since the estimated ρ contribution in the absence of enhancement is small ($<1\%$ at all p_T). The total cocktail systematic uncertainty increases from 10% (at $p_T = 0.4$ GeV/c) to 15% (at $p_T = 5$ GeV/c), dominated by the systematic error of the pion input spectra ($\approx 8\%$–10%). Other systematic uncertainties, mainly the η/π^0 normalization and, at high p_T, the contribution from direct radiation, are much smaller. The background cocktail calculated here and the photonic electron background measured via the converter method [12] agree within 10%.

After subtracting the cocktail from the inclusive electron data, the invariant spectrum of electrons from heavy flavor decays is shown in Fig. 1(a) for minimum bias collisions. For $p_T > 2$ GeV/c the signal to background ratio is larger than 1. Figure 1(b) shows the electron spectra from heavy flavor decays in four centrality classes, 0%–10%, 10%–20%, 20%–40%, and 40%–60% central collisions. More peripheral collisions have insufficient electron statistics to reach $p_T = 5$ GeV/c.

PHENIX has also measured electrons from heavy flavor decays in $p + p$ collisions at $\sqrt{s} = 200$ GeV [9]. The curves shown in Fig. 1(b) depict the best fit of the corresponding spectrum from $p + p$ collisions, scaled by the nuclear overlap integral $\langle T_{AA} \rangle$ calculated within a Glauber model [2] for each Au + Au centrality class. At low p_T the Au + Au spectra are in reasonable agreement with the $p + p$ fit in all centrality bins, but a clear suppression of the spectra in Au + Au with respect to $p + p$ develops towards high p_T.

To quantify this effect we calculate for each individual bin in p_T the nuclear modification factor R_{AA} defined as

$$R_{AA} = \frac{dN_{\mathrm{Au+Au}}}{\langle T_{AA} \rangle d\sigma_{p+p}}, \tag{1}$$

where $dN_{\mathrm{Au+Au}}$ is the differential electron yield from heavy flavor decays in Au + Au collisions and $d\sigma_{p+p}$ is the corresponding differential cross section in $p + p$ collisions [9] in any given p_T bin.

Figure 2 shows R_{AA} as a function of p_T in the four Au + Au centrality classes. At low p_T, the electron R_{AA} is consistent with one within substantial uncertainties in all centrality classes, in agreement with the observation of binary collision scaling of the total charm yield in Au + Au collisions at RHIC [12]. Since the ratio of electrons from heavy flavor decays to background increases with increasing p_T, the systematic uncertainties of R_{AA} decrease towards high p_T. R_{AA} falls well below one for electron $p_T \geq 2$ GeV/c, providing clear evidence for heavy quark medium modifications. The observed high p_T suppression is most significant for central collisions. However, the limited statistics do not allow one to quantify the centrality dependence of heavy quark medium modifications. At the highest p_T, the electron R_{AA} becomes as small as that for π^0 [2], indicating substantial energy loss of heavy quarks in the medium. It is important to note that electrons at a given p_T originate from decays of higher p_T D or B

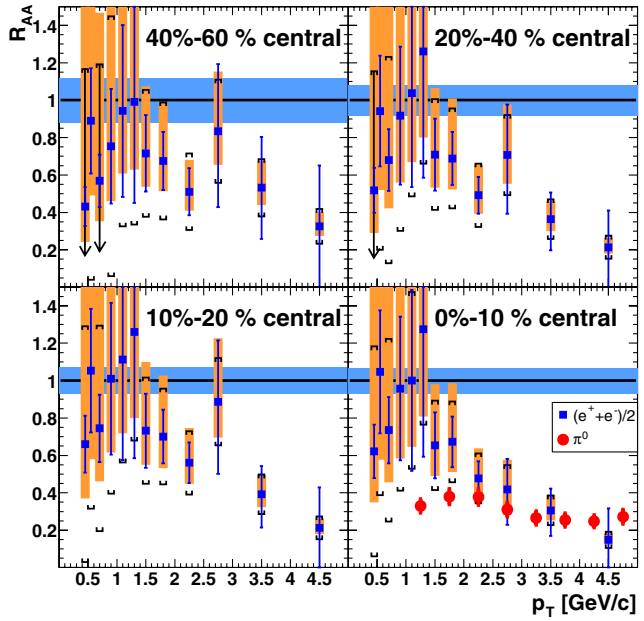

FIG. 2 (color online). Nuclear modification factor R_{AA} for electrons from heavy flavor decays as function of p_T in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV for the different centrality classes. The error bars are statistical only. Error brackets (boxes) indicate the systematic errors related to the uncertainties in the Au + Au ($p + p$) measurements. The bands around one show the relative systematic uncertainties in T_{AA}. For the most central collisions the π^0 R_{AA} is shown for comparison [2]. For these data, a 13% p_T independent systematic uncertainty (not plotted) represents the uncertainty in $\langle T_{AA} \rangle$ and in the π^0 yield normalization.

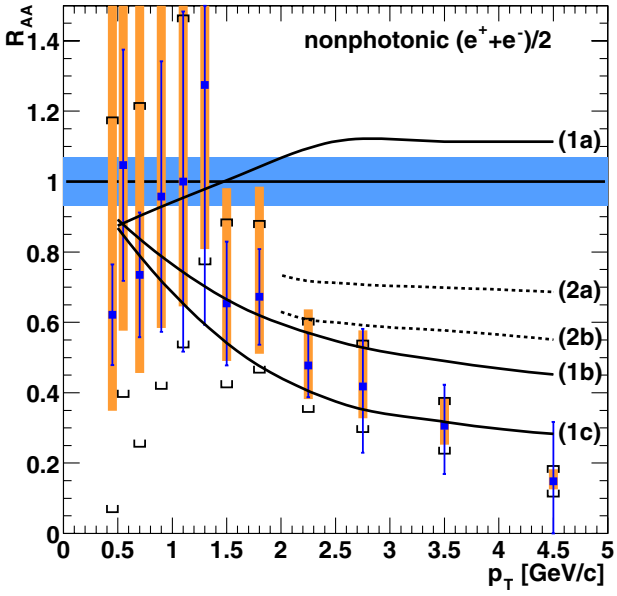

FIG. 3 (color online). Nuclear modification factor R_{AA} for electrons from heavy quark decays as function of p_T for the 10% most central Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV in comparison with predictions from models incorporating charm quark energy loss. Curves (1a)–(1c) and (2a)–(2b) are taken from [24,25], respectively, where contributions from B meson decays are included in (2a) and (2b) only. Experimental uncertainties are shown as described in Fig. 2.

mesons, making model independent comparisons of R_{AA} for light and heavy quarks impossible.

The observed R_{AA} is remarkable, as electrons with $p_T > 3.5$ GeV/c are expected to include significant contributions from B meson decays, and B mesons should suffer less than D mesons from medium modifications. Depending on their time scales, mechanisms by which heavy quarks are produced after the initial hard parton scattering, such as gluon splitting in jets, might lead to an attenuation at high p_T which then is due to a mixture of light parton and heavy quark energy loss in the medium created at RHIC.

Figure 3 confronts current model calculations [24,25] utilizing induced gluon radiation as the heavy quark energy loss mechanism with the data for the 10% most central collisions. The three curves (1a)–(1c) include electrons from charm decays only [24]. They correspond to different values of the time-averaged transport coefficient $\hat{q}$, which denotes the average squared transverse momentum transferred from a hard parton per unit path length while traversing the medium and, as such, is proportional to the density of scattering centers in the medium. Curve (1a) applies for the case without the presence of any medium causing heavy quark energy loss ($\hat{q} = 0$ GeV^2/fm). The $\hat{q}$ values of 4 and 14 GeV^2/fm, which correspond to curves (1b) and (1c), lead to light quark energy losses which bracket the observed high p_T suppression of neutral pions and charged hadrons. Predictions for charm energy loss from [24] for medium densities at the extreme high end of those allowed by the observed light quark energy loss are consistent with the electron data. Contributions from bottom decays, which are expected to be significant for $p_T > 3$ GeV/c, should lead to an increase of the predicted R_{AA} since b quarks are presumably less affected by energy loss than c quarks [6]. Curves (2a) and (2b) are taken from [25]. They include electrons from both D and B meson decays and correspond to initial gluon densities of $dN_g/dy = 1000$ and 3500 for curves (2a) and (2b), respectively, which again lead to light parton energy losses bracketing the observed high p_T pion suppression. However, at high p_T the predicted R_{AA} for electrons from heavy flavor decays is larger than observed. The present data pose a challenge to existing calculations of radiative energy loss in the medium produced at RHIC, and will help to distinguish between different energy loss scenarios.

In conclusion, we have measured electron spectra from heavy flavor decays in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. In central collisions, nuclear modification factors $R_{AA} \ll 1$ are observed at high p_T, providing clear evidence for strong medium effects. Current models involving energy loss via induced gluon radiation for heavy quarks traversing the medium created in heavy ion collisions at RHIC are challenged by the data even considering extremely high medium densities.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 7 October 2005; published 10 May 2006)

Dihadron correlations at high transverse momentum p_T in $d+$Au collisions at $\sqrt{s_{NN}} = 200$ GeV at midrapidity are measured by the PHENIX experiment at the Relativistic Heavy Ion Collider. From these correlations, we extract several structural characteristics of jets: the root-mean-squared transverse momentum of fragmenting hadrons with respect to the jet $\sqrt{\langle j_T^2 \rangle}$, the mean sine-squared of the azimuthal angle between the jet axes $\langle \sin^2 \phi_{jj} \rangle$, and the number of particles produced within the dijet that are associated with a high-p_T particle (dN/dx_E distributions). We observe that the fragmentation characteristics of jets in $d+$Au collisions are very similar to those in $p+p$ collisions and that there is little dependence on the centrality of the $d+$Au collision. This is consistent with the nuclear medium having little influence on the fragmentation process. Furthermore, there is no statistically significant increase in the value of $\langle \sin^2 \phi_{jj} \rangle$ from $p+p$ to $d+$Au collisions. This constrains the effect of multiple scattering that partons undergo in the cold nuclear medium before and after a hard collision.

I. INTRODUCTION

Jet production in high energy collisions is a useful tool to study the passage of scattered partons through a nuclear

*Deceased.
†PHENIX spokesperson: zajc@nevis.columbia.edu

medium. A dominant hard-scattering process is two partons scattering to produce two high-transverse momentum (high-p_T) partons which then fragment to produce a dijet. In a nuclear environment, the partons that participate in the collision can undergo multiple scattering within the nucleus, potentially changing the structure of the dijet. Such changes can provide information on the interaction of colored partons with the cold nuclear medium.

Some information on this interaction is already available at Relativistic Heavy Ion Collider (RHIC) energies via the Cronin enhancement of the p_T spectra [1]. In d + Au collisions at RHIC [2–4], the cross section for high-p_T particle production in d + Au collisions is enhanced compared to $p + p$ collisions, consistent with multiple scattering in the cold nuclear medium increasing the transverse momentum of the partons. In this paper, we report on a complementary observable to the Cronin effect: the broadening of dijet distributions. Such broadening is directly related to the additional transverse momentum delivered to the partons during multiple scattering, and hence it provides a complementary tool for comparing experiment against theory.

Interpreting both d + Au and Au + Au collisions requires solid knowledge of baseline $p + p$ collisions, especially those dijet events at midrapidity that contain two nearly back-to-back jets produced from a hard (large Q^2) parton-parton interaction. Experimentally, the jets were not exactly back to back, and the acoplanarity momentum vector $\vec{k}_T$ was measured in $p + p$ collisions at the Intersecting Storage Rings at CERN (ISR) to have a magnitude k_T on the order of 1 GeV/c [5]. This was much larger than the magnitude expected if k_T was due to an intrinsic parton transverse momentum governed by the hadron size, which would lead to $k_T \sim 300$ MeV/c. It was realized early [6] that additional gluon radiation either before or after the hard scattering will increase the value of k_T and the dijet acoplanarity.

In collisions involving nuclei at laboratory energies from 400 to 800 GeV/c, multiple scattering within the nucleus increases the parton transverse momentum. Fermilab experiments E557 [7], E609 [8], and E683 [9] all measured an increase in the dijet acoplanarity with atomic mass of the target. In E683, they measured an $A^{\frac{1}{3}}$ dependence of $\langle k_T^2 \rangle$ for both $\gamma + A$ and $\pi + A$ collisions. This dependence is expected since the number of scatterings should be proportional to the length traversed in the nucleus ($L \sim A^{\frac{1}{3}}$). For large A, the extracted $\langle k_T^2 \rangle$ values are about 50% above those for collisions with the hydrogen target, implying that the multiple-scattering effects are as important to the broadening of the dijets as are the initial state effects at that energy. In the case of $p + A$ reactions, the measured $\langle k_T^2 \rangle$ values increase more slowly than $A^{\frac{1}{3}}$ [8]. Since the $\langle k_T^2 \rangle$ values show a strong energy dependence [9], we need to establish the initial and multiple-scattering contributions to $\langle k_T^2 \rangle$ for $p + A$ reactions at RHIC energies. The $\langle k_T^2 \rangle$ values are also known to be dependent on the Q^2 of the parton-parton interaction, increasing with rising Q^2 [10,11].

No model is currently available that can reproduce all data on the Cronin effect and dijet broadening, although most include multiple scattering as the underlying mechanism. A recent review [12] considered two large classes of models: (1) soft or Glauber scattering where the multiple scattering is at either the hadronic or partonic level and (2) semihard multiple scattering where the multiple scattering is at the partonic level.

In both the soft and hard scattering models, the increase $\Delta\langle k_T^2 \rangle = \langle k_T^2 \rangle_{p+A} - \langle k_T^2 \rangle_{p+p}$ is proportional to the product of the scattering cross section and the nuclear thickness function,

$$\Delta\langle k_T^2 \rangle \propto \nu(b, \sqrt{s}) - 1 = \sigma_{\mathrm{MS}}(\sqrt{s}) T_A(b), \tag{1}$$

where $\nu(b, \sqrt{s})$ is the number of interactions, b is the impact parameter of the collision, σ_{MS} is the multiple-scattering cross section, and $T_A(b)$ is the nuclear thickness function. For the soft scattering models, σ_{MS} is defined to be $\sigma_{NN}(\sqrt{s})$, the nucleon-nucleon scattering cross section: while for the semihard models, σ_{MS} is $\sigma_{i|H}^{N}(\sqrt{s})$, the parton-nucleon semihard cross section. In the specific case of hard sphere nucleon scattering [13],

$$\nu(b, \sqrt{s}) = \sigma_{NN}(\sqrt{s}) \frac{3A}{2\pi R^2} \sqrt{1 - \frac{b^2}{R^2}}$$

where R is the nuclear radius, which gives an $A^{\frac{1}{3}}$ increase in $\Delta\langle k_T^2 \rangle$.

Both types of these models give the same trend in centrality and the same dependence on the target's atomic mass. The difference between them is in the strength of the increase with respect to $T_A(b)$ and how this changes with beam energy. We will compare the data in this paper to two specific implementations of the hard-scattering models from Qiu and Vitev [14] and Barnafoldi *et al.* [15].

An alternative view of the Cronin effect was recently proposed by Hwa and Yang [16]. These authors calculate the recombination of hard partons with soft partons released during the multiple collisions. Because this model reproduces the measured Cronin effect at RHIC without imparting successive transverse momentum kicks to the scattered partons, the authors suggest that there may be little to no increase in k_T from $p + p$ to d + Au collisions.

We also use jet-fragmentation observables to probe multiple scattering in cold nuclei, in particular, $\sqrt{\langle j_T^2 \rangle}$, the rms of the mean transverse momentum of hadrons with respect to the fragmenting parton, and the fragmentation function of the parton, $D(z, Q^2)$, where z is the fraction of the parton's momentum that a hadron carries. If the parton suffers semihard inelastic collisions within the nuclear environment, the parton will lose energy and its subsequent hadronization will produce fewer high-z fragments and more low-z fragments. We cannot directly measure fragmentation functions via dihadron correlations, but we can measure the distribution of hadrons produced in association with a high-p_T trigger particle. We plot these distributions as a function of x_E, where x_E is defined as

$$x_E = \frac{\vec{p}_{T,\mathrm{trig}} \cdot \vec{p}_{T,\mathrm{assoc}}}{|\vec{p}_{T,\mathrm{trig}}|^2}. \tag{2}$$

The motivation for the variable x_E can be most easily seen in the simple case where $\langle z \rangle = 1$ for the trigger particle and the two hadrons are emitted back to back. In this case, $p_{T,\mathrm{trig}}$ is the transverse momentum of the scattered parton

($q_{T,\mathrm{parton}}$), and for the far side, $x_E = z_{\mathrm{assoc}} = p_{T,\mathrm{assoc}}/q_{T,\mathrm{parton}}$. Relaxing the assumption on z_{trig}, there is still a simple relation between x_E and z for back-to-back jets at high p_T, where $x_E \simeq z_{\mathrm{assoc}}/z_{\mathrm{trig}}$. Hence the dN/dx_E distribution for hadrons emitted back to back from the trigger hadron can be related to the fragmentation function; for more details, see the end of Sec. II.

There is considerable information on x_E distributions from $p + p$ collisions. The CCHK Collaboration [5] demonstrated that the x_E distribution scaled, i.e., the distribution was approximately independent of $p_{T,\mathrm{trig}}$. Scaling at higher $p_{T,\mathrm{trig}}$ was also established by Fisk *et al.* [17] and the CCOR Collaboration [18,19], providing support for the idea that fragmentation of high-p_T partons is independent of the momentum of the parton.

This scaling is, however, approximate, and scaling violation was understood by Feynman *et al.* [6] to be caused by the radiation of semihard gluons. Scaling violation of the fragmentation function $D(z, Q^2)$ is now well established experimentally ([20] and references therein). For the Q^2 range considered in this paper ($10 < Q^2 < 1000\ \mathrm{GeV}/c^2$), the fragmentation functions used in next-to-leading order (NLO) calculations [21] drop by 25% for $z = 0.6$ over the range $10 < Q^2 < 100\ \mathrm{GeV}/c^2$. At higher Q^2, the fragmentation functions are less dependent on Q^2, e.g., the fragmentation drops by less than 20% at $z = 0.6$ over the much larger range of $100 < Q^2 < 1500\ \mathrm{GeV}/c^2$.

In this paper, we quantify the extent to which our measured x_E distributions in d + Au collision scale, and we compare the x_E distributions to those from $p + p$ collisions at RHIC. The goal is to establish whether inelastic scattering in the cold medium or the recombination mechanism changes the effective fragmentation function. The x_E distributions provide a stringent test of the recombination model from Hwa and Yang [22]. This model reproduces the Cronin effect in d + Au collisions through a shower thermal recombination mechanism and predicts an increase in jet-associated multiplicity [22,23], i.e., an increase in the near-angle dN/dx_E, in d + Au relative to $p + p$ collisions.

The measured x_E distributions in d + Au also serve as a critical baseline for Au + Au collisions, where the strong energy loss in the dense, hot medium is expected to dramatically change the shape of these distributions.

Our three goals for this paper are (1) to report the characteristics of jet structures in d + Au collisions at RHIC energies, (2) to establish the extent to which multiple scattering changes these structures as a function of centrality and by comparison with data from $p + p$ collisions, and (3) to establish the baseline for jet-structure measurements in heavy ion reactions. Any difference between jet properties in Au + Au and d + Au collisions should be attributable to the hot, dense nuclear matter created in the heavy ion collisions. The main results in this paper are presented in Sec. IV, which details the measured values of $\langle j_T^2 \rangle$ and $\langle \sin^2 \phi_{jj} \rangle$ and the p_T and x_E distributions from d + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. These results are derived from the fitted widths and yields of two-particle azimuthal correlations, which are reported in Sec. IV. The experimental methods used to obtain these correlations are described in Sec. III, and the jet quantities we use throughout the paper are fully defined in Sec. II.

II. JET ANGULAR (AZIMUTHAL) CORRELATIONS

A. Two-particle correlation

The defining characteristic of a jet is the production of a large number of particles clustered in a cone in the direction of the fragmenting parton. Traditionally, energetic jets are identified directly using standard jet reconstruction algorithms [24,25]. In heavy ion collisions, the large amount of soft background makes direct jet reconstruction difficult. Even in $p + A$ or $p + p$ collisions, the range of energy accessible to direct jet reconstruction is probably limited to $p_T > 5{-}10\ \mathrm{GeV}/c$, below which the jet cone becomes too broad and contamination from the "underlying event" background is significant. Jet identification is even more complicated for detectors with limited acceptance, such as the PHENIX central arms, because of leakage of the jet cone outside the acceptance.

The two-particle azimuthal angle correlation technique provides an alternative way to access the properties of jets. It is based on the fact that the fragments are strongly correlated in azimuth ϕ and pseudorapidity η. Thus, the jet signal manifests itself as a narrow peak in $\Delta\phi$ and $\Delta\eta$ space. Jet properties can be extracted on a statistical basis by accumulating many events to build a $\Delta\phi$ distribution or a $\Delta\phi$ correlation function. Furthermore, we assume that the soft background is isotropic. Distributions in $\Delta\phi$ were initially used in the 1970s to search for jet signals in $p + p$ collisions at CERN's ISR facility [5,10,26]. More recently, $\Delta\phi$ distributions and correlation functions have been exploited for analysis of jet correlations at RHIC [27–31]. A detailed discussion of the two-particle correlation method can be found in [32]. These approaches overcome problems due to background and limited acceptance, and they extend the study of jet observables to lower p_T.

In the correlation method, two classes of particles are correlated with each other: trigger particles and associated particles. Although the distinction between these two classes is artificial, trigger particles are typically selected from a higher p_T range. In this work, we distinguish between two primary categories of correlations:

(i) Assorted-p_T correlation, where the p_T ranges for the trigger and associated particles do not overlap.
(ii) Fixed-p_T correlation, where the p_T ranges for the trigger and associated particles are identical.

In this paper, correlations are further categorized via a scheme which uses the identity of the trigger and associated particles. Denoting the trigger-particle p_T as $p_{T,\mathrm{trig}}$ and associated-particle p_T as $p_{T,\mathrm{assoc}}$, we present four different types of such correlations:

(i) $h^{\pm} - h^{\pm}$ fixed-p_T correlations. The p_T range of both the trigger and associated particle is $1 < p_T < 5\ \mathrm{GeV}/c$.

(ii) $h^{\pm} - h^{\pm}$ assorted-p_T correlations. There are three different selections:
   (a) $2.5 < p_{T,\mathrm{trig}} < 4\ \mathrm{GeV}/c$ with $0.5 < p_{T,\mathrm{assoc}} < 2.5\ \mathrm{GeV}/c$.
   (b) $4 < p_{T,\mathrm{trig}} < 6\ \mathrm{GeV}/c$ with $0.5 < p_{T,\mathrm{assoc}} < 4\ \mathrm{GeV}/c$.
   (c) $3 < p_{T,\mathrm{trig}} < 5\ \mathrm{GeV}/c$ with $0.5 < p_{T,\mathrm{assoc}} < 3\ \mathrm{GeV}/c$.

(iii) $\pi^0 - h^{\pm}$ assorted-p_T correlations. The trigger particle is a neutral pion and the associated particle is a charged hadron, where $5 < p_{T,\mathrm{trig}} < 10\ \mathrm{GeV}/c$ with $1 < p_{T,\mathrm{assoc}} < 5\ \mathrm{GeV}/c$.

(iv) $\pi^{\pm} - h^{\pm}$ assorted-p_T correlations. The trigger particle is a charged pion and the associated particle is a charged hadron, where $5 < p_{T,\mathrm{trig}} < 16\ \mathrm{GeV}/c$ with $1 < p_{T,\mathrm{assoc}} < 5\ \mathrm{GeV}/c$.

For each type of correlation, we study jet structure as a function of centrality and the momentum of the trigger and associated particles.

B. Extraction of j_T, $\sin^2\phi_{jj}$ from the correlation function

In this section, we discuss the framework for the two-particle correlation method. Figures 1 and 2 illustrate the relation between the two particles and their parent jet when the parents are the same jet or the dijet, respectively. The figures also show the relationship between j_T, $\sin^2(\phi_{jj})$, and the kinematic variables describing the trigger and associated particle. j_T is the component of the particle momentum perpendicular to the jet momentum. Its projection into the azimuthal plane is j_{T_y}. The quantity p_{out} (denoted with N or F for near or far side, respectively) is the component of the associated particle's p_T that is perpendicular to the trigger particle's p_T. The vector sum of $k_{T,1}$ and $k_{T,2}$ produces the dijet acoplanarity, and the azimuthal angle between the jet axes is ϕ_{jj}.

The rms value of j_{T_y} can be derived from the correlation functions. For the single jet fragmentation of Fig. 1, if we denote $\Delta\phi$, ϕ_{tj}, and ϕ_{aj} as the angles between trigger-associated, trigger-jet, and associated-jet, respectively, then the following relations are true:

$$\sin(\phi_{tj}) = \frac{j_{T_y,\mathrm{trig}}}{p_{T,\mathrm{trig}}} \equiv x_{j,\mathrm{trig}},$$
$$\sin(\phi_{aj}) = \frac{j_{T_y,\mathrm{assoc}}}{p_{T,\mathrm{assoc}}} \equiv x_{j,\mathrm{assoc}},$$

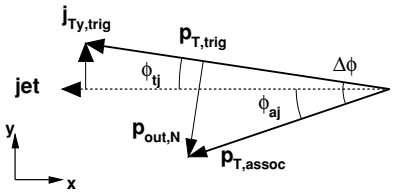

FIG. 1. Near-side or single jet fragmentation kinematics in the azimuthal plane perpendicular to the beam axis. Angles ϕ_{tj} and ϕ_{aj} are the angles (in the plane transverse to the beam axis) between the trigger-jet and associated-jet axes, respectively. Also shown are the p_T vectors for the trigger and associated particles, as well as p_{out} and j_{T_y} of the trigger particle.

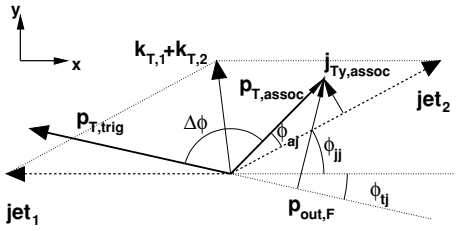

FIG. 2. Far-side jet fragmentation kinematics in the azimuthal plane perpendicular to the beam axis. Similar to Fig.1, the ϕ indices aj, jj, and tj denote the angles between the associated-jet, jet-jet, and trigger-jet axes.

$$\sin(\Delta\phi) = \frac{p_{\mathrm{out},N}}{p_{T,\mathrm{assoc}}},$$
$$\Delta\phi = \phi_{tj} + \phi_{aj}. \tag{3}$$

Assuming ϕ_{tj} and ϕ_{aj} are statistically independent, we have (cross terms average to 0) for the near side,

$$\langle \sin^2 \Delta\phi_N \rangle = \langle \sin^2 \phi_{tj} \rangle \cos^2 \phi_{aj} + \langle \sin^2 \phi_{aj} \rangle \cos^2 \phi_{tj}. \tag{4}$$

Substituting the sine and cosine terms from Eq. (3) into Eq. (4), we obtain the equation for the rms value of j_{T_y}

$$\sqrt{\left\langle j_{T_y}^2 \right\rangle} = \sqrt{\left\langle p_{\mathrm{out},N}^2 \right\rangle / \left(1 + \left\langle x_h^2 \right\rangle - 2\left\langle x_{j,\mathrm{trig}}^2 \right\rangle\right)}, \tag{5}$$

where $x_h = p_{T,\mathrm{assoc}}/p_{T,\mathrm{trig}}$.

In the Gaussian approximation for the near-side azimuthal distributions, a simple Taylor expansion connects p_{out} with the jet width σ such that

$$\left\langle p_{\mathrm{out}}^2 \right\rangle = \left\langle p_{T,\mathrm{assoc}}^2 \sin^2 \Delta\phi \right\rangle \approx \left\langle p_{T,\mathrm{assoc}}^2 \right\rangle \left[\sin\langle \Delta\phi^2 \rangle - \frac{\langle \Delta\phi^4 \rangle}{3} \right]$$
$$\approx \left\langle p_{T,\mathrm{assoc}}^2 \right\rangle [\sin\sigma^2 - \sigma^4]. \tag{6}$$

Since Eq. (5) contains the variable $x_{j,\mathrm{trig}}$ that depends on j_{T_y}, we should calculate $\sqrt{\langle j_{T_y}^2 \rangle}$ iteratively. In cases when trigger and associated particle p_T are much larger than the typical j_T value, the near-side jet width σ_N is small and $x_{j,\mathrm{trig}} \approx 0$. Hence Eq. (5) can be simplified as

$$\sqrt{\left\langle j_{T_y}^2 \right\rangle} \simeq \frac{\sigma_N \langle p_{T,\mathrm{assoc}} \rangle}{\sqrt{1 + \left\langle x_h^2 \right\rangle}} \simeq \sigma_N \frac{\langle p_{T,\mathrm{trig}} \rangle \langle p_{T,\mathrm{assoc}} \rangle}{\sqrt{\langle p_{T,\mathrm{trig}} \rangle^2 + \langle p_{T,\mathrm{assoc}} \rangle^2}}. \tag{7}$$

Since j_{T_y} is the projection of hadron p_T perpendicular to $p_{T,\mathrm{jet}}$, j_{T_y} is necessarily less than p_T. So, for any given p_T range, there is always an upper kinematic cutoff on the j_{T_y} distribution. This effect, known as the "seagull effect", leads to a reduction in the observed $\sqrt{\langle j_{T_y}^2 \rangle}$ from the expected value. It is important at low $p_{T,\mathrm{trig}}$ and becomes negligible once $p_{T,\mathrm{trig}} \gg \sqrt{\langle j_{T_y}^2 \rangle}$. The seagull effect can be parametrized and removed from the j_{T_y} values [33].

For the far-side correlation from Fig. 2 we have

$$\pi - \Delta\phi_F = \phi_{tj} + \phi_{aj} + \phi_{jj},$$
$$\sin(\Delta\phi_F) = \frac{p_{\mathrm{out},F}}{p_{T,\mathrm{assoc}}}, \tag{8}$$

where ϕ_{jj} is the azimuthal angle between the two jet axes. Expanding $\sin^2 \Delta\phi_F$ and dropping all cross terms (which average to 0), we get

$$\begin{aligned}\langle \sin^2 \Delta\phi_F \rangle = &\langle (\sin\phi_{tj} \cos\phi_{aj} \cos\phi_{jj})^2 \rangle \\ &+ \langle (\sin\phi_{aj} \cos\phi_{tj} \cos\phi_{jj})^2 \rangle \\ &+ \langle (\sin\phi_{jj} \cos\phi_{aj} \cos\phi_{tj})^2 \rangle \\ &+ \langle (\sin\phi_{tj} \sin\phi_{aj} \sin\phi_{jj})^2 \rangle. \end{aligned} \quad (9)$$

We substitute Eq. (4) to get

$$\begin{aligned}&\langle \sin^2 \Delta\phi_F \rangle \\ &= \langle \sin^2 \Delta\phi_N \rangle \langle \cos^2 \phi_{jj} \rangle + \langle \cos^2 \Delta\phi_N \rangle \langle \sin^2 \phi_{jj} \rangle \\ &= \langle \sin^2 \Delta\phi_N \rangle \langle 1 - \sin^2 \phi_{jj} \rangle + \langle 1 - \sin^2 \Delta\phi_N \rangle \langle \sin^2 \phi_{jj} \rangle \\ &= \langle \sin^2 \Delta\phi_N \rangle + \langle \sin^2 \phi_{jj} \rangle - 2 \langle \sin^2 \Delta\phi_N \rangle \langle \sin^2 \phi_{jj} \rangle. \end{aligned} \quad (10)$$

Collecting terms in ϕ_{jj} produces

$$\langle \sin^2 \phi_{jj} \rangle = \frac{\langle \sin^2 \Delta\phi_F \rangle - \langle \sin^2 \Delta\phi_N \rangle}{1 - 2\langle \sin^2 \Delta\phi_N \rangle}. \quad (11)$$

Note that since ϕ_{jj} is the azimuthal angle between the jet axes, $\sin^2(\phi_{jj})$ is one measure of the extent to which the jets are not back to back, and hence it is a quantity that is sensitive to any additional scattering in $d + \mathrm{Au}$ collisions. We express the right side in terms of the observables σ_N and σ_F, the rms widths of distribution that we measure by expanding the sine term

$$\langle \sin^2 \Delta\phi \rangle = \sigma^2 - \sigma^4 + 2/3\sigma^6, \quad (12)$$

which is good to 2% for rms widths at 0.5 rad and good to 0.6% for rms widths of 0.2 rad. Therefore,

$$\langle \sin^2 \phi_{jj} \rangle = \frac{\left(\sigma_F^2 - \sigma_F^4 + 2/3\sigma_F^6\right) - \left(\sigma_N^2 - \sigma_N^4 + 2/3\sigma_N^6\right)}{1 - 2\left(\sigma_N^2 - \sigma_N^4 + 2/3\sigma_N^6\right)}. \quad (13)$$

The right-hand side is now in terms of experimental observables which we will use to extract $\sin(\phi_{jj})$.

We have attempted to extract k_T from $\sin^2(\phi_{jj})$. This requires assumptions on the scattered quark distribution, the magnitude of the momentum asymmetry between the partons due to the k_T kick, as well as the detailed shape of the fragmentation function. The current paper is focused on the comparison between $p + p$ and $d + \mathrm{Au}$ collisions, which can be made with $\sin^2(\phi_{jj})$. Hence, we leave the extraction of k_T to future work.

In this paper, we report the rms values of j_T and $\sin(\phi_{jj})$, where $\sqrt{\langle j_T^2 \rangle} = \sqrt{2}\sqrt{\langle j_{T_y}^2 \rangle}$. In the literature, a j_T value is sometimes reported as the geometrical mean $\langle |j_{T_y}| \rangle$. The relation to the rms value is $\langle |j_{T_y}| \rangle = \sqrt{2/\pi}\sqrt{\langle j_{T_y}^2 \rangle}$.

C. Conditional yields

We also present in this paper the associated yield per trigger particle, referred to as the conditional yield (CY), as a function of p_T and x_E. CY is the number of particles produced in the same or opposite jet associated with a trigger particle,

$$\mathrm{CY}(p_T) = \frac{1}{N_{\mathrm{trig}}} \frac{dN_h}{dp_T}, \quad (14)$$

$$\mathrm{CY}(x_E) = \frac{1}{N_{\mathrm{trig}}} \frac{dN_h}{dx_E}, \quad (15)$$

and can be directly extracted from the measured Gaussian yields in the correlation functions.

To emphasize the importance of the CY, we note that it is related to the single- and two-particle cross sections:

$$\mathrm{CY} = \frac{d^2\sigma}{dp_a dp_b} \Big/ \frac{d\sigma}{dp_T}. \quad (16)$$

The interpretation for the two-particle cross section depends on whether one is studying the near- or far-side jet correlations. The conditional yield for particles from the near-side jet depends on the dihadron fragmentation function, while the conditional yield from the far side jet depends on two independent fragmentation functions: one parton fragments to produce a hadron with $p_{T,\mathrm{trig}}$, while the other scattered parton on the far side fragments to produce a hadron with $p_{T,\mathrm{assoc}}$. For the far side conditional yield at high p_T, $x_E \simeq z_{\mathrm{assoc}}/z_{\mathrm{trig}}$ [see Eq. (2)]. Hence, $d(x_E) \simeq d(z_{\mathrm{assoc}})/z_{\mathrm{trig}}$, and the slope of the far-side $\mathrm{CY}(x_E)$ is z_{trig} times the slope of the fragmentation function $D(z)$.

III. EXPERIMENT AND DATA ANALYSIS

A. Data collection

The data presented in this paper were collected by the PHENIX experiment at the RHIC facility during the $d + \mathrm{Au}$ and $p + p$ run of January–May 2003. During that time, integrated luminosities were recorded of 2.7 nb^{-1} for $d + \mathrm{Au}$ collisions and 0.35 pb^{-1} for $p + p$ collisions each at $\sqrt{s_{NN}} = 200$ GeV.

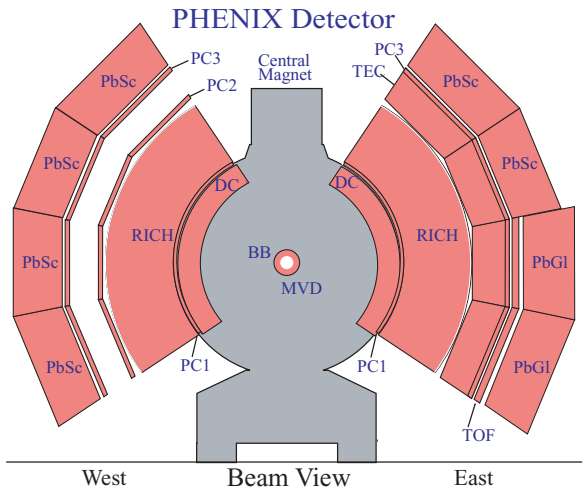

FIG. 3. (Color online) Two central spectrometer arms of the PHENIX experiment used to collect the charged hadron and charged and neutral pion tracks.

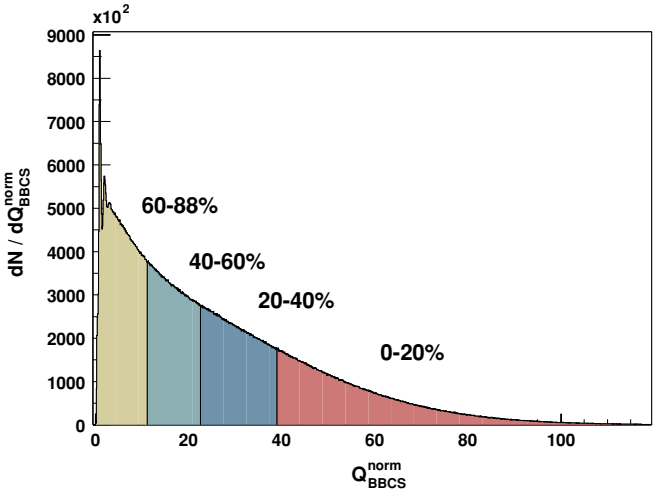

FIG. 4. (Color online) Total charge distribution on the Au-going side BBC for d + Au collisions and the centrality selection (see Table I).

The PHENIX detector consists of two central spectrometer arms, two forward muon arms, and several global detectors used for triggering, vertex detection, and centrality selection. This analysis utilizes the two central spectrometer arms that each cover a region of $|\eta| < 0.35$ units of pseudorapidity and 90° in azimuth. The spectrometer arms are not exactly back to back in azimuth; so while there is large acceptance for the detection of two particles separated by 180°, there is also finite acceptance for two particles separated by 90°. Figure 3 shows a beam cross-section view of the PHENIX central spectrometer arms. A complete overview of the whole PHENIX detector is found in Ref. [34]. In this section, we will only focus on those subsystems relevant to the analysis of the dihadron data.

1. Global event characteristics

For event characterization, the beam-beam counters (BBCs) [35] are utilized. The BBCs are sets of 64 Cherenkov counters placed symmetrically along the beam line, covering $3 < |\eta| < 3.9$ units of pseudorapidity and located 144 cm from the center of the interaction region. The BBCs determine the initial collision time t_0 and the event vertex from the time difference between particles reaching each BBC. For this analysis, we include only events with an offline cut of $|z_{\text{vertex}}| < 30$ cm.

The BBC facing the direction of the Au beam was used to determine the centrality. Figure 4 shows the BBC charge distribution and the centrality classes used in this analysis. The centrality is defined as

$$\%\text{Centrality} = 88.5\%(1 - \text{frac}(Q_{\text{BBC}})), \tag{17}$$

where $\text{frac}(Q_{\text{BBC}})$ is the fraction of the total BBC charge distribution integrated from zero to Q_{BBC}, and 88.5% is the efficiency of the minimum-bias trigger. This centrality can be related to the mean number of Au participants $\langle N_{\text{part}} \rangle$ and mean number of collisions $\langle N_{\text{coll}} \rangle$. To determine the centrality, we model the BBC charge distribution as a negative binomial distribution with a width and mean proportional to N_{part}. So, for a given centrality, several negative binomial distributions (defined by N_{part}) contribute to the overall distribution, and as such N_{part} is not uniquely defined. We calculate a weighted average of N_{part}, where the weight is given by the negative binomial distribution for a given N_{part} and the probability for having a collision with N_{part}. The latter probabilities were computed using a Glauber model, with a Hulthen wave function for the deuteron and an inelastic cross section of 42 mb. Finally, the $\langle N_{\text{coll}} \rangle$ was determined for a given $\langle N_{\text{part}} \rangle$ from the same Glauber model. The resulting centrality bins and $\langle N_{\text{coll}} \rangle$ used in this analysis are outlined in Table I.

TABLE I. Mean number of collisions for d + Au, N_{coll}, the percentage of the total inelastic cross section, and nuclear overlap function $T_A(b)$.

Percent σ_{inel}	$\langle N_{\text{coll}} \rangle$	$\langle T_A(b) \rangle (\text{mb}^{-1})$
0–20%	15.4 ± 1.0	0.367 ± 0.024
20–40%	10.6 ± 0.7	0.252 ± 0.017
40–88%	4.7 ± 0.3	0.112 ± 0.007

The dihadron events were recorded using several different level-1 triggers. The minimum-bias trigger required at least one hit in each of the BBCs and a collision vertex (computed online) that satisfies $|z_{\text{vertex}}| < 75$ cm. It was sensitive to 88.5% of the inelastic d + Au cross section. PHENIX also employed a series of level-1 triggers to select electrons, photons, and, with lower efficiency, high-p_T hadrons. These triggers utilized the ring imaging cherenkov (RICH) for electron identification, together with the electromagnetic calorimeter (EMC) [36], which consists of eight sectors, six of which are lead-scintillator (PbSc) sampling calorimeters and two are lead-glass (PbGl) Cherenkov counters. The EMC has excellent timing and energy resolution for electromagnetic showers. The triggers are called EMC/RICH triggers (ERTs) and were produced by summing signals from tiles, which were 4×5 photomultipliers (PMTs) in the RICH and either 2×2 or 4×4 PMTs in the EMC.

The electron trigger was defined by the coincidence between the minimum-bias trigger and the RICH and EMC 2×2 triggers where the threshold for the RICH tile was three photo-electrons and the EMC threshold varied between 400 and 800 MeV. Three different thresholds were available for the 4×4 photon triggers. These thresholds differed between the PbGl and PbSc and varied within and between the $p + p$ and d + Au runs. The lowest threshold setting (1.4–2.8 GeV) was most sensitive to hadron showers in the EMC. The threshold values and rejection factors (rejection = $N_{\text{minBiasEvents}}/N_{\text{triggerEvents}}$) for the ERT triggers, in coincidence with the minimum-bias trigger, are given in Table II. The $h^{\pm} - h^{\pm}$ correlations use only the minimum-bias-triggered data, while the $\pi^0 - h^{\pm}$ correlations use only the ERT photon triggers. The $\pi^{\pm} - h^{\pm}$ correlations use the minimum-bias, ERT photon, and ERT electron triggers. Above the energy threshold, the ERT electron trigger typically reached an efficiency of approximately 75%, and the ERT photon triggers reached efficiencies of 85–90%. A detailed knowledge of the ERT trigger efficiency is not necessary, since we present

TABLE II. EMC threshold and rejection factors for the electron and photon ERT triggers in coincidence with the minimum-bias trigger for $p + p$ and $d +$ Au. The photon triggers are defined by the energy sum of 4×4 PMTs in the EMC above threshold. The electron trigger requires the coincidence of the RICH trigger (threshold of three photoelectrons for both $p + p$ and $d +$ Au runs) and the energy sum of 2×2 PMTs in the EMC above threshold.

	$p + p$		$d +$ Au		$p + p$	$d +$ Au
	PbSc threshold (GeV)	PbGl threshold (GeV)	PbSc threshold (GeV)	PbGl threshold (GeV)	Rejection	Rejection
Gamma 1	2.1	2.1	2.8	3.5	400–1200	125–300
Gamma 2	2.8	2.8	2.8–3.5	3.5–4.2	1500–3100	450–900
Gamma 3	1.4	1.4	2.1	2.8	70–160	15–60
Electron	0.4–0.8	0.4–0.8	0.6–0.8	0.6–0.8	5–1200	30–170

the conditional yield distributions per trigger, for which this efficiency cancels out.

2. Tracking and particle identification

In this section, we discuss the tracking and identification of the particles used in the different correlation analyses. Three types of particles are included. Charged hadrons are used in all analyses, neutral pions are used as trigger particles for the $\pi^0 - h^\pm$ correlations, and charged pions are used as trigger particles for the $\pi^\pm - h^\pm$ correlations.

Charged hadron tracks are measured outside the PHENIX central magnetic field by the drift chamber (DC), located 2.0 m from the vertex, and two layers of multiwire proportional chamber (PC1 and PC3), located 2.5 and 5.0 m, respectively, from the vertex [37]. The DC determines the momentum and the azimuthal position of the track, while PC1 determines the polar angle [38]. The momentum resolution is determined to be $0.7\% \oplus 1.1\% p$ (GeV/c) [2]. Tracks are confirmed by requiring that an associated hit in PC3 lies within a 2.5σ (for $h^\pm - h^\pm$) or 3σ (for $\pi - h^\pm$) matching window in both the ϕ and z directions. This cut reduces the background from particles not originating in the direction of the vertex. The remaining background tracks are mainly decays and conversion particles [39]. The background level for single tracks is less than 5% below 3 GeV/c, increasing to about 30% at 5 GeV/c. However, the background is smaller for high-p_T triggered events (see Sec. III B). The charged particle tracking efficiency for the active region of the DC, PC1, and PC3 is better than 98%. Since we perform a pair analysis, the two-track resolution is important. For the DC, the two-track separation is better than 1.5 mm, while at PC1 it is 4 cm, and at PC3 it is 8 cm.

Neutral pions are detected by the statistical reconstruction of their $\gamma\gamma$ decay channel. These decay photons are detected by the EMC and identified by their time of flight (TOF) and shower shape. The electromagnetic shower shape is typically characterized by the χ^2 variable [36],

$$\chi^2 = \sum_i \frac{\left(E_i^{\text{meas}} - E_i^{\text{pred}}\right)^2}{\sigma_i^2}, \tag{18}$$

where E_i^{meas} is the energy measured at tower i and E_i^{pred} is the predicted energy for an electromagnetic particle of total energy $\sum_i E_i^{\text{meas}}$. This χ^2 value is useful for the discrimination of electromagnetic from hadron showers. The χ^2 and TOF cuts used give a very clean sample of photons with contamination of other particles at $\ll 1\%$.

Using pairs of photons that pass these EMC cuts, we create the invariant mass spectra for each photon pair p_T. A sample invariant mass distribution with a signal/background S/B of approximately 12 is given in Fig. 5. The background distribution can be reproduced by mixing clusters from different events and normalizing that distribution to the real event distribution outside the π^0 mass region. The peak position and width of the invariant mass distribution were parametrized as a function of pair p_T, in order to select π^0 candidates from a region of invariant mass within 2σ of the peak position. The S/B for a π^0 with $p_T > 5$ GeV is 10−20, increasing as a function of p_T. There is a slight dependence on centrality with the $\pi^0 S/B$ decreasing with increasing centrality.

PHENIX identifies high momentum charged pions with the RICH and EMC detectors. Charged particles with velocities above the Cherenkov threshold of $\gamma_{\text{th}} = 35$ (CO_2 radiator) emit Cherenkov photons, which are detected by photomultiplier tubes (PMTs) in the RICH [40]. This threshold corresponds to 18 MeV/c for electrons, 3.5 GeV/c for muons, and 4.9 GeV/c for charged pions. In a previous PHENIX publication [39], we showed that charged particles with reconstructed p_T above

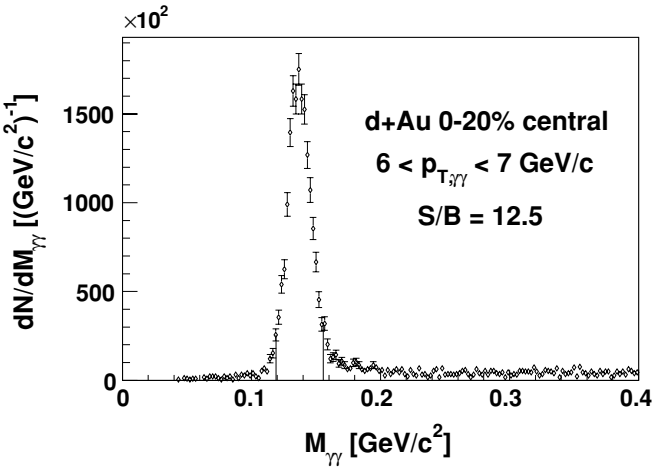

FIG. 5. Measured $\gamma\gamma$ invariant mass distribution for $6 < p_T < 7$ GeV/c in central $d +$ Au collisions. The peak is fitted with a Gaussian to extract the centroid mass and σ. The S/B within 2σ of the centroid ranges from ∼6 at 3 GeV/c up to 20 at ∼8 GeV/c.

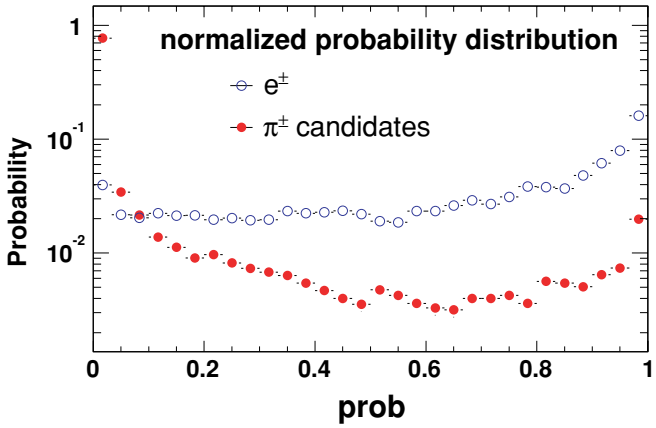

FIG. 6. (Color online) Probability distribution for charged pion candidates and electrons. Histogram integral has been normalized to unity.

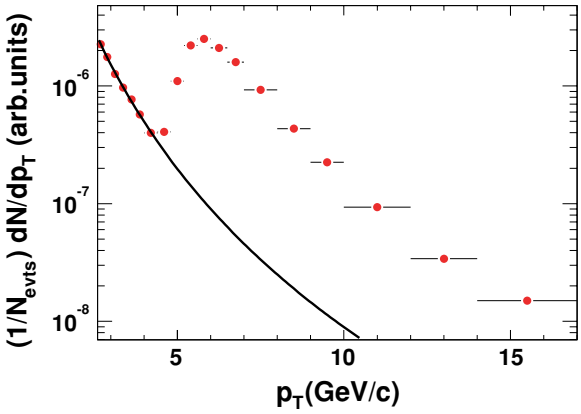

FIG. 7. (Color online) Raw charged pion transverse momentum spectrum, with the final cuts applied. Remaining background level is estimated from an extrapolation from low p_T and is shown as a black line.

4.9 GeV/c, which have an associated hit in the RICH, are dominantly charged pions and background electrons from photon conversions. The efficiency for detecting charged pions rises quickly past 4.9 GeV/c, reaching an efficiency of >90% at $p_T > 6$ GeV/c.

To reject the conversion backgrounds in the pion candidates, the shower information at the EMC is used. Since most of the background electrons are genuine low-p_T particles that were misreconstructed as high-p_T particles, simply requiring a large deposit of shower energy in the EMC is very effective in suppressing the electron background. In this analysis, a momentum-dependent energy cut applied at EMC is

$$E > 0.3 + 0.15\, p_T. \tag{19}$$

In addition to this energy cut, the shower shape information [36] is used to further separate the broad hadronic showers from the narrow electromagnetic (EM) showers and hence reduce the conversion backgrounds. In this analysis, we use the probability (prob) calculated from the χ^2 value [Eq. (18)] for an EM shower. The probability values range from 0 to 1, with a flat distribution expected for an EM shower and a peak around 0 for a hadronic shower. Figure 6 shows the probability distribution for the pion candidates and electrons, normalized by the integral, where the pion candidates were required to pass the energy cut and the electrons were selected using particle ID cuts similar to that used in Ref. [41]. Indeed, the electron distribution is relatively flat, while the charged pions peak at 0. A cut of prob <0.2 selects pions above the energy cut with an efficiency of $\gtrsim$80%. Detailed knowledge of the pion efficiency is not necessary, since we present in this paper the per-trigger pion conditional yield distributions, for which this efficiency cancels out.

Since the energy and prob cuts are independent of each other, we can fix one cut and then vary the second to check the remaining background level for conversions. The energy cut in Eq. (19) is chosen such that the raw pion yield is found to be insensitive to the variation in prob. Figure 7 shows the raw pion spectra for ERT-triggered events as a function of p_T, with the above cuts applied. The pion turnon from 4.9 to 7 GeV/c is clearly visible. Below a p_T of 5 GeV/c, the remaining background comes mainly from the random association of charged particles with hits in the RICH detector. The background level is less than 5% from 5 to 16 GeV/c, which is the p_T range for the charged pion data presented in this paper.

B. Data analysis

In this section, we outline the method used to obtain correlation functions and distributions. From these, we extract the jet shapes and yields outlined in Sec. II. For the extraction of the jet yield from the azimuthal distributions, we discuss how we obtain the absolute normalization of the distribution; while for the jet shape properties, j_{T_y} and $\langle \sin^2\phi_{jj} \rangle$, the absolute normalization is not necessary.

1. Correlation functions

Azimuthal correlation functions are generally defined as

$$C(\Delta\phi) \propto \frac{N_{\rm cor}(\Delta\phi)}{N_{\rm mix}(\Delta\phi)}. \tag{20}$$

Similarly, one can also define the correlation function in pseudorapidity as

$$C(\Delta\eta) \propto \frac{N_{\rm cor}(\Delta\eta)}{N_{\rm mix}(\Delta\eta)}. \tag{21}$$

The same-event pair distribution, $N_{\rm cor}(\Delta\phi)$ or $N_{\rm cor}(\Delta\eta)$, is constructed for trigger-associated particle pairs. The mixed-event pair distribution, $N_{\rm mix}(\Delta\phi)$ or $N_{\rm mix}(\Delta\eta)$, is determined by combining trigger particles with associated particles from randomly selected events.

This definition of the correlation function relies on the fact that detector acceptance and efficiency cancel out. It is therefore important that the pair efficiencies of the average mixed-event background and the average foreground distributions are the same. For this reason, we generate mixed-event distributions only for events with similar centralities and event vertices. More precisely, mixed events were required to match within ±10% centrality, and the event vertices were required to

be within ±3 cm. For $h^{\pm} - h^{\pm}$ correlations, the real and mixed events are minimum-bias data. For $\pi^0 - h^{\pm}$ correlations, the real and mixed events are ERT-triggered data. For $\pi^{\pm} - h^{\pm}$ correlations, the real events are ERT-triggered and minimum-bias data, while the mixed events mix ERT-triggered events with minimum-bias events.

For $h^{\pm} - h^{\pm}$ and $\pi^{\pm} - h^{\pm}$ correlations, due to finite two-track resolution for charged particles at the DC and PC, the reconstruction efficiency for same-event charged track pair drops at small $\Delta\phi$ and $\Delta\eta$. To minimize the difference in the pair efficiency between $N_{\rm cor}(\Delta\phi)$ and $N_{\rm mix}(\Delta\phi)$, the pairs are required to have a minimal separation of about two times the resolution at the various tracking detectors. This corresponds to about 0.28, 8, and 15 cm at the DC, PC1, and PC3, respectively. However, these pair cuts are not required for $\pi^0 - h^{\pm}$ correlations, because different detector subsystems are used for reconstructing trigger-π^0 and the associated charged tracks as outlined earlier.

Given the similarity of the analysis techniques between $\Delta\phi$ and $\Delta\eta$ correlations, in this paper we focus on the $\Delta\phi$ correlation. The $\Delta\phi$ correlation functions are obtained with two different normalizations. For $h^{\pm} - h^{\pm}$ assorted correlations, the correlation function is area normalized

$$C_{\rm norm}(\Delta\phi) = \frac{N_{\rm cor}(\Delta\phi)}{N_{\rm mix}(\Delta\phi)} \times \frac{\int d\Delta\phi (N_{\rm mix}(\Delta\phi))}{\int d\Delta\phi (N_{\rm cor}(\Delta\phi))}. \quad (22)$$

The details concerning this normalization are discussed in Sec. IV A. The second normalization is used in both the $\pi^0 - h^{\pm}$ and $\pi^{\pm} - h^{\pm}$ correlations. It was shown in Ref. [32] that the CY can be derived from the measured correlation function with an appropriate normalization,

$$\frac{1}{N^0_{\rm trig}} \frac{dN_0}{d\Delta\phi} = \frac{R_{\Delta\eta}}{N_{\rm trig}\epsilon} \frac{\frac{dN_{\rm cor}}{d\Delta\phi}(\Delta\phi)}{\frac{2\pi N_{\rm mix}(\Delta\phi)}{\int d\Delta\phi N_{\rm mix}(\Delta\phi)}}, \quad (23)$$

where $N^0_{\rm trig}$ and $N_{\rm trig}$ are the true and detected number of triggers, respectively, and ϵ is the average single-particle efficiency for the associated particles in 2π in azimuth and ± 0.35 in pseudorapidity. $R_{\Delta\eta}$ corrects for the loss of jet pairs outside a given $\Delta\eta$ acceptance, determined by PHENIX's finite acceptance in η. This second normalization is defined so that the integral of the resulting correlation function should be $N_0/N^0_{\rm trig}$, the total number of pairs per trigger particle in a given azimuthal and η range.

For the normalization in Eq. (23), two separate efficiencies must be determined, the $\Delta\eta$ correction and the single-particle efficiency. The near-side correlation has a well-behaved peak around $\Delta\eta = 0$. As we show in Sec. IV A, the near-side jet width in $\Delta\phi$ and $\Delta\eta$ are consistent with each other within errors. So we correct the near-side yield to the full-jet yield assuming the shape of the jet is Gaussian and the widths are equal in $\Delta\phi$ and $\Delta\eta$. This correction, according to Ref. [32], is

$$R_{\Delta\eta} = \frac{1}{\int_{-0.7}^{0.7} d\Delta\eta \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{\Delta\eta^2}{2\sigma^2}\right] {\rm acc}(\Delta\eta)}, \quad (24)$$

where $\mathrm{acc}(\Delta\eta)$ represents the PHENIX pair acceptance function in $|\Delta\eta|$. It can be obtained by convoluting two flat distributions in $|\eta| < 0.35$, so $\mathrm{acc}(\Delta\eta)$ has a simple triangular shape: $\mathrm{acc}(\Delta\eta) = (0.7 - |\Delta\eta|)/0.7$. The PHENIX single-particle acceptance is flat in η to within 5%.

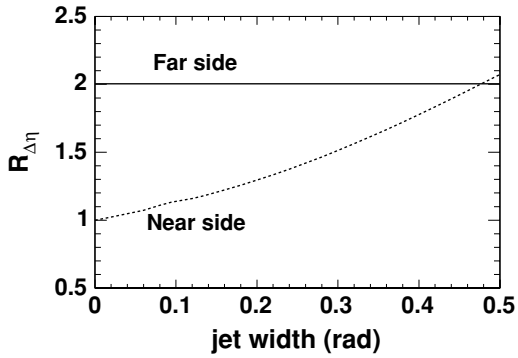

FIG. 8. Correction factor $R_{\Delta\eta}$ plotted as function of jet width for near and far sides.

In the far side, the jet signal is much broader than the PHENIX acceptance due to the broad range of momentum fraction x of the partons that participate in the hard scattering. In fact, we studied the far-side jet shape for the $\pi^{\pm} - h^{\pm}$ correlation (Fig. 17b) and found the true jet correlation strength to be almost constant in the PHENIX pair acceptance $|\Delta\eta| < 0.7$. Based on that, we assume that the far-side jet strength is constant and correct the far-side yield to the corresponding accessible pair range of $|\Delta\eta| < 0.7$,

$$R^{\rm far}_{\Delta\eta} = \frac{2 \times 0.7}{\int_{-0.7}^{0.7} d\Delta\eta \left[\frac{0.7 - |\Delta\eta|}{0.7}\right]} = 2. \quad (25)$$

$R^{\rm far}_{\Delta\eta}$ equals 2 because the pair efficiency has a triangular shape in $|\Delta\eta| < 0.7$, which results in 50% average efficiency when the real jet pair distribution is flat in $|\Delta\eta| < 0.7$. Figure 8 shows the correction factor $R_{\Delta\eta}$ as a function of jet width. The typical range of the near-side jet width in all analyses (see Sec. IV A) is below 0.5 rad. The maximum correction is about a factor of 2 for the near-side jet.

The single-particle efficiency for associated particles ϵ includes detector acceptance and reconstruction efficiency. It is evaluated in a way similar to previously published Au + Au [39] and d + Au [2] analyses. However, the jet-associated charged hadron spectrum in d + Au is much flatter than the inclusive charged hadron spectra [48],[1] so the corrections due to momentum scale and momentum resolution are much smaller than those for inclusive charged hadrons. For the same reason, the background contamination at high p_T, mainly coming from decay and photon conversions which are falsely reconstructed as high-p_T tracks [2,39], is also reduced. We studied both effects using a full GEANT simulation of PYTHIA events through PHENIX detectors. The jet-associated yields were extracted in the same manner as for the real data analysis. By comparing it with the input jet-associated yield spectra, we can quantitatively study the effect of momentum smearing and high-p_T background contamination. The corrections due to

[1]For example, in Fig. 21, the jet associated yields decrease by a factor of 100 from 0.5 to 5 GeV/c. However, the typical single inclusive hadron spectra decrease by a factor of 100 000 [2].

momentum scale and resolution are found to be less than 5% with 3% systematic errors. For high-p_T triggered events, the background contamination to the associated charged hadrons is found to be 5% independent of p_T from 1−5 GeV/c.

2. Extracting jet properties

The normalized correlation functions and conditional yield distributions are both fitted with a sum of two Gaussians to extract the jet widths and the conditional yield of hadrons in the near side ($\Delta\phi \sim 0$) and far side ($\Delta\phi \sim \pi$). The fit for the normalized correlation functions is described in Sec. IV A. For the conditional yield, we fit with the function

$$\frac{1}{N^0_{\rm trig}}\frac{dN_0}{d\Delta\phi} = B + \frac{{\rm Yield}_N}{\sqrt{2\pi}\sigma_N}\exp\left[\frac{-\Delta\phi^2}{2\sigma_N^2}\right] + \frac{{\rm Yield}_F}{\sqrt{2\pi}\sigma_F}\exp\left[\frac{-(\Delta\phi-\pi)^2}{2\sigma_F^2}\right], \quad (26)$$

where B reflects the combinatoric background level in the real distribution relative to the mixed distribution, and the other two terms represent the near-side jet and far-side jet signal, respectively. The resulting widths, σ_N and σ_F, are then used to calculate the jet shapes via Eqs. (7) and (13). For each choice of trigger and associated particle p_T range, Yield$_N$ and Yield$_F$ directly reflect the jet-associated yield $dN/dp_{T,\rm assoc}$ at the near and far side, respectively.

Two methods were used to calculate the dN/dx_E distribution. The first method was used for $\pi^0 - h^\pm$ correlations. Since these correlations are binned in p_T there is a distribution of x_E for each trigger-associated p_T bin. This distribution is approximately Gaussian. The fitted peak value is used as the bin center of the dN/dx_E distributions and the fitted Gaussian width is used as the horizontal error bar. To estimate the bin width in x_E, we used the definition Eq. (2) which can be written as (ignoring the sign) $x_E = p_{T,\rm assoc}\cos(\Delta\phi)/p_{T,\rm trig}$. We estimate $\cos(\Delta\phi) \approx 1$ and write the bin width as

$$\Delta x_E = \frac{p^{\rm max}_{T,\rm assoc} - p^{\rm min}_{T,\rm assoc}}{\langle p_{T,\rm trig}\rangle}, \quad (27)$$

where we have an associated p_T bin from $[p^{\rm min}_{T,\rm assoc}, p^{\rm max}_{T,\rm assoc}]$ and a trigger p_T bin with a mean $\langle p_{T,\rm trig}\rangle$.

The second method is adopted by $\pi^\pm - h^\pm$ analysis. It is statistically based and can be used to calculate the distribution for any pair variable $p_{T,\rm trig}$, $p_{T,\rm assoc}$, $\Delta\phi$, $\Delta\eta$, x_E, $p_{\rm out}$ etc. In the following we show two examples: the $dN/d\Delta\phi$ and dN/dx_E distributions. For each pair we calculate the $\Delta\phi$ and x_E value, then from Eq. (23) we calculate the same correction factor that was used for the $dN/d\Delta\phi$ distribution.

$$w(\Delta\phi) = \frac{R_{\Delta\eta}}{N_{\rm trig}\epsilon}\frac{1}{\frac{2\pi N_{\rm mix}(\Delta\phi)}{\int d\Delta\phi N_{\rm mix}(\Delta\phi)}}. \quad (28)$$

If this weight is used to fill the $\Delta\phi$ histogram for the real and mixed distribution, we obtain the CY for the true real pairs, and for the mixed pair the sum is,

$$\begin{aligned}{\rm background}(\Delta\phi) &= \sum_{\rm mix}\delta(\Delta\phi)w(\Delta\phi)\\ &= N_{\rm mix}(\Delta\phi)w(\Delta\phi)\\ &= \frac{N_{\rm trig}\epsilon}{R_{\Delta\eta}}\frac{\int d\Delta\phi N_{\rm mix}(\Delta\phi)}{2\pi}\end{aligned} \quad (29)$$

we have used the fact that $N_{\rm mix}(\Delta\phi) = \sum_{\rm mix}\delta(\Delta\phi)$.

Thus the jet signal can be extracted from Eq. (26) as

$$\begin{aligned}\frac{1}{N^0_{\rm trig}}\frac{dN^{\rm jet}_0}{d\Delta\phi} &= \sum_{\rm real}\delta(\Delta\phi)w(\Delta\phi) - B\\ &= \sum_{\rm real}\delta(\Delta\phi)w(\Delta\phi) - C\sum_{\rm mix}\delta(\Delta\phi)w(\Delta\phi),\end{aligned} \quad (30)$$

where

$$C = \frac{BR_{\Delta\eta}}{N_{\rm trig}\epsilon}\frac{2\pi}{\int d\Delta\phi N_{\rm mix}(\Delta\phi)}. \quad (31)$$

When this weight is used to fill the x_E histogram for both real and mixed distributions, we obtain the dN/dx_E by subtracting the mixed x_E distribution from the real x_E distribution,

$$\frac{1}{N^0_{\rm trig}}\frac{dN^{\rm jet}_0}{dx_E} = \sum_{\rm real}\delta(x_E)w(\Delta\phi) - C\sum_{\rm mix}\delta(x_E)w(\Delta\phi). \quad (32)$$

Equation (31) is rather trivial, because the weighting procedure is equivalent to Eq. (23), for which we know the shape of the distribution (Eq. (26)). But the advantage of the weighting procedure is that it allows for the determination of the absolute background pair distribution in any pair variables.

Similarly, the statistical method is used to extract the $p_{T,\rm assoc}$ and $p_{\rm out}$ spectra as

$$\frac{1}{N^0_{\rm trig}}\frac{dN^{\rm jet}_0}{dp_{T,\rm assoc}} = \sum_{\rm real}\delta(p_{T,\rm assoc})w(\Delta\phi) - C\sum_{\rm mix}\delta(p_{T,\rm assoc})w(\Delta\phi) \quad (33)$$

$$\frac{1}{N^0_{\rm trig}}\frac{dN^{\rm jet}_0}{dp_{\rm out}} = \sum_{\rm real}\delta(p_{\rm out})w(\Delta\phi) - C\sum_{\rm mix}\delta(p_{\rm out})w(\Delta\phi). \quad (34)$$

By construction, the integral of the jet yield should be conserved independent of the pair variable used, i.e.:

$$\begin{aligned}\int d\Delta\phi\frac{dN_0}{d\Delta\phi} &= \int dx_E\frac{dN^{\rm jet}_0}{dx_E}\\ \int dp_{T,\rm assoc}\frac{dN^{\rm jet}_0}{dp_{T,\rm assoc}} &= \int dp_{\rm out}\frac{dN^{\rm jet}_0}{dp_{\rm out}}.\end{aligned} \quad (35)$$

C. Systematic uncertainties

The correlation analyses presented here consist of several steps ranging from the generation of correlation functions to the extraction of the final physics variables [j_T, $\sin(\phi_{jj})$, per-trigger yields, etc.] from these correlation functions. Systematic error estimations for each of these steps have been evaluated and combined to determine the overall error quoted for each measurement. All errors quoted are maximum extent.

Systematic errors associated with the generation of correlation functions can result from shape distortions in either the foreground or background distributions. These distortions can arise if the requisite quality cuts (see Sec. III A) are not stable. In order to minimize such errors, the track pair and quality cuts were assigned such that the correlation functions were essentially insensitive to reasonable cut variations. Systematic errors associated with such cut variations are estimated to be less than 4%. A further source of systematic error is related to the efficiency of the background rejection when requiring a confirmation hit in the outer pad chamber. The yields have been corrected for remaining background. The systematic error on the background estimate is ≈3% for tracks with a transverse momentum (p_T) < 4 GeV/c and ≈7% for particles with 4 < p_T < 6 GeV/c. For the calculation of the conditional yields, the systematic error is dominated by the uncertainties associated with the determination of the efficiency corrected single-particle yields. These systematic errors have been estimated to be ≈10% as obtained from Ref. [2]. This error on the efficiency has two parts: the normalization error includes the error on PC3 matching and active area; the momentum smearing error includes contributions from momentum resolution and momentum scale.

A separate error is estimated for $\pi^0 - h^{\pm}$ correlations due to the background contamination of the π^0 within the mass bin. To estimate the width and yield contribution of the background $\gamma\gamma$ pairs, we created correlations of $\gamma\gamma$ outside the π^0 mass with hadrons. From these, we extrapolated the background contribution at the π^0 mass. These systematic errors are p_T dependent. For the near and far angle width, the variation is 1−3%, the near yield variation is 1%, the far yield variation is 1−5% and increases with increasing p_T.

The event-mixing technique has been used to correct for the limited detector acceptance and inefficiency. In addition, the CY has been corrected for limited $\Delta\eta$ coverage. To cross-check these procedures, we ran a detailed simulation using the PYTHIA event generator [42] coupled to a single-particle acceptance filter that randomly accepts charged particles according to the detector efficiency. In the following, we shall use $\pi^{\pm} - h^{\pm}$ as an example for this cross-check. Figure 9 shows a typical PHENIX two-dimensional single-particle acceptance used in this analysis.

We generated 1 million PYTHIA events, each required to have at least one >6 GeV/c charged pion. To speed up the event generation, a Q^2 cut of 100 GeV^2 on the underlying parton-parton scattering was required. These events were filtered through the single-particle acceptance filter. As an approximation, we ignore the p_T dependence of acceptance. The same event and mixed pair $\Delta\phi$ distributions were then

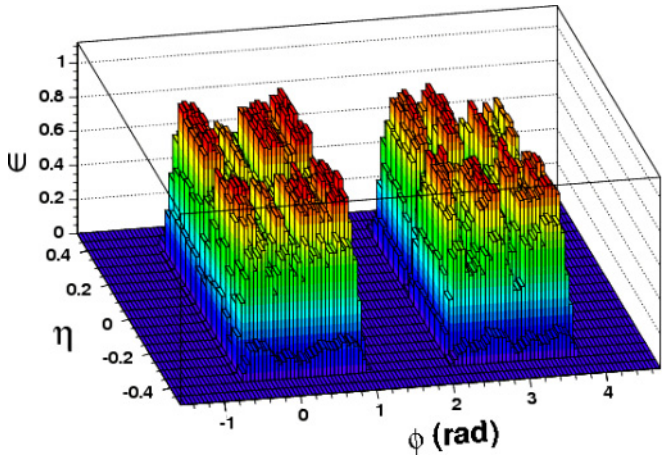

FIG. 9. (Color online) Typical PHENIX single-particle acceptance for charged hadrons.

built by combining the accepted $\pi^{\pm}$ and charged hadrons. The jet width and raw yield were extracted by fitting the $\frac{dN_{\rm fg}}{d\Delta\phi} / \frac{dN_{\rm mix}}{d\Delta\phi}$ with a constant plus double Gaussian function. The raw yields were then corrected via Eq. (24) to full jet yield for the near side and the yield in $|\Delta\eta| < 0.7$ for the far side. We also extracted the true CY and jet width without the acceptance requirement. The comparison of the CY and jet width with and without the acceptance requirement are shown in Fig. 10. The trigger particles are $\pi^{\pm}$ with 6 < $p_{T,\rm trig}$ < 10 GeV/c, the associated particles are $h^{\pm}$. In the near side, the corrected yield (top left panel) and width (bottom left panel) are compared with those extracted without the acceptance filter. In the far side, the yield corrected back to $|\Delta\eta| < 0.7$ and the width are compared with those extracted without the acceptance filter. The data requiring the acceptance filter are always indicated

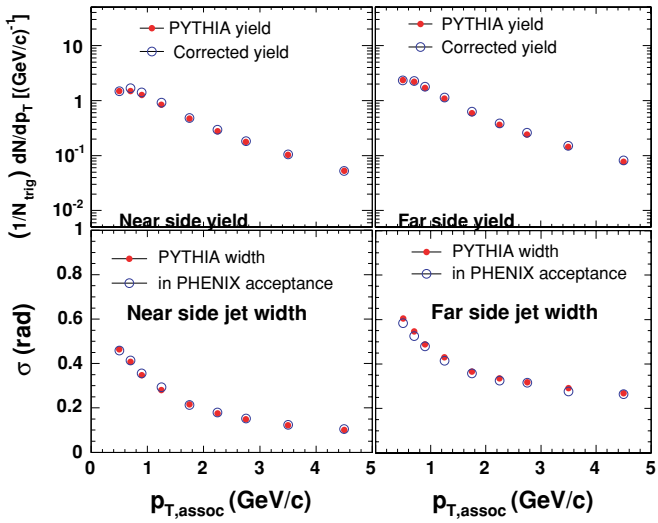

FIG. 10. (Color online) Comparison of near-side yield, near-side width, far-side yield, and far-side width as functions of p_T of charged hadrons. These are obtained for $\pi^{\pm} - h^{\pm}$ correlation from PYTHIA, with a trigger pion of 6−10 GeV/c. Filled circles represent quantities calculated with PHENIX acceptance filter.

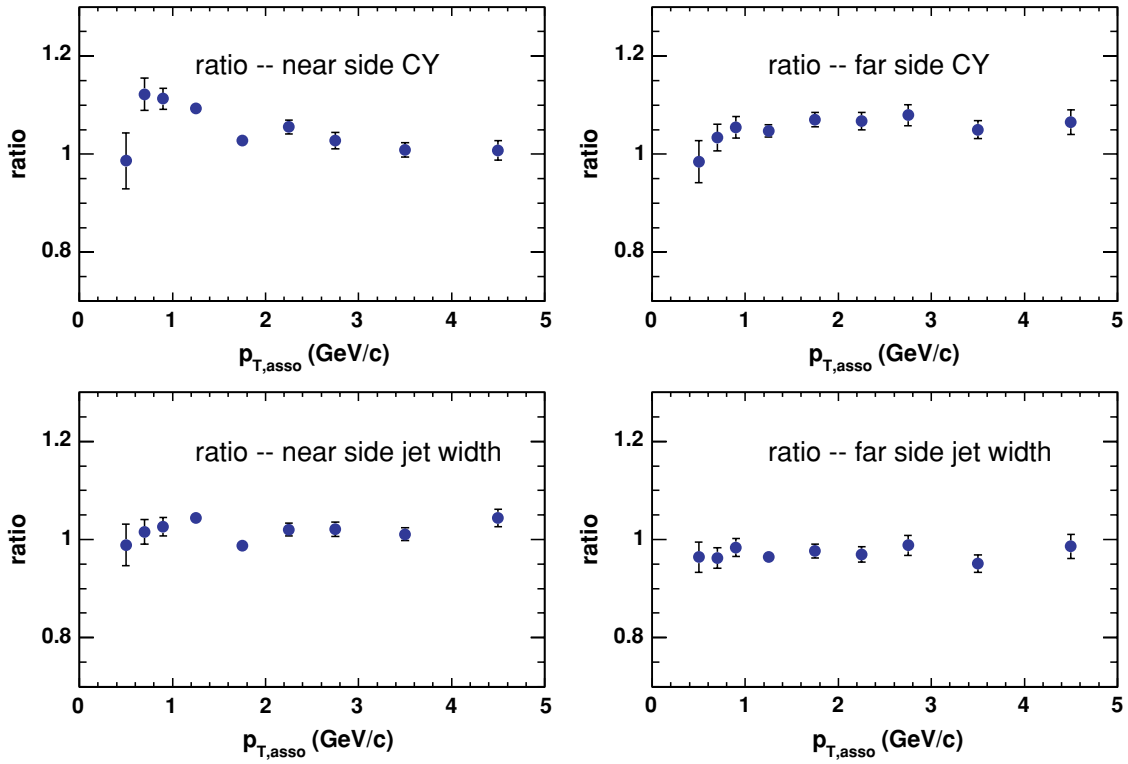

FIG. 11. (Color online) Ratio of the jet width or corrected yield obtained from the event-mixing method to those without the acceptance filter.

by the filled circles, while the expected yield or width are indicated with open circles.

The agreement between the two data sets can be better seen by plotting the ratios, which are shown in Fig. 11. The yields agree within 10% and the widths agree within 5%. Since $\sqrt{\langle j_T^2 \rangle}$, $\langle \sin^2(\phi_{jj}) \rangle$ are derived from the jet widths, the agreement in width naturally leads to the agreement in the $\sqrt{\langle j_T^2 \rangle}$ and $\langle \sin^2(\phi_{jj}) \rangle$. One notices that there are some systematic differences in the comparison of the yield at low $p_{T,\text{assoc}}$. This might indicate that the Gaussian assumption is not good enough when the jet width is wide and the extrapolation for $|\Delta\eta| > 0.7$ becomes sizable. (At $p_{T,\text{assoc}} = 0.5$ GeV/c, the jet width $\sigma_N = 0.5$ rad and the extrapolation is about 20%.)

The approximations in the formulas used to extract j_{T_y} and $\sin^2(\phi_{jj})$ are used to estimate the systematic error on these quantities. We estimate the systematic uncertainty in the formulation at the level of 5% for $\sqrt{\langle j_T^2 \rangle}$ and 3–4% for $\sqrt{\langle \sin^2(\phi_{jj}) \rangle}$.

Table III summarizes the systematic errors for the extracted widths $\sqrt{\langle j_T^2 \rangle}$ and $\sqrt{\langle \sin^2(\phi_{jj}) \rangle}$, while Tables IV, V, and VI summarize the list of systematic errors on the CY for the hadron-hadron, neutral pion-hadron, and charged pion-hadron correlations, respectively. Table VII outlines the systematic errors on the p_{out} extraction from pion-hadron correlations.

IV. RESULTS

We present the minimum-bias and centrality-dependent results on extracted jet widths and yields in Sec. IV A,

TABLE III. Summary of the systematic errors on the widths and j_T, $\langle \sin^2(\phi_{jj}) \rangle$.

which are used in Sec. IV B to calculate quantities describing the jet structures: the values of $\sqrt{\langle j_T^2 \rangle}$, $\langle \sin^2(\phi_{jj}) \rangle$, and jet fragmentation conditional yields dN/dp_T and dN/dx_E. The minimum-bias $d + \text{Au}$ results are compared with results from $p + p$ in Sec. IV C to establish the extent of effects due to medium modification in $d + \text{Au}$ with as much statistical precision as possible. The $d + \text{Au}$ centrality dependence of the derived quantities is presented in Sec. IV D. This provides a larger lever arm in nuclear thickness function, at the cost of dividing the available minimum-bias data into different centrality bins.

A. Correlation functions, widths, and yields

The baseline data from which jet structures are extracted are the correlation functions and conditional pair distributions that were defined in Sec. II. Figure 12 shows representative correlation functions between two charged hadrons, while Figs. 13 and 14 show representative conditional yield distributions triggered on neutral pions (π^0) and charged pions, respectively. All three correlation sets (Figs. 12–14) show relatively narrow peaks centered at $\Delta\phi = 0$ and π radians. The widths of these structures decrease with larger p_T, which is consistent with narrowing of the jet cone for increasing p_T. The fractional area under the jet peak relative to the flat underlying background also increases significantly as a function of associated-particle p_T, indicating increasing (di)jet

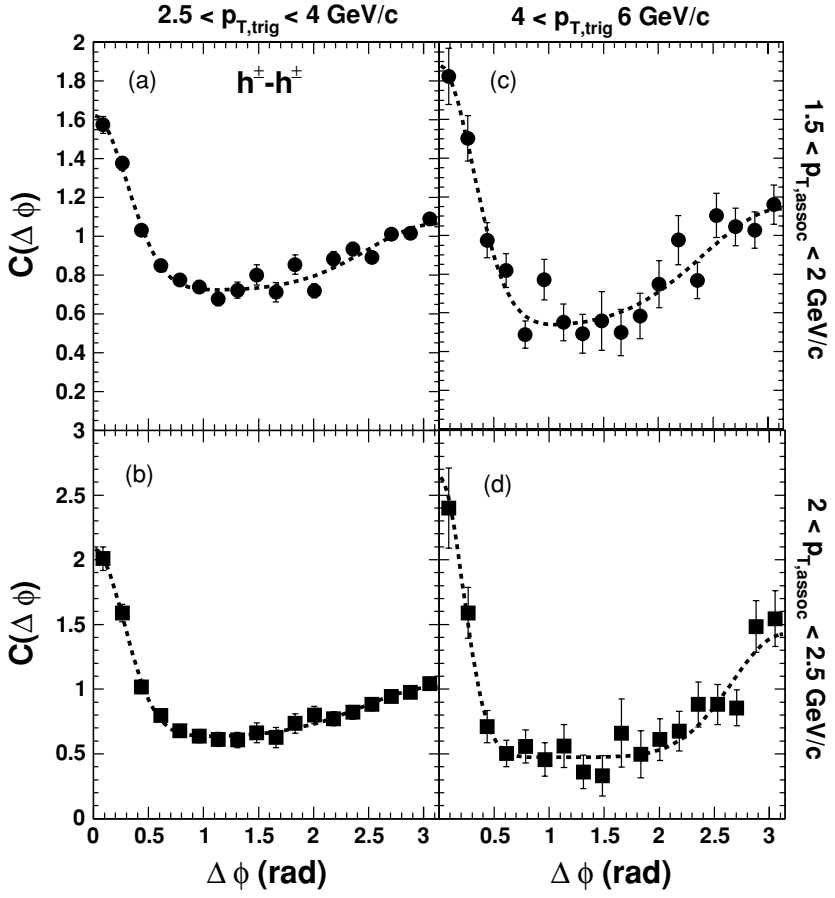

FIG. 12. Assorted $h^{\pm} - h^{\pm}$ correlation functions from $d + \text{Au}$ collisions for centrality 0–80% and several p_T cuts. Trigger p_T range is $2.5 < p_{T,\text{trig}} < 4.0$ GeV/c in (a) and (b) and $4.0 < p_{T,\text{trig}} < 6.0$ in (c) and (d). Associated hadron is in the range $1.5 < p_T < 2.0$ GeV/c or $2.0 < p_T < 2.5$ GeV/c. Correlations are for the centrality class 0−80%. Dashed line represents a fit to the correlation function using Eq. (37).

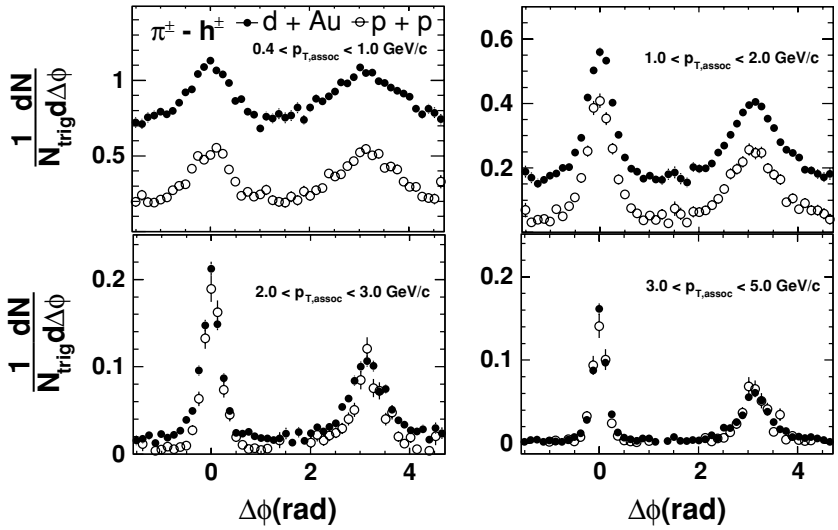

FIG. 13. Fully corrected assorted charged pion-hadron conditional pair distributions for $d+$Au collisions for centrality 0−88% and $p+p$ collisions. Trigger $\pi^{\pm}$ are within $5 < p_{T,\mathrm{trig}} < 10$ GeV/c and are correlated with hadrons with four $p_{T,\mathrm{assoc}}$ ranges as given in each plot.

contributions to the correlation function. In particular, Fig. 13 shows that for events where there is a high-p_T trigger, a large fraction of the low-p_T (as low as 0.4−1 GeV/c) particles are coming from the dijet fragmentation, and the jet contribution dominates at $p_T > 2$ GeV/c. Events tagged with a high-p_T jet are much harder than a typical minimum-bias event.

We characterize the jet correlations shown in Figs. 12–14 by assuming that there are only two contributions to the correlation function—(di)jet correlations and an isotropic underlying event. This scenario can then be expressed as

$$C(\Delta\phi) = A_o(1 + J(\Delta\phi)), \tag{36}$$

where A_o denotes the isotropic background and $J(\Delta\phi)$ is the jet function. Approximating the jet function as the sum of two Gaussians, we fit the correlations with

$$C(\Delta\phi) = A_o\left[1 + \frac{\lambda_N}{\sqrt{2\pi}\sigma_N}\exp\left(\frac{-\Delta\phi^2}{2\sigma_N^2}\right) + \frac{\lambda_F}{\sqrt{2\pi}\sigma_F} \times \exp\left(\frac{-(\Delta\phi-\pi)^2}{2\sigma_F^2}\right)\right]. \tag{37}$$

Here, $\lambda_{N,F}$ are the normalized Gaussian areas and $\sigma_{N,F}$ are the Gaussian widths for the near- and far-side jets, respectively. For the pair distribution functions, we fit with the same shaped function, but with a different normalization [Eq. (26)] as outlined in Sec. III B.

Figure 15 shows the associated-p_T dependence of the extracted widths for both the near- and far-side peaks[2] from the charged-hadron correlation functions with the trigger range for the charged hadron being 3−5 GeV/c. The data are tabulated in Table VIII.

In Fig. 16, we present the same quantities from the high-p_T identified pion correlations, where there is excellent agreement between the π^0 and charged-pion data sets. For both types of identified pions, the trigger p_T range is 5−10 GeV/c; these data are tabulated in Tables IX and X.

The far-side widths shown in Figs. 15 and 16 are larger than the near-side widths, as expected, since the far-side structure is a convolution of two jet fragmentations as well as any k_T of

[2]The results here are not sensitive to the slightly different range in centrality used.

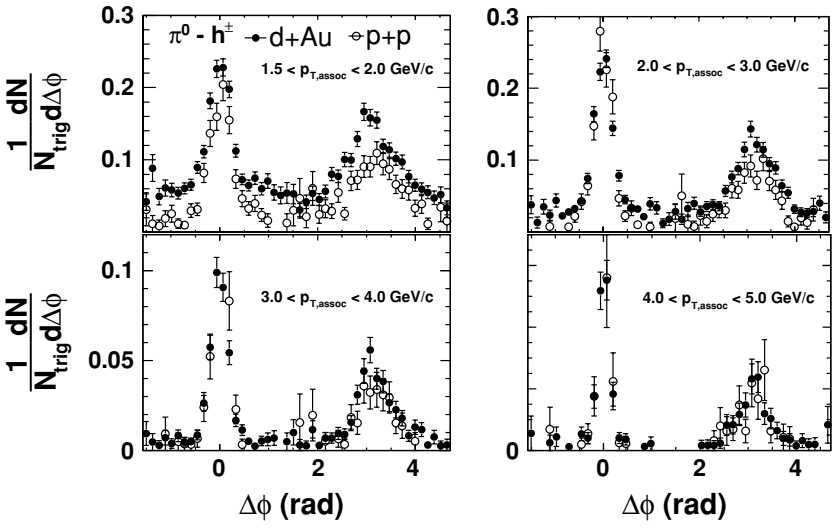

FIG. 14. Fully corrected assorted π^0-hadron conditional pair distributions for $d+$Au collisions for centrality 0−88% and $p+p$ collisions. Trigger π^0 are within $5 < p_{T,\mathrm{trig}} < 10$ GeV/c and are correlated with hadrons with four $p_{T,\mathrm{assoc}}$ ranges as given in each plot.

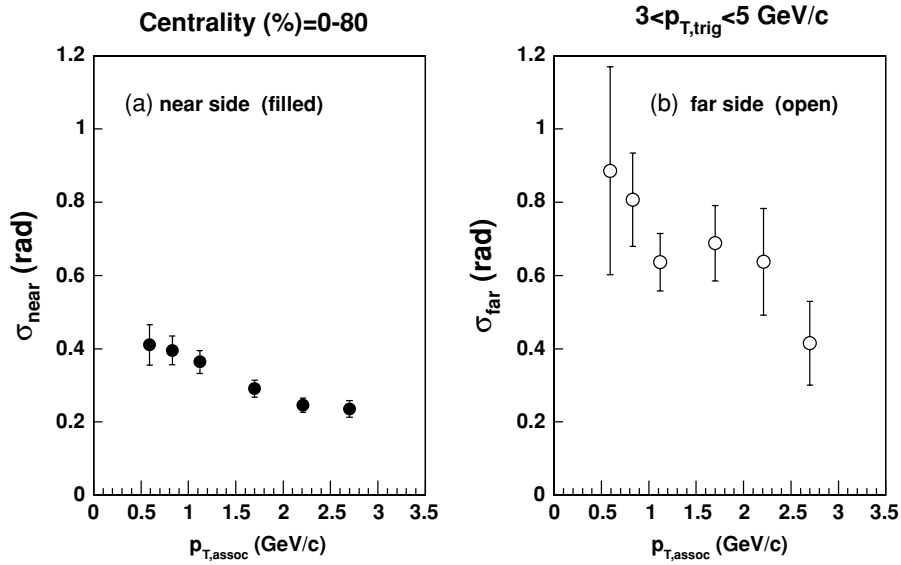

FIG. 15. Near- and far-side widths as a function of $p_{T,\mathrm{assoc}}$ for charged hadron azimuthal correlations from minimum-bias d + Au collisions (see text). Bars are statistical errors.

the scattered partons. The widths of the correlation functions also steadily decrease as a function of $p_{T,\mathrm{assoc}}$ as expected from (di)jet fragmentation. For completeness, we also tabulate the near- and far-side widths extracted as a function of $p_{T,\mathrm{trig}}$ for identified pions. These data are tabulated in Tables XI and XII.

Although the PHENIX single-particle acceptance is limited to $|\eta| < 0.35$, it can sample jet pairs in twice as large of a window in $\Delta\eta$ ($|\Delta\eta| < 0.7$) with varying pair efficiency. Similar to azimuthal correlation, the pair efficiency in $\Delta\eta$ can be estimated via mixed events and can subsequently be divided out [Eq. (21)]. Assuming that the underlying event is flat[3] in $|\Delta\eta| < 0.7$, we fix the background level to be equal to that in azimuthal correlation function Eq. (36) and subsequently extract the jet distribution as a function of $\Delta\eta$. In Fig. 17(a), we compare the near-side jet shape in $\Delta\phi$ and $\Delta\eta$ in the angular range of $|\Delta\phi, \Delta\eta| < 0.7$ for the $\pi^{\pm} - h^{\pm}$ correlation with $1.0 < p_{T,\mathrm{assoc}} < 2.0$ GeV/c. There is no significant difference

TABLE VIII. Near- and far-side widths as a function of $p_{T,\mathrm{assoc}}$ for charged hadron triggers (3−5 GeV/c) and associated charged hadrons from d + Au collisions.

$\langle p_{T,\mathrm{assoc}} \rangle$ (GeV/c)	σ_{near} (rad)	σ_{far} (rad)

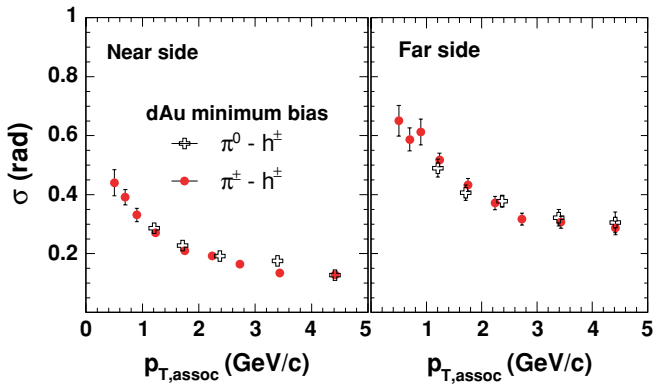

FIG. 16. (Color online) Near- and far-side widths as a function of $p_{T,\mathrm{assoc}}$ from pion-hadron azimuthal correlations for charged pion (closed symbols) and neutral pion (open symbols) triggers from the $p_{T,\mathrm{trig}}$ range of 5−10 GeV/c in minimum-bias d + Au collisions (see text). Bars are statistical errors.

[3] η dependence of the single-particle yield is very weak in $0 < |\eta| < 1$ [43]. Thus, the underlying pair distribution in $|\Delta\eta| < 0.7$ is almost flat.

in jet shape between $\Delta\eta$ and $\Delta\phi$, and the widths are consistent in both directions. Figure 17(b) shows the far-side jet shape in $\Delta\eta$; the associated pair distribution is flat within $\pm 10\%$.

Figure 18(a) shows the comparison of the near-side jet widths in $\Delta\phi$ and $\Delta\eta$ from d + Au. There is overall very good agreement between the two data sets. However, the width in $\Delta\eta$ is systematically lower than that in $\Delta\phi$ at small $p_{T,\mathrm{assoc}}$. This is because the underlying background is not completely flat in $\Delta\eta$, but varies by up to 10% in $|\Delta\eta| < 0.7$. Thus the procedure of dividing by the mixed-event distribution [Eq. (21)] introduces some distortion of the jet shape at large $\Delta\eta$ and consequently leads to a slightly different value for the jet width. In fact, for $p + p$ collisions, Fig. 18(b) indicates a similar discrepancy between $\Delta\phi$ and $\Delta\eta$ at small $p_{T,\mathrm{assoc}}$ for $p + p$ collisions. Thus this deviation is not likely due to the cold medium effect in d + Au.

We extract not only the widths of the jet structures but also the conditional yields of how many hadrons are in the near- and far-side structures for each high-p_T trigger. The conditional yield defined in Eq. (14) can be obtained from either a correlation function or conditional pair distribution, both of which produce identical results. For the conditional pair distributions, the conditional yield is directly extracted from the fit parameters [Eq. (26)]; for correlation functions, several normalization factors need to be applied to obtain the per-trigger yield [44, 45], as described below.

For correlation functions, it is convenient to define the fraction of jet-correlated particle pairs per event, $n_{\mathrm{jet\,pair}}/n_{\mathrm{total\,pair}}$. Following the basic ansatz outlined in Eq. (36), the fraction of jet-correlated particle pairs is obtained by summing the jet function over all bins in $\Delta\phi$ and dividing by the total sum of the correlation function such that

$$\frac{n_{\mathrm{jet\,pair}}}{n_{\mathrm{total\,pair}}} = \frac{\sum A_o J(\Delta\phi)}{\sum C(\Delta\phi)}. \tag{38}$$

Such pair fractions are shown as a function of $p_{T,\mathrm{assoc}}$ for a trigger hadron of $3.0 < p_T < 5.0$ GeV/c and a centrality selection of 0−80% in Fig. 19. The results, shown for both

TABLE XII. Same as Table XI, but for neutral pion triggers.

$\langle p_{T,\mathrm{trig}}\rangle$ (GeV/c)	σ_{near} (rad)	σ_{far} (rad)
5.39	0.207 ± 0.007	0.409 ± 0.025
6.40	0.151 ± 0.008	0.304 ± 0.034
7.66	0.144 ± 0.012	0.295 ± 0.035

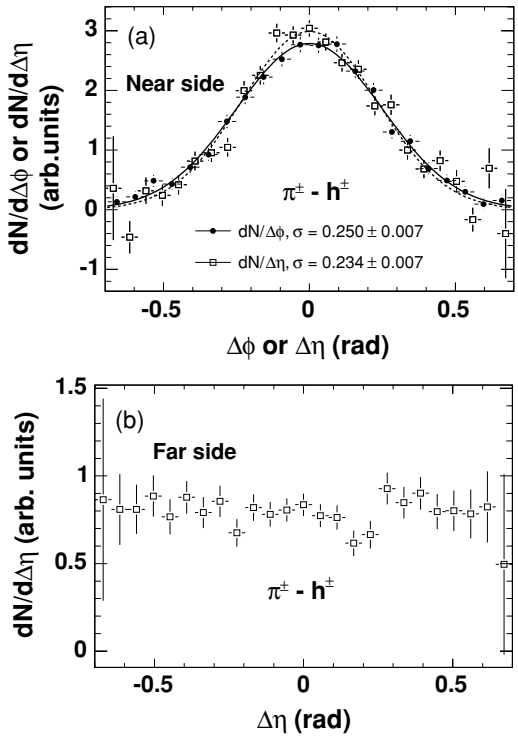

FIG. 17. Jet shapes in $\Delta\phi$ and $\Delta\eta$ from $\pi^{\pm} - h^{\pm}$ correlation with $5 < p_{T,\mathrm{trig}} < 10$ GeV/c and $1.0 < p_{T,\mathrm{assoc}} < 2.0$ GeV/c from minimum-bias d + Au collisions. (a) Near-side jet shape in $\Delta\phi$ and $\Delta\eta$. (b) Far-side jet shape in $\Delta\eta$.

the near- and far-side jets, indicate an increase in the average fraction of jet-correlated particle pairs with p_T as might be expected if jet fragmentation becomes the dominant particle production mechanism as p_T is increased.

The pair fraction is multiplied by the ratio $n_{\mathrm{pairs}}/n_{\mathrm{trig}}n_{\mathrm{assoc}}$ to obtain

$$\frac{n_{\mathrm{jet\,pair}}}{n_{\mathrm{trig}}n_{\mathrm{assoc}}} = \frac{n_{\mathrm{jet\,pair}}}{n_{\mathrm{total\,pair}}} \times \frac{n_{\mathrm{pairs}}}{n_{\mathrm{trig}}n_{\mathrm{assoc}}}, \tag{39}$$

where n_{pairs} denotes the average number of detected particle pairs per event, and n_{trig} and n_{assoc} are the detected

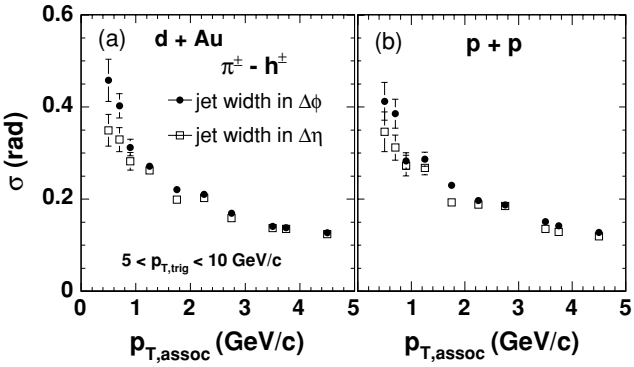

FIG. 18. Comparison of jet widths as function of $p_{T,\mathrm{assoc}}$ in $\Delta\phi$ and $\Delta\eta$ from $\pi^{\pm} - h^{\pm}$ correlation with $5 < p_{T,\mathrm{trig}} < 10$ GeV/c. (a) Results for d + Au. (b) Results for $p + p$. Bars are statistical errors.

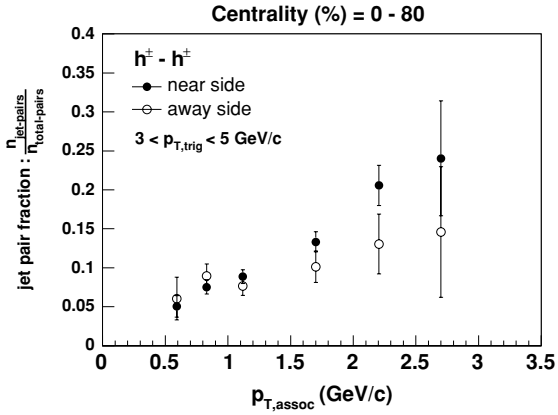

FIG. 19. Average jet pair fraction per event as a function of $p_{T,\mathrm{assoc}}$. Results are shown for the trigger hadron selection $3.0 < p_T < 5.0$ GeV/c from $d+$Au collisions and a centrality of 0−80%. Bars are statistical errors.

single-particle yields per event for trigger and associated particles, respectively. This gives the average number of jet-correlated pairs per event over the combinatoric background $n_{\mathrm{jet\,pair}}/n_{\mathrm{trig}}n_{\mathrm{assoc}}$. The conditional per-trigger yield, $n_{\mathrm{jet\,pair}}/n_{\mathrm{trig}}$, is obtained via multiplication by the efficiency corrected single-particle yield $n_{\mathrm{assoc}}^{\mathrm{eff\text{-}corr.}}$ for the selected associated p_T bin of interest;

$$\frac{n_{\mathrm{jet\,pair}}}{n_{\mathrm{trig}}} = \frac{n_{\mathrm{jet\,pair}}}{n_{\mathrm{trig}}n_{\mathrm{assoc}}} \times n_{\mathrm{assoc}}^{\mathrm{eff\text{-}corr.}}. \tag{40}$$

The per-trigger yields for hadron triggers [found using Eq. (40)] are corrected for the azimuthal acceptance and tracking efficiency but are reported within the PHENIX η acceptance for the central arms, i.e., no $R(\Delta\eta)$ correction is applied to the hadron-triggered conditional yields.

Figure 20 plots the near- and far-side invariant conditional yields extracted via Eq. (40) for different trigger p_T selections as indicated. An approximate exponential decrease with p_T is observed, i.e., there are more low-p_T particles associated with each high-p_T trigger hadron. The data are tabulated in Tables XIII and XIV.

In Fig. 21, the conditional yields for identified pion triggers are plotted as a function of $p_{T,\mathrm{assoc}}$ for both near- and far-side correlations. For this high-p_T data, the conditional yields are extracted from the fits to the data in Figs. 13 and 14 using Eq. (26), then corrected for pair efficiency in $\Delta\eta$ using Eqs. (24) and (25). The conditional yields are tabulated in Tables XV and XVI.

TABLE XIII. Near- and far-side conditional yields as a function of $p_{T,\mathrm{assoc}}$ for charged hadron triggers (2.5−4 GeV/c) and associated charged hadrons from $d+$Au collisions.

2.205	0.042 ± 0.006	0.028 ± 0.009

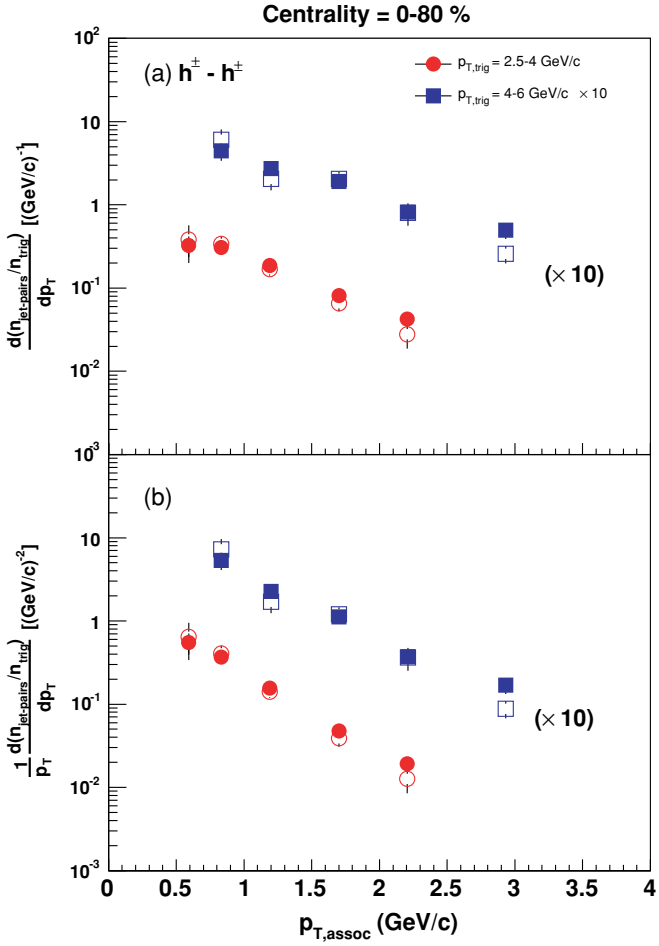

FIG. 20. (Color online) Per-trigger yield (a) and invariant conditional yield (b) as a function of $p_{T,\mathrm{assoc}}$ for the trigger hadron ranges shown. Closed points are the near-side yields; open points are the far-side yields. Centrality range is 0−80% in $d+$Au collisions. Yields are corrected for efficiency and reported in the PHENIX η acceptance. Bars are statistical errors.

The agreement between the two pion-triggered data sets is good, which indicates that the jet fragmentation function is independent of whether a neutral pion or a charged pion trigger is used. The difference in the magnitudes of the far- and near-side yields reflects the fact that the far-side correlation measure a hadron triggered effective fragmentation while the near-side correlation measures dihadron fragmentation.

The conditional yields presented in Figs. 20 and 21 can be considered as the basic information, whereas the near and far

TABLE XIV. Same as Table XIII, but for charged hadron triggers (4−6 GeV/c).

$\langle p_{T,\mathrm{assoc}}\rangle$ (GeV/c)	dN/dp_T^{near}	dN/dp_T^{far}

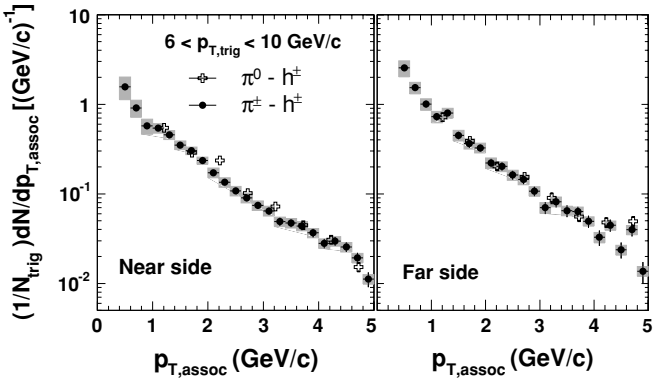

FIG. 21. Conditional yield as function of $p_{T,\mathrm{assoc}}$ for near- and far-side correlations from minimum-bias $d+$ Au collisions. Bars are statistical errors. Shaded boxes represent the total systematic error on each point.

dN/dx_E distributions in Sec. IV B have a closer relationship to parton fragmentation functions, as described in Sec. II.

Since multiple scattering should increase with centrality, we examine whether these jet characteristics exhibit any centrality dependence. Figure 22 reports on widths and conditional yields in the PHENIX η acceptance for dihadron correlations with a trigger hadron in the range $2.5 < p_{T,\mathrm{trig}} < 4$ GeV/c. The data are tabulated in Tables XVII and XVIII. Centrality-dependent widths for the $\pi^0 - h^{\pm}$ correlations are shown in Fig. 23 for a mean $\pi^0 p_T$ of approximately 5.4 GeV/c. The data for the widths are tabulated in Table XIX, while the yields can be found in Table XX.

Neither the widths nor the per-trigger yields change significantly with centrality, indicating that the influence of multiple scattering on jet properties is small in this region. This work is extended in Sec. IV D, where we present the centrality dependence of various jet-structure observables.

TABLE XV. Near- and far-side conditional yields as a function of $p_{T,\mathrm{assoc}}$ for charged pion triggers (5−10 GeV/c) and associated charged hadrons from minimum-bias $d+$ Au collisions.

$\langle p_{T,\mathrm{assoc}}\rangle$ (GeV/c)	dN/dp_T^{near}	dN/dp_T^{far}

40−80%	0.325 ± 0.018	0.628 ± 0.070

B. Jet properties in minimum-bias d + Au collisions

From the angular widths and yields discussed in the previous section, we calculate the following quantities that characterize the jet structures: transverse momentum of hadrons with respect to the jet (j_T), the dijet acoplanarity $\langle \sin^2(\phi_{jj}) \rangle$, and the dN/dx_E distributions. These quantities are first presented for minimum-bias d + Au collisions, which have the highest statistical precision, and are then compared with results from $p + p$ in Sec. IV C.

Figure 24 shows the compilation of $\sqrt{\langle j_T^2 \rangle}$ values extracted from $\pi^0 - h$ and $\pi^\pm - h$ correlations, and assorted-p_T and fixed-p_T correlation results for $h - h$ at low p_T. The $\sqrt{\langle j_T^2 \rangle}$ values were calculated using Eq. (7). The systematic errors are mainly due to the uncertainties of Eq. (7) and the fitting procedure, which are about 5% (independent of p_T) and are approximately the same for all four analyses. The $\sqrt{\langle j_T^2 \rangle}$ values for $\pi^\pm - h$ and $\pi^0 - h$ indicate a steady increase at p_T below 2 GeV/c followed by a saturation around 560−640 MeV/c at $p_T > 2$ GeV/c. The initial increase is due to the seagull effect [46,47]. The approximately constant behavior of $\sqrt{\langle j_T^2 \rangle}$ above 2 GeV/c is consistent with the scaling behavior of the fragmentation functions. The $\sqrt{\langle j_T^2 \rangle}$ results from the $h - h$ correlation analyses have a similar increase and saturation behavior. They seem to reach a slightly higher plateau value at a lower p_T (around 1.5 GeV/c).

A combined fit based on $\sqrt{\langle j_T^2 \rangle}$ data points at $p_T > 2$ GeV/c gives a plateau value of $\sqrt{\langle j_T^2 \rangle} = 0.64 \pm 0.02(\text{stat}) \pm 0.04(\text{sys})$ GeV/c for minimum-bias d + Au collisions.

TABLE XVIII. Same as Table XVII, but for near- and far-side conditional yields.

0–20%	0.199 ± 0.009	0.387 ± 0.024
20–40%	0.195 ± 0.009	0.401 ± 0.031
40–88%	0.190 ± 0.008	0.376 ± 0.024

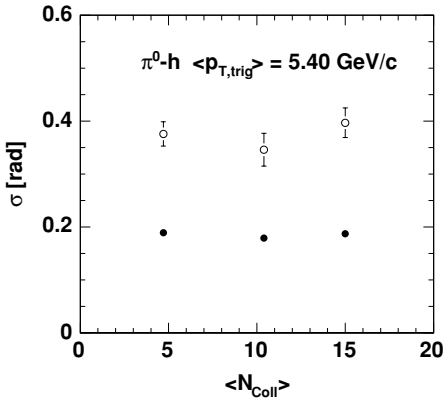

FIG. 23. Near- and far-side widths for several centrality selections from d + Au collisions. Results are shown for $\pi^0 - h$ correlations with the trigger π^0 $5 < p_T < 10$ GeV/c and the associated p_T range of $2 < p_T < 3$ GeV/c. Bars are statistical errors.

A key quantity that provides information on multiple scattering in the cold nuclear medium is $\langle \sin^2(\phi_{jj}) \rangle$, where ϕ_{jj} is the azimuthal angle between the jet axes. As described in Sec. II, we calculate $\langle \sin^2 \phi_{jj} \rangle$ from the experimental values of the near- and far-side widths [Eq. (13)]. Figure 25 shows $\langle \sin^2 \phi_{jj} \rangle$ as function of $p_{T,assoc}$ for high-p_T pion triggers. We observe that the rms of the sine of the angle between the jet axes, $\langle \sin^2 \phi_{jj} \rangle$, decreases as higher-$p_T$ associated particles are selected. There is good agreement between the two data sets. Figure 26 plots $\langle \sin^2 \phi_{jj} \rangle$ as a function of $p_{T,trig}$, where a similar decrease with p_T is observed.

In the next section we will calculate the quadrature difference $\langle \sin^2 \phi_{jj} \rangle$ between d + Au and $p + p$ collisions and use that to quantify the affect of additional final-state scattering in d + Au collisions.

In Sec. II we defined the near and far-side p_{out}. With this observable, it is possible to move beyond calculating means or rms values, and hence the p_{out} distribution potentially carries more information about the dijet acoplanarity. The measured p_{out} distributions for $\pi^\pm - h^\pm$ are shown in Fig. 27 for the near and far sides. The far-side p_{out} has a broader distribution than the near-side p_{out}, reflecting the fact that k_T is larger than j_T. The p_{out} distributions have a power law tail, possibly due to strong radiative processes driving large values of p_{out}.

In Sec. IV A we reported the yields of associated hadrons per trigger particle, or the conditional yield. A more comprehensive way of quantifying the fragmentation function is to plot the conditional yields as a function of x_E. This is shown in Fig. 28 for $\pi^\pm - h$ and $\pi^0 - h$.

TABLE XX. Same as Table XIX, but for near- and far-side conditional yields.

Centrality	dN/dp_T^{near}	dN/dp_T^{far}
0–20%	0.0816 ± 0.0037	0.116 ± 0.008
20–40%	0.0947 ± 0.0045	0.141 ± 0.011
40–88%	0.0967 ± 0.0043	0.144 ± 0.009

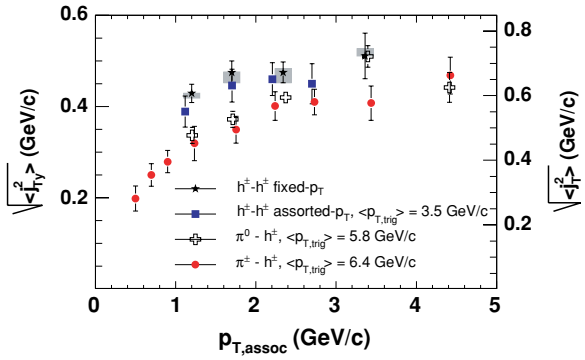

FIG. 24. (Color online) Extracted $\sqrt{\langle j_T^2 \rangle}$ for minimum-bias d + Au collisions from all four dihadron correlations. Trigger p_T ranges are 3–5, 5–10, and 5–10 GeV/c, respectively, for $h^{\pm} - h^{\pm}$, $\pi^0 - h^{\pm}$, and $\pi^{\pm} - h^{\pm}$ assorted-p_T correlations. Statistical and systematic errors are combined for the assorted-p_T correlations; the fixed-p_T correlation shows the systematic error separately as shaded boxes.

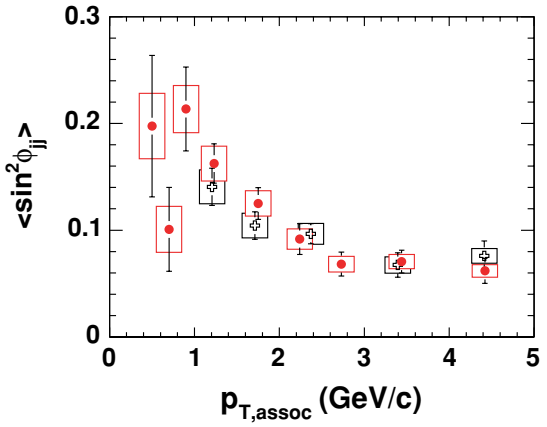

FIG. 25. (Color online) $\langle \sin^2 \phi_{jj} \rangle$ for minimum-bias d + Au collisions as function of associated particle p_T for $\pi^{\pm} - h^{\pm}$ (filled circles) and $\pi^0 - h^{\pm}$ (open crosses) correlations where the trigger particles have a p_T between 5 and 10 GeV/c. Data points are plotted at the mean $p_{T,\mathrm{assoc}}$. Bars are statistical errors. Boxes represent the total systematic error on each point.

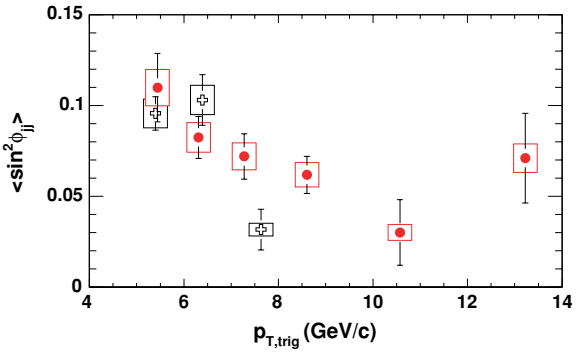

FIG. 26. (Color online) Same as Fig. 25, but as function of trigger particle p_T.

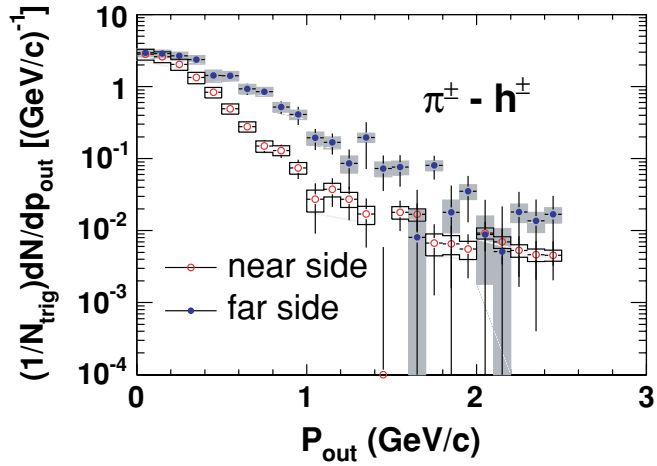

FIG. 27. (Color online) Near- and far-side p_{out} distributions for minimum-bias d + Au collisions obtained from $\pi^{\pm} - h^{\pm}$ correlation. The trigger is $5 < p_{T,\mathrm{trig}} < 10$ GeV/c, the associated particle is $0.5 < p_{T,\mathrm{assoc}} < 5.0$ GeV/c. Bars are statistical errors. Boxes represent the total systematic error on each point.

Previously, in ISR experiments, the slope of the x_E distribution had been determined to be around 5.3 [26]. In Fig. 29, the conditional yields as a function of x_E are plotted for the trigger p_T range of 5–6 GeV/c. In order to compare data with the previous ISR results, we determine the exponential inverse slope for $0.3 < x_E < 0.7$ and obtain the inverse slope parameter of 6.0 ± 0.3 in the near side and 7.1 ± 0.5 in the far side. The near-side x_E inverse slope is smaller than that for the far side, reflecting the difference between dihadron fragmentation and single hadron fragmentation. By requiring a trigger particle on the near side, one reduces the jet energy available for fragmenting to the second hadrons, and consequently a smaller inverse slope occurs for the near side. Note, however, that the x_E distributions do not have pure exponential shape, and the fitted inverse slope is sensitive to the fitting ranges.

It is well known that fragmentation functions $D(z)$ approximately scale in e^+e^- or $p + p$ collisions, i.e., they are

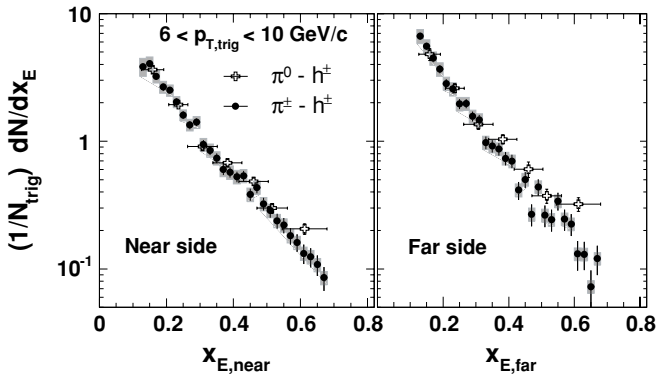

FIG. 28. Conditional yield as a function of x_E for near- and far sides for $\pi^{\pm} - h^{\pm}$ and $\pi^0 - h^{\pm}$ from minimum-bias d + Au collisions. Bars are statistical errors. Boxes represent the total systematic error on each point.

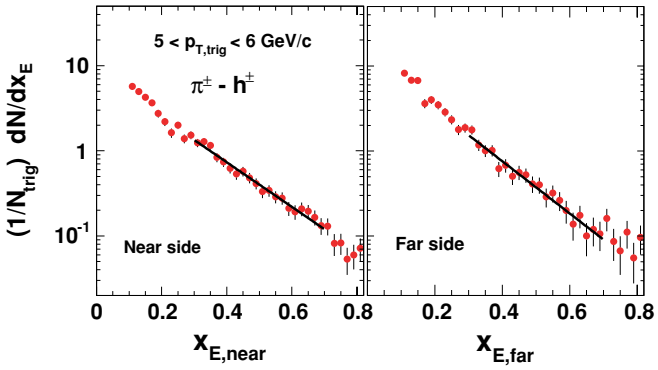

FIG. 29. (Color online) Conditional yield as a function of x_E for near- and far-side correlations for $\pi^{\pm} - h^{\pm}$ correlations from minimum-bias d + Au collisions. Trigger pions are $5 < p_{T,\mathrm{trig}} < 6$ GeV/c, and the black lines are fits to an exponential function for $0.3 < x_E < 0.7$. Bars are statistical errors.

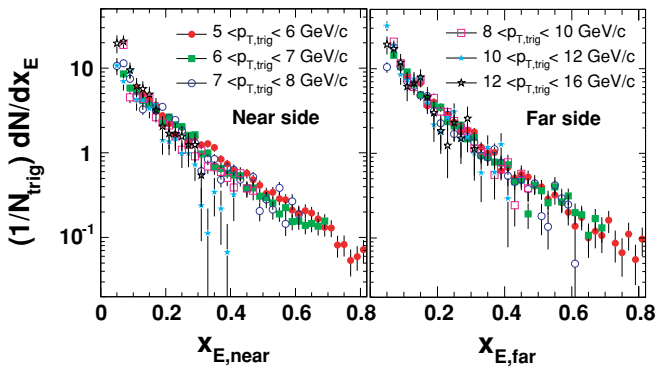

FIG. 30. (Color online) Conditional yield as a function of x_E for near- and far-side correlations for $\pi^{\pm} - h^{\pm}$ correlations for several different trigger p_T's for minimum-bias d + Au collisions. Bars are statistical errors.

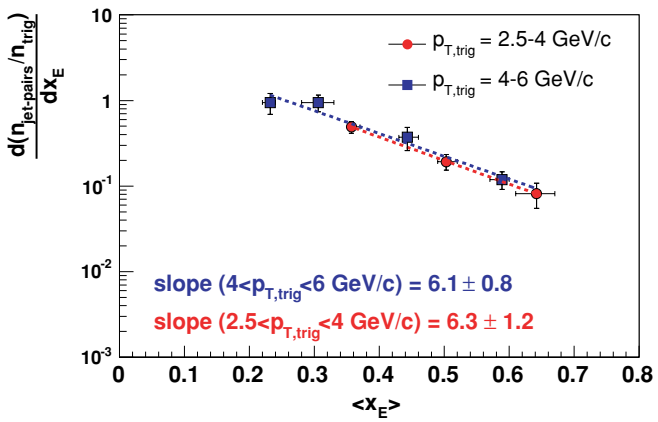

FIG. 31. (Color online) Conditional yield as a a function of $\langle x_E \rangle$ for the far-side $h - h$ correlations for two trigger p_T ranges. Dashed lines are exponential fits to the data. Bars are statistical errors.

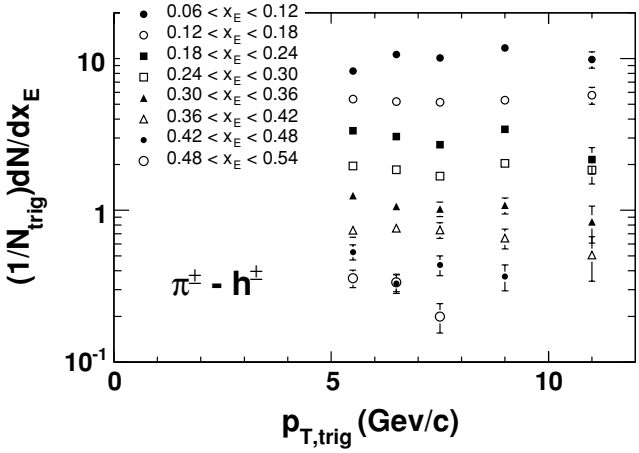

FIG. 32. Far-side conditional yield as a function of $p_{T,\mathrm{trig}}$ for different ranges of x_E for $\pi^{\pm} - h^{\pm}$ correlation for minimum-bias d + Au collisions. Bars are statistical errors.

independent of jet energy. To check whether this is still true in d + Au collisions, we plot in Fig. 30 the conditional yield as a function of x_E for different ranges of trigger p_T from $\pi^{\pm} - h^{\pm}$ correlations. All curves fall on top of each other, indicating a universal behavior of the jet fragmentation function.

At lower p_T, we have x_E distributions from the $h - h$ correlations. In Fig. 31, far-side conditional yields as obtained from charged hadron correlation functions are plotted versus $\langle x_E \rangle$. Here, $\langle x_E \rangle$ has been calculated from the $\langle p_{T,\mathrm{trig}} \rangle$, $\langle p_{T,\mathrm{assoc}} \rangle$ and extracted angular widths. Results are shown for two trigger p_T ranges, $2.5 < p_{T,\mathrm{trig}} < 4$ GeV/c and $4 < p_{T,\mathrm{trig}} < 6$ GeV/c, respectively. The slopes extracted are 6.3 ± 1.2 for the lower trigger p_T range and 6.1 ± 0.8 for the higher trigger p_T window. Within the statistics of the charged hadron data set, we do not observe a strong sensitivity of the slope of the x_E distributions to the trigger p_T.

A direct way of quantifying the scale dependence of the x_E distribution is to plot the far-side conditional yields versus $p_{T,\mathrm{trig}}$ for a fixed range of x_E. This is shown in Fig. 32, where the conditional yields are found to be independent of $p_{T,\mathrm{trig}}$, i.e., there is no significant deviation from scaling. We will quantify any scaling violation in these data when we compare these x_E distributions from d + Au to distributions from $p + p$ collisions in Sec. IV C.

C. Comparison between d + Au and $p + p$

As discussed in Sec. I, multiple scattering in the cold nuclear medium may broaden the far-side correlation and possibly modify the fragmentation properties. In the previous section, we presented the measured jet structures from minimum-bias d + Au collisions. In this section, we compare that data to results from $p + p$ collisions. The goal is to establish the extent to which the nuclear medium modifies the properties of jets.

Figure 33 compares the extracted $\sqrt{\langle j_T^2 \rangle}$ values as functions of $p_{T,\mathrm{assoc}}$ from d + Au and $p + p$ collisions. The $\sqrt{\langle j_T^2 \rangle}$ values show no change from $p + p$ to d + Au collisions.

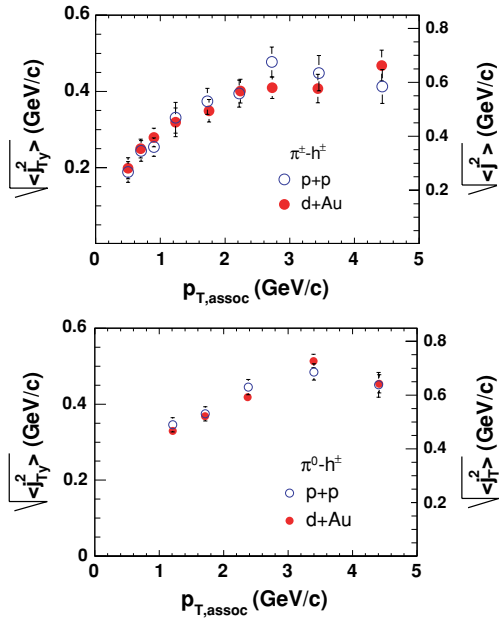

FIG. 33. (Color online) Comparison of $\sqrt{\langle j_T^2 \rangle}$ values between $d+$ Au and $p+p$ for $\pi^{\pm}-h^{\pm}$ and $\pi^0-h^{\pm}$ correlations. Trigger pion range is 5–10 GeV/c. Bars are statistical errors. Systematic errors are given in Table III.

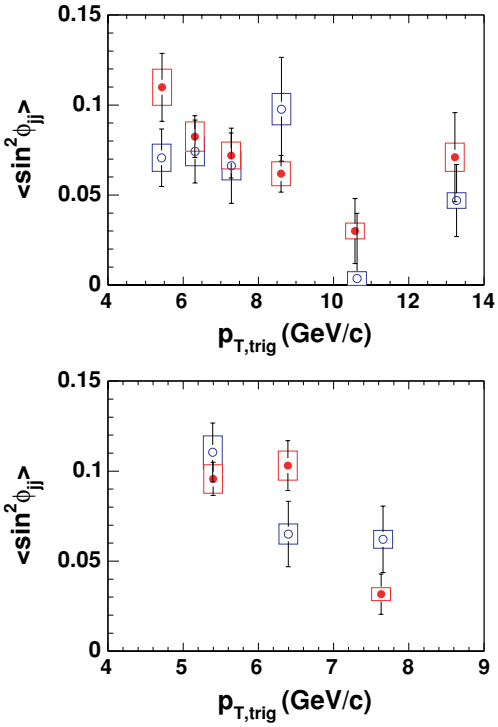

FIG. 34. (Color online) Comparison of $\langle \sin^2(\phi_{jj}) \rangle$ values between $d+$ Au (filled circles) and $p+p$ (open circles) for $\pi^{\pm}-h^{\pm}$ correlations (top panel) and $\pi^0-h^{\pm}$ correlations (lower panel). Associated hadron range is $2 < p_{T,\mathrm{assoc}} < 4.5$ GeV/c for the charged pion triggers and $2.5 < p_{T,\mathrm{assoc}} < 5$ GeV/c for the neutral pions. Bars are statistical errors. Boxes represent the total systematic error on each point.

Similarly, the $\langle \sin^2(\phi_{jj}) \rangle$ values shown in Fig. 34 for $d+$ Au are comparable to those from $p+p$ within errors, although the values from $d+$ Au collisions are systematically higher for $\pi^{\pm}-h^{\pm}$. Since there is no strong difference between the $d+$Au and $p+p$ results, there is little indication for increased multiple scattering in the $d+$ Au final state.

Any additional radiation can be quantified by calculating the point-by-point quadrature difference in $\langle \sin^2 \phi_{jj} \rangle$ between $d+$ Au and $p+p$ collisions. As shown in Fig. 35, this difference is consistent with zero. The average value for π^0-h is $\Delta\langle \sin^2 \phi_{jj} \rangle = -0.005 \pm 0.012(\mathrm{stat}) \pm 0.003(\mathrm{sys})$; for $\pi^{\pm}-h$, $\Delta\langle \sin^2 \phi_{jj} \rangle = 0.011 \pm 0.011(\mathrm{stat}) \pm 0.010(\mathrm{sys})$. Combining the two data sets, we find $\Delta\langle \sin^2 \phi_{jj} \rangle = +0.004 \pm 0.008(\mathrm{stat}) \pm 0.009(\mathrm{sys})$.

Figure 36 shows the comparison of the p_{out} distribution between central $d+$Au and $p+p$ from $\pi^{\pm}-h^{\pm}$ correlations; no apparent differences are observed in either the near or far side. This is consistent with the observation that both $\sqrt{\langle j_T^2 \rangle}$ and $\langle \sin^2 \phi_{jj} \rangle$ are similar between $d+$ Au and $p+p$.

A second set of comparisons between $d+$ Au and $p+p$ collisions is the number of hadrons in the near- and far-angle jet structures associated with a high-p_T trigger. Figure 37 shows the comparison of the conditional yield as function of x_E and no apparent difference between $d+$ Au and $p+p$ collisions is observed for either the near or far side.

In the previous section, we examined the level of scaling violations in the far-side dN/dx_E distribution for $d+$ Au collisions by plotting different x_E ranges as a function of $p_{T,\mathrm{trig}}$ (Fig. 32). The comparable plot for $p+p$ collisions is shown in Fig. 38. For both $d+$ Au and $p+p$ collisions, the amount of scaling violations, i.e., the dependence of dN/dx_E on $p_{T,\mathrm{trig}}$, can be quantified by fitting the data in each x_E range with a straight line as a function of $p_{T,\mathrm{trig}}$, that is,

$$\frac{dN}{dx_E} = \frac{dN}{dx_{E\,0}}(1+\beta p_T). \tag{41}$$

The fitted slopes β represent the fractional change in dN/dx_E per GeV/c and are shown in Fig. 39. For the $d+$ Au data,

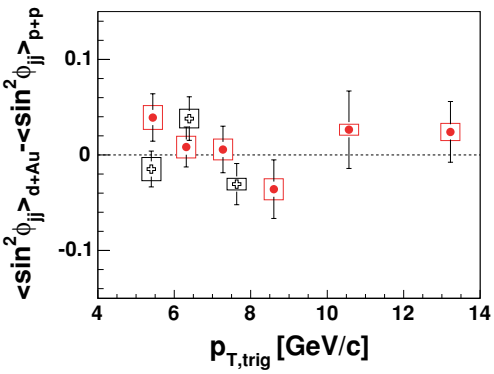

FIG. 35. (Color online) Quadrature difference between minimum-bias $d+$ Au and $p+p$ $\langle \sin^2 \phi_{jj} \rangle$ values. Closed circles are $\pi^{\pm}-h$ values and the open circles are π^0-h values. Bars are statistical errors. Boxes represent the total systematic error on each point.

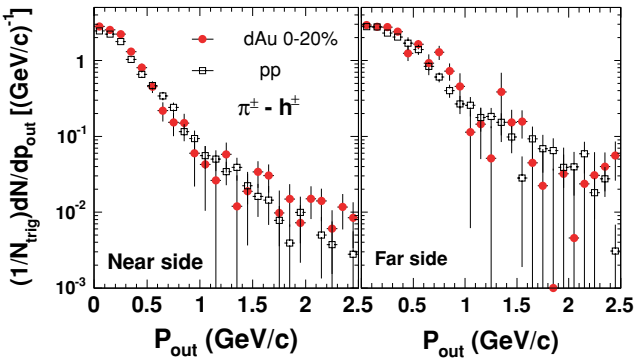

FIG. 36. (Color online) Comparison of the $p_{\rm out}$ distribution at the near and far sides between central $d+$Au collisions and $p+p$ collisions. Results are obtained for $\pi^{\pm}-h^{\pm}$ correlations with the associated hadron range $0.5 < p_{T,\rm assoc} < 5$ GeV/c and trigger pion range of $5 < p_{T,\rm trig} < 10$ GeV/c. Bars are statistical errors.

β is consistent with zero, i.e., there is no significant scaling violation across the whole x_E range, while there may be a slight scaling violation at high x_E for the $p+p$ data. On a point-by-point basis, there is no systematic difference between the $d+$Au and $p+p$ data.

Taken as a whole, all the results presented in this section indicate that the presence of the cold nuclear medium causes no significant change in jet fragmentation between $d+$Au and $p+p$ collisions. In addition, no strong evidence supports an increase in $\langle\sin^2(\phi_{jj})\rangle$ due to multiple scattering in the Au nucleus. Using the minimum-bias $d+$Au data has the advantage of the highest statistical precision. In the next section, we examine whether there is any change in jet structures as a function of collision centrality in $d+$Au, i.e., we split the statistics into a few centrality classes to increase the lever arm of the nuclear thickness function.

D. Centrality dependence

As discussed in Sec. I, $\langle\sin^2(\phi_{jj})\rangle$ is expected to increase as $d+$Au collisions become more central because of increased multiple scattering. Models of multiple scattering [12] predict that the increase in $\langle k_T^2\rangle$ is proportional to $T_A(b)$, the nuclear

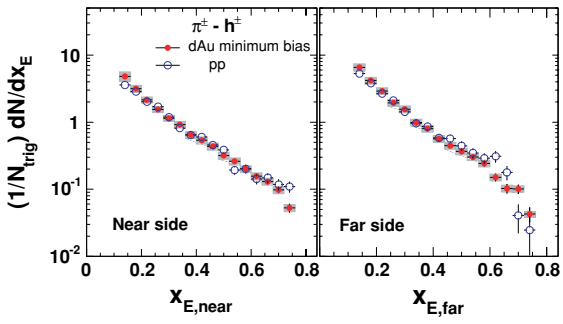

FIG. 37. (Color online) Comparison of the x_E distribution from $\pi^{\pm}-h^{\pm}$ correlations at the near and far sides between minimum-bias $d+$Au collisions and $p+p$ collisions. Triggers are $\pi^{\pm}$ from 5−10 GeV/c. Bars are statistical errors. Boxes represent the total systematic error on each point.

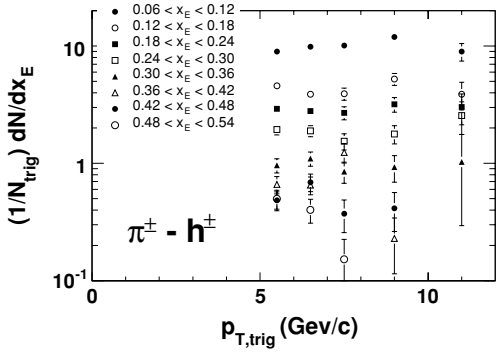

FIG. 38. Far-side conditional yield as function of $p_{T,\rm trig}$ for different ranges of x_E from $p+p$ collisions; triggers are $\pi^{\pm}$ from 5−10 GeV/c. Bars are statistical errors.

thickness function. We are not aware of predictions of how $\langle\sin^2(\phi_{jj})\rangle$ will change with centrality, but note that any increase in $\langle k_T^2\rangle$ will also increase $\langle\sin^2(\phi_{jj})\rangle$.

To probe this physics, we measured angular correlations in three centrality bins for $d+$Au collisions (0–20%, 20–40%, and 40–88%) to extract angular widths of the jet structures and hence $\sqrt{\langle j_T^2\rangle}$ and $\langle\sin^2(\phi_{jj})\rangle$. Figure 40 shows the independent data sets of $\langle\sin^2(\phi_{jj})\rangle$ including results from $p+p$ collisions and the three centrality classes from $d+$Au collisions.

All the $\langle\sin^2(\phi_{jj})\rangle$ data in Fig. 40 have been simultaneously fit with the following linear equation in $T_A(b)$:

$$\langle\sin^2(\phi_{jj})\rangle = \langle\sin^2(\phi_{jj})\rangle_0(1 + a_{\rm frac}T_A(b)). \qquad (42)$$

The slope parameter $a_{\rm frac}$ is assumed to be common to all data sets, while the pre-factors $\langle\sin^2(\phi_{jj})\rangle_0$ depend on the p_T of the trigger and associated particles. The extracted slope $a_{\rm frac} = -0.01 \pm 0.40$ mb with χ-squared per degree of freedom, $\chi^2/\nu = 27/22$. This slope is consistent with zero; i.e., we do not observe any significant increase in $\langle\sin^2(\phi_{jj})\rangle$ with centrality.

This can be compared to predictions from Hwa and Yang [16], who assume no increase in k_T with centrality to reproduce the Cronin effect data at RHIC, and Qiu and Vitev [14], who calculate

$$\langle k_T^2\rangle_{\rm dijet} = 2\langle k_T^2\rangle_{\rm vac} + \frac{0.72}{T_{A\,\rm minbias}}T_A(b). \qquad (43)$$

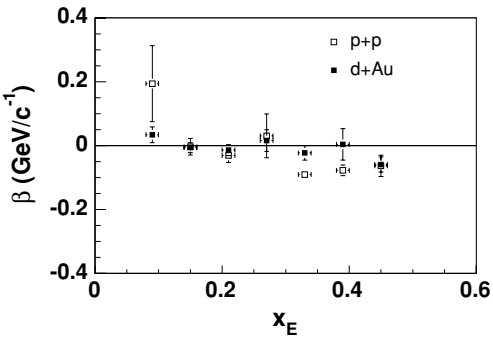

FIG. 39. Fitted fractional change in dN/dx_E per unit $p_{T,\rm trig}$ [β in Eq. (41)] of the far-side conditional yield for different ranges of x_E. Bars are statistical errors.

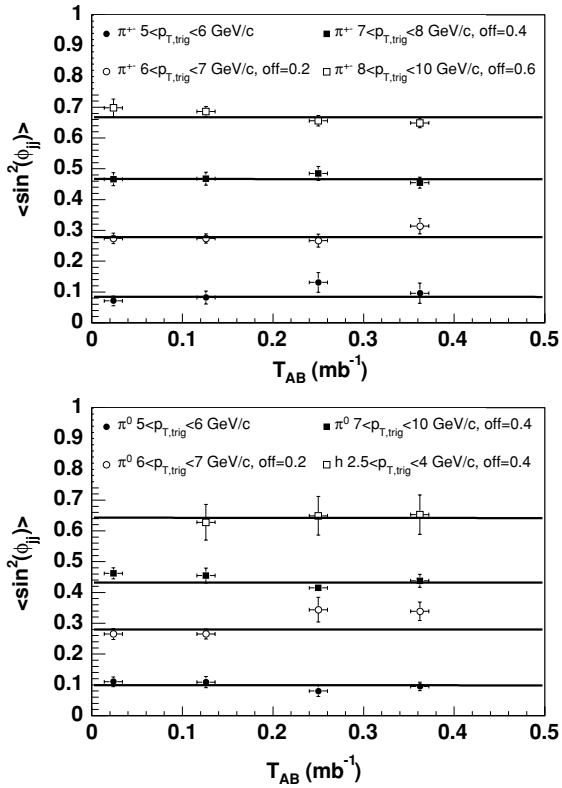

FIG. 40. Measured values of $\langle \sin^2(\phi_{jj})\rangle$ as a function of the nuclear thickness function $T_A(b)$. Left-most points are from $p+p$ collisions; other points are from the three centrality classes in $d+$Au collisions. Data sets are offset as indicated for clarity. Top plot shows data for $\pi^{\pm}$; bottom plot, for π^0 and hadron triggered data. Lines are a simultaneous fit to all the data with Eq. (42) to extract a common fractional increase in $\langle \sin^2(\phi_{jj})\rangle$ with $T_A(b)$. Bars are statistical errors.

To gain some insight into the magnitude of Qiu and Vitev's predicted effect compared to our experimental results, we recast Eq. (43) into the same form as Eq. (42).

$$\langle k_T^2\rangle_{\rm dijet} = 2\langle k_T^2\rangle_{\rm vac}\left(1+\frac{0.72}{2\langle k_T^2\rangle_{\rm vac} T_{A\,\rm minbias}}T_A(b)\right). \quad (44)$$

Hence, their prediction for the fractional increase in $\langle k_T^2\rangle$ with $T_A(b)$ is from 0.51 to 0.72 depending on the range $0.25 < \langle k_T^2\rangle_{\rm vac} < 0.35$ (GeV/c)^2 suggested by Qiu and Vitev [14].[4] Though the predicted fractional increase is of a different quantity, it should provide an estimate of the magnitude of the fractional increase in $\langle \sin^2(\phi_{jj})\rangle$. The prediction is slightly larger than one standard deviation (statistical) from our experimental result, $a_{\rm frac} = -0.01 \pm 0.40$ mb. If the measured value for $\langle k_T^2\rangle_{\rm vac}$ at RHIC turns out to be larger than assumed by Qiu and Vitev [14], then the predicted fractional increase in Eq. (44) will be smaller.

Barnafoldi *et al.* [15] have also predicted the increase in k_T due to multiple scattering in $d+$Au collisions at RHIC. They calculated that $\langle k_T^2\rangle$ increases by $C = 0.35$(GeV/c)^2 per collision up to the first four collisions, then it saturates. Their prediction is

$$\langle k_T^2\rangle = \langle k_T^2\rangle_0\left(1+\frac{0.35}{\langle k_T^2\rangle_0}(40\times T_A)\right), \qquad T_A < 0.1,$$
$$\langle k_T^2\rangle = \langle k_T^2\rangle_0\left(1+\frac{0.35}{\langle k_T^2\rangle_0}(40\times 0.1)\right), \qquad T_A > 0.1. \quad (45)$$

Barnafoldi *et al.* do not provide values for $\langle k_T^2\rangle_0$; however, if we use the range $0.25 < \langle k_T^2\rangle_0 < 0.35$ (GeV/c)^2 suggested by Qiu and Vitev [14] then the fractional increase with T_A is 40 to 56 for $T_A < 0.1$ followed by no further increase. This rapid increase is not observable in our data set because the model saturates already in the most peripheral $d+$Au bin, where $\langle T_A\rangle = 0.11$ mb^{-1}.

As discussed in Sec. I, inelastic scattering of the hard parton in the cold medium may also increase the conditional yields (CY) of hadrons that are associated with a high-p_T trigger. Figure 41 shows the centrality dependence of the extracted CY, together with CY from $p+p$ collisions. The difference can be better illustrated by taking the ratio ($d+$Au/$p+p$) of the per-trigger yield as shown in Fig. 42. There is a possible increase in near-side particle yield for $p_T < 1$ GeV/c in the $d+$Au collisions. In other momentum ranges, there is no consistent difference between yields in $d+$Au and $p+p$ collisions. The recombination model of Ref. [22] predicted a factor of 2 increase in CY peripheral to central $d+$Au collisions which is much larger than observed in the data. A later recombination calculation by the same authors [23] using

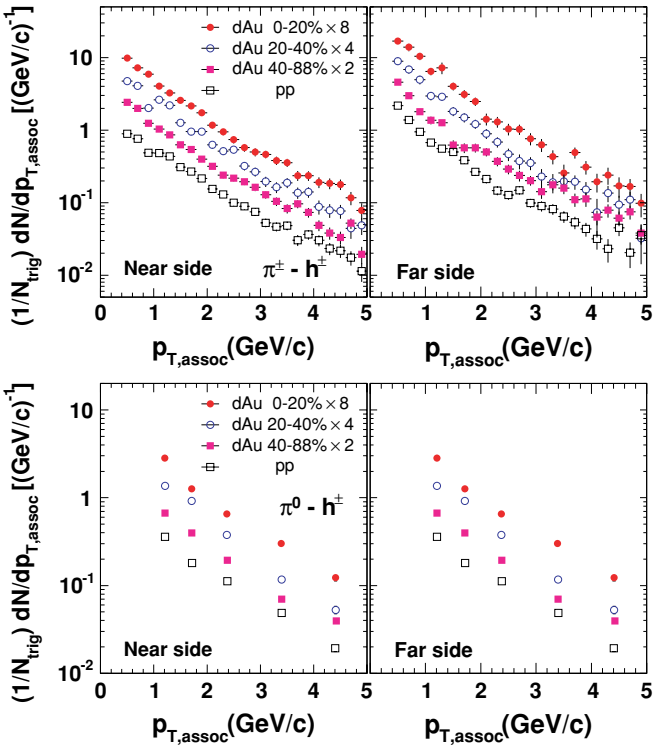

FIG. 41. (Color online) Centrality dependence of near and far CY(p_T) for $\pi^{\pm}-h^{\pm}$ and $\pi^0-h^{\pm}$ correlations. Bars are statistical errors.

[4]For 0−88% $d+$Au collisions, $T_{A\,\rm minbias} = 0.20$ mb^{-1}.

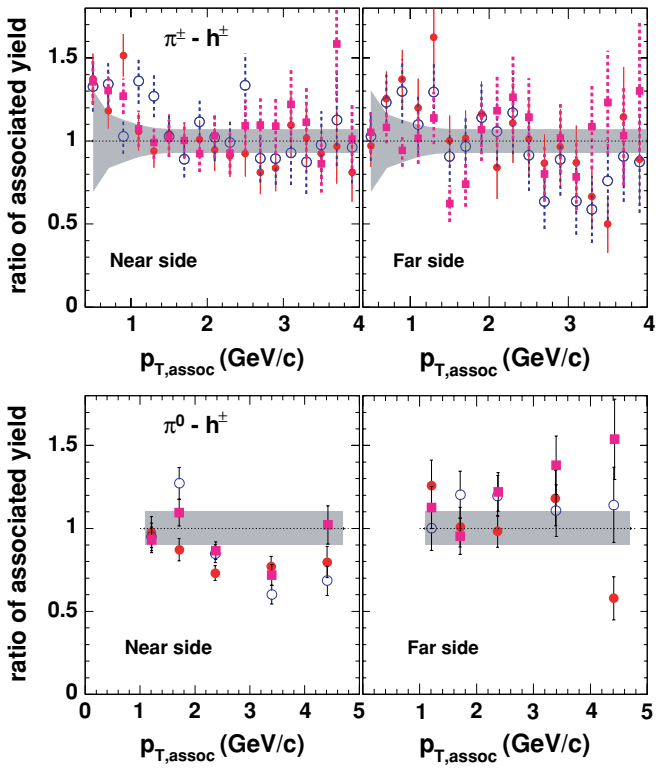

FIG. 42. (Color online) Centrality dependence related to the ratio of near and far CY(p_T) for d + Au to $p + p$ from the $\pi^{\pm} - h^{\pm}$ and $\pi^0 - h^{\pm}$ correlations. Shaded bands are the systematic errors due to normalization of the yields. Symbols are the same as in Fig. 41.

the same definition as the experiment [Eq. (16)] postdicted only a 30% increase in CY for associated particles at $p_T = 2$ GeV/c, which is comparable to or perhaps slightly larger than observed in the data.

V. CONCLUSIONS

We have measured several properties of jet fragmentation and dijet correlations using two-particle correlations with three different particle combinations: $h^{\pm} - h^{\pm}$, $\pi^0 - h^{\pm}$, and $\pi^{\pm} - h^{\pm}$. From the correlation functions, we have extracted the widths of the near- and far-angle correlations as a function of the momentum of the two hadrons, $p_{T,\mathrm{trig}}$ and $p_{T,\mathrm{assoc}}$. These widths decrease as a function of both the trigger and associated particle's momenta. From the near-angle widths, we calculate $\sqrt{\langle j_T^2 \rangle}$, the rms of the transverse momentum of fragmented hadrons with respect to the hard parton. The value of $\sqrt{\langle j_T^2 \rangle}$ saturates at $0.64 \pm 0.02(\mathrm{stat}) \pm 0.04(\mathrm{sys})$ GeV/c for $p_{T,\mathrm{assoc}} > 2$ GeV/c and is consistent with being independent of $p_{T,\mathrm{trig}}$ and trigger species. The $\sqrt{\langle j_T^2 \rangle}$ is similar for d + Au and $p + p$ collisions, which is consistent with the fragmentation process not being affected by the presence of the cold nuclear medium.

We have also compared the measured x_E distributions in d + Au collisions to the baseline distributions from $p + p$ collisions. The x_E distributions extracted from the far-angle correlations provide information on the fragmentation of a back-to-back parton triggered on a high-p_T hadron in the opposite hemisphere. The measured dN_{far}/dx_E distributions in d + Au are approximately independent of $p_{T,\mathrm{trig}}$; i.e., they scale. We have quantified the level of scaling violation by extracting the slope $\beta = d(dN/dx_E)/dp_{T,\mathrm{trig}}$ for different ranges of x_E. The slopes are consistent with zero for d + Au collisions; i.e., there is no significant scaling violation. Point by point, the scaling-violation slopes for $p + p$ collisions are not significantly different than the d + Au data. This suggests that if there is any additional gluon radiation in d + Au reactions due to multiple scattering, then it has little observable influence on the fragmentation of the hard parton.

We observe no centrality dependence of the conditional yield in d + Au, and these yields are very similar to those from $p + p$ collisions. The recombination model of Ref. [23] postdicted a 30% increase in conditional yield between d + Au and $p + p$, which is perhaps slightly larger than observed in the data.

We have extracted the dijet acoplanarity $\langle \sin^2(\phi_{jj}) \rangle$ from the widths of the back-to-back correlations in d + Au and $p + p$ collisions. In collisions involving nuclei, multiple interactions within the nucleus would tend to increase the parton transverse momentum which would be observable as a larger dijet acoplanarity; i.e., the back-to-back distribution of jets should broaden. However, in d + Au collisions, the extracted values of $\langle \sin^2(\phi_{jj}) \rangle$ are very similar to those observed in $p + p$ collisions. Indeed, the quadrature difference Δ between $\langle \sin^2(\phi_{jj}) \rangle$ in d + Au and $p + p$ is consistent with zero, $\Delta \langle \sin^2(\phi_{jj}) \rangle = +0.004 \pm 0.008(\mathrm{stat}) \pm 0.000(\mathrm{sys})$. The extracted $\langle \sin^2(\phi_{jj}) \rangle$ is also measured to be independent of the nuclear thickness function $T_A(b)$, which is in contrast to the strong A dependence of k_T observed at lower beam energies [7–9].

We have compared the centrality dependence of the extracted $\langle \sin^2(\phi_{jj}) \rangle$ with the multiple-scattering model of Qiu and Vitev [14]. This model reproduces the measured Cronin effect of single-particle spectra at RHIC [2–4] and predicts a finite increase of k_T with nuclear thickness function. When converted to a fractional increase, the prediction is at a level that is within the experimental uncertainty of the current data. Hence, our present data on $\langle \sin^2(\phi_{jj}) \rangle$ are not inconsistent with the level of multiple scattering deduced from the single-particle Cronin effect.

Taken together, we observe no change in fragmentation and no indication of the effects of multiple scattering; i.e., the jet structures are very similar in d + Au and $p + p$ collisions at RHIC energies. Our measurements also provide a critical baseline for jet measurements in Au + Au collisions at RHIC.

ACKNOWLEDGMENTS

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions. The azimuthal distribution of identified π^0 and inclusive photons has been measured in $\sqrt{s_{NN}} = 200$ GeV Au + Au collisions with the PHENIX experiment at the Relativistic Heavy-Ion Collider (RHIC). The second-harmonic parameter (v_2) was measured to describe the observed anisotropy of the azimuthal distribution. The measured inclusive photon v_2 is consistent with the value expected for the photons from hadron decay and is also consistent with the lack of direct photon signal over the measured p_T range 1–6 GeV/c. An attempt is made to extract v_2 of direct photons.

DOI: 10.1103/PhysRevLett.96.032302 PACS numbers: 25.75.Dw

Among the most exciting features of the experimental data from the Relativistic Heavy-Ion Collider (RHIC) are the suppression of high p_T hadron yields [1–5], the baryon excess at intermediate p_T [6–9], and the quark number scaling of the identified hadron v_2 [10,11]. Theoretically, the observed high p_T suppression has been attributed to energy loss of the hard-scattered partons [12,13]. Experimentally, the absence of the suppression in d + Au collisions has shown that it is a final-state effect due to the hot and dense matter created in central Au + Au collisions [14–17]. The quark number scaling of the measured elliptic flow parameter v_2 and the nuclear modification factor $R_{\rm cp}$ of baryons versus mesons may suggest the existence of a thermalized partonic phase before hadronization [18,19].

The second-harmonic coefficient parameter v_2 of the azimuthal distribution of the particles produced in heavy-ion collisions is defined by

$$\frac{dN}{d\phi} \propto 1 + 2v_2 \cos[2(\phi - \Phi_{\rm RP})], \tag{1}$$

where ϕ is the azimuthal direction of the particle and $\Phi_{\rm RP}$ is the direction of the nuclear impact parameter (reaction plane) in a given collision. The v_2 in high-energy heavy-ion collisions is considered to be sensitive to the initial geometric overlap of the colliding nuclei as well as the later expansion driven by the initial pressure. Theoretically, the dominant source of v_2 at low p_T is the expansion of the dense matter in the direction of the short axis of the overlap zone, and at high p_T is the parton energy loss given by the shape of the geometrical overlap. The quark coalescence (recombination) might be responsible for the v_2 in the intermediate p_T region. However, the experimental definition of v_2 includes any second-harmonic correlation with respect to the event plane, which is given by the beam direction and the impact parameter direction. Detailed v_2 measurements of identified particles at higher p_T than 2 GeV/c, where hydrodynamics alone does not describe the measurements, would enable us to understand the different mechanisms that generate v_2 and to investigate the transition region from low to high p_T. Especially, the v_2 of identified π^0 will give a baseline measurement of inclusive photon v_2 to extract the direct photon v_2.

The direct photons produced in hard scattering are penetrating probes of the produced dense matter in heavy-ion collisions. Recently, we observed that the centrality dependence of the direct photon yield in $\sqrt{s_{NN}} = 200$ GeV Au + Au collisions is consistent with binary collision scaling [20]. The lack of suppression of direct photons is further evidence in favor of the final-state effect in hadron suppression. In addition to the initially produced hard photons that should inherently follow binary scaling, there may be other counteracting effects resulting in apparent binary scaling. For example, some fraction of the photons may originate from partons having experienced energy loss, causing an analogous suppression of these photons [21] similar to hadrons. On the other hand, the parton energy loss may enhance the photon yield via bremsstrahlung while passing through the hot and dense matter [22]. The thermal emission of photons radiated from the hot and dense matter is also expected to increase direct photon yield for central Au + Au collisions [23].

The v_2 measurement of the direct photons could help to confirm that the observed binary scaling of the direct photon excess is attributable to the direct photon production being dominated by the initial hard scattering. The v_2 measurement of the direct photons would give additional and complementary information to help disentangle the various scenarios of direct photon production, as well as to provide more information on the dynamics and properties of the produced hot and dense matter. The v_2 of photons from the initial Compton-like hard scattering is expected to be zero if they do not interact with the hot and dense matter produced during the collision. However, when the v_2 of high p_T hadrons is given purely by the parton energy loss, the photons from the parton fragmentation outside of the reaction zone should have v_2 similar to the hadrons at high p_T. Such photon fraction is expected to be about 50% of total direct photon yield at 3.5 GeV/c in p_T [21,22]. On the other hand, one would expect that the photons originating from bremsstrahlung due to the passage of partons through the hot and dense matter should have the opposite (negative) sign in v_2 compared with hadrons, because the parton energy loss is larger in the long axis of the overlapping region (out-of-plane). Finally, the photons from the thermal radiation should reflect the dynamical evolution of the produced hot and dense matter. There are recent theoretical predictions for different mechanisms [24].

In this Letter we present measurements of the v_2 of π^0 and inclusive γ, as a function of transverse momentum and collision centrality, and we discuss the implications for the yield and v_2 of direct photons. The data are for 200 GeV Au + Au collisions from the PHENIX experiment [25] recorded during Run 2 at RHIC. The event trigger and centrality definition are given by the beam-beam counters (BBCs) and the zero degree calorimeters (ZDCs). The number of charged particles measured with the BBCs and the neutral spectators measured with the ZDCs are correlated with the number of participating nucleons, thus together providing a measure of the centrality. The event plane, which is a measure of reaction plane, is determined using the two BBCs at $|\eta| = 3.1 \sim 3.9$, where each counter consists of 64 photomultiplier tubes (PMTs) with quartz Cherenkov radiators in front, surrounding the beam pipe. The elliptic axis of the event plane $\Phi_{\rm measured}$ is calculated by the angle weighted with the PMT amplitude using the second-harmonic moment as described in Refs. [10,26]. The measured event anisotropy is corrected for a finite resolution of the measured event plane. The

estimated event plane resolution $\sigma_{\mathrm{RP}} = \langle \cos[2(\Phi_{\mathrm{measured}} - \Phi_{\mathrm{RP}})] \rangle$ is 0.3 on average, with a maximum of ~0.4 in the midcentral collisions. The corrected v_2 is calculated via the formula $v_2 = \langle \cos[2(\phi - \Phi_{\mathrm{measured}})] \rangle / \sigma_{\mathrm{RP}}$. The phase space used for the determination of the event plane for this analysis is 3–4 units away from the midrapidity, while the inclusive photon and the identified π^0 are measured at $|\eta| < 0.35$.

The photon identification and the π^0 reconstruction are performed in the same way as presented elsewhere [4]. The photon candidate clusters for both inclusive photon and π^0 measurement are first selected by their times of flight and the corresponding shower profiles in the electromagnetic calorimeter (EMCal). Neutral pions are reconstructed via $\pi^0 \rightarrow \gamma\gamma$ decay channel with an invariant mass analysis of γ pairs. An additional energy asymmetry cut, $|E_{\gamma 1} - E_{\gamma 2}|/(E_{\gamma 1} + E_{\gamma 2}) < 0.8$ is applied to the pairs of photon candidates in the π^0 reconstruction. The combinatorial background is estimated and subtracted by mixing pairs from different events with similar centrality, z-vertex position, and event plane orientation. The background is normalized in a region outside the π^0 mass peak for each bin in relative angle with respect to the measured event plane direction. A typical signal over background ratio is about 1 to 1 at $p_T = 3$ GeV/c in midcentral collisions (20–40% centrality). The v_2 of π^0 is calculated from the azimuthal distribution after the combinatorial background is subtracted for each centrality and p_T bin. For the inclusive photon analysis, the charged particle contamination in the sample of the photon candidate cluster is identified by associating the photon candidates with charged particle hits in the pad chamber (PC3) directly in front of the EMCal. The fraction of photon candidates removed by this charge veto cut is about 15–25% depending on centrality. The effect of hadron contamination on the measured v_2 of inclusive photons is estimated by varying the size of the charged particle association window in the PC3, and no significant effect is seen. Neutron and antineutron contamination and off-vertex photons in the identified photon sample are studied with full detector Monte Carlo simulation. The correction for these effects is applied to the data; it is 2% relative to the measured v_2 at 2 GeV/c and negligible at 4 GeV/c. The systematic error includes the effects from the π^0 and photon identification cuts and from the event plane determination: 5% for π^0 and 5% for photon identification and 5–10% for event plane determination given by the error on the correction factor from the finite event plane resolution. The analysis includes both a minimum-bias sample (30×10^6 events) and a Level 2 trigger sample (equivalent to 55×10^6 events), where the Level 2 algorithm is described in Ref. [20].

Figure 1 shows the measured v_2 of π^0 and inclusive photons as a function of p_T for different centrality selections. Data are compared with previous measurements of charged pions [10]. The p_T and centrality dependences of

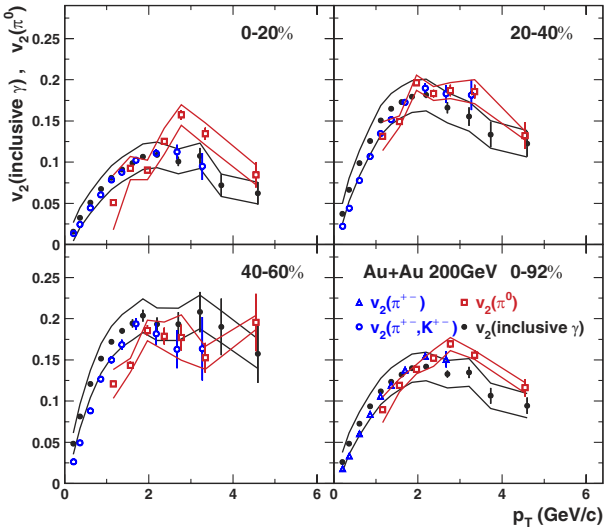

FIG. 1 (color online). The measured v_2 of inclusive photon ($v_2^{\mathrm{inclusive}\gamma}$, solid circles) and v_2 of π^0 ($v_2^{\pi^0}$, open squares) for 4 centrality selections. The statistical (vertical error bars) and systematic errors (lines) are plotted separately. The highest p_T point corresponds to 4–6 GeV/c. Charged pion data are from previous measurements [10].

both the π^0 and the inclusive photon v_2 is consistent with that of other mesons [10]. The v_2 values are significantly above zero up to the highest p_T points. The nonzero v_2 of π^0 up to the highest p_T cannot be explained by flow effects alone, but may be attributed to jet quenching and/or quark coalescence (recombination).

Figure 2 compares for different centralities the v_2 of inclusive photons with the expected photon v_2 from hadronic decays. The expected photon v_2 from hadronic decays (v_2^{bg}) is calculated by Monte Carlo simulation with the measured v_2 of π^0 and other hadronic sources of photon. The relative yield of other sources (mainly η) is about 20% of the total hadronic decay photons, which corresponds to about 4% relative contribution in v_2 at 1 GeV/c and negligible at 3 GeV/c. In the simulation, we assume that the v_2 of η is similar to the kaon (the closest in mass particle) v_2 measured in [10,11].

The v_2 of the inclusive photons $v_2^{\mathrm{inclusive}\gamma}$ can be expressed as

$$v_2^{\mathrm{inclusive}\gamma} = \frac{v_2^{\mathrm{direct}\gamma} N_{\mathrm{direct}\gamma} + v_2^{\mathrm{bg}} N_{\mathrm{bg}}}{N_{\mathrm{direct}\gamma} + N_{\mathrm{bg}}}, \qquad (2)$$

where $v_2^{\mathrm{direct}\gamma}$ is the direct photon v_2, $N_{\mathrm{direct}\gamma}$ is the direct photon yield, and N_{bg} is the background photon yield. Using the direct photon excess ratio $R = (N_{\mathrm{direct}\gamma} + N_{\mathrm{bg}})/N_{\mathrm{bg}}$, previously measured in Ref. [20], one can express the direct photon v_2 as

$$v_2^{\mathrm{direct}\gamma} = \frac{R v_2^{\mathrm{inclusive}\gamma} - v_2^{\mathrm{bg}}}{R - 1}. \qquad (3)$$

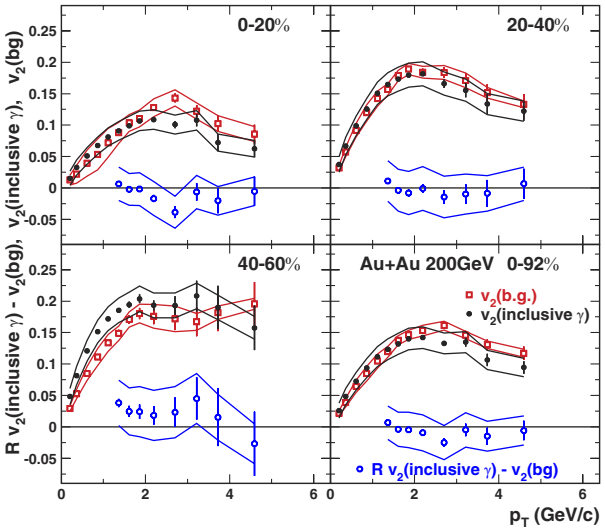

FIG. 2 (color online). The measured v_2 of inclusive photons ($v_2^{\text{inclusive}\gamma}$, solid circles) and expected photon v_2 from hadronic decay (v_2^{bg}, open squares). A subtracted v_2 quantity $Rv_2^{\text{inclusive}\gamma} - v_2^{\text{bg}}$ is plotted at the bottom of each panel (open circles), where $R = (N_{\text{direct}\gamma} + N_{\text{bg}})/N_{\text{bg}}$. The quantity corresponds to a product of the direct photon v_2 and a positive factor $R - 1$, ($v_2^{\text{direct}\gamma}(R - 1)$).

The bottom data points in each panel of Fig. 2 show the difference: $Rv_2^{\text{inclusive}\gamma} - v_2^{\text{bg}}$ (the numerator in the above equation), which corresponds to a product of the direct photon v_2 times a positive factor $R - 1$, $v_2^{\text{direct}\gamma}(R - 1)$. Alternatively, it would be possible to calculate $v_2^{\text{direct}\gamma}$ using the measured ratio R [20]. However, we have chosen this subtracted quantity in order to show the direct photon v_2 and its sign, because $R - 1$ is measured to be small, especially at low p_T, and is sometimes negative experimentally. The comparison between $v_2^{\text{inclusive}\gamma}$ and v_2^{bg} in each panel indicates that the measured inclusive photon v_2 is consistent with the expected photon v_2 from hadronic decay over the measured p_T range. The subtracted points are close to zero, which is also expected because of the lack of the direct photon signal in the measured p_T range, where R is close to unity [20]. The subtraction is especially meaningful where the measured R value goes above 1.0 at about 4–6 GeV/c and higher p_T in central Au + Au collisions [20]; a region where one could extract the direct photon v_2. The measurement indicates that v_2 of the direct photon is small at least in the highest p_T (4–6 GeV/c) range in central Au + Au collisions. However, some hidden important trends (slightly negative or positive v_2 of direct photon) as a function of p_T and centrality could be extracted, once the errors on those two v_2's and on the measured R are small enough. This is because the plotted subtracted quantity needs to be magnified by $1/(R - 1)$ in order to get the direct photon v_2. The extracted direct photon v_2 at 4–6 GeV/c is -1.5% with $\pm 6.4\%$ statistical and $\pm 6.4\%$ systematic errors for 0–20% central events and $-2.4\% \pm 6.7\%$(sta.) $\pm$ 9.8%(sys.) for 0–92% (minimum-bias) events.

Figure 3 shows the ratio of $v_2^{\text{bg}}/v_2^{\text{inclusive}\gamma}$ and a comparison to the measured ratio R of the yields from [20]. If the direct photon v_2 is assumed to be zero, the ratio R should be equal to $v_2^{\text{bg}}/v_2^{\text{inclusive}\gamma}$ according to the Eq. (3). If the measured direct photon excess comes from the initial hard scattering, that would correspond to zero $v_2^{\text{direct}\gamma}$, then the measured v_2 ratio $v_2^{\text{bg}}/v_2^{\text{inclusive}\gamma}$ gives a consistent check of the direct photon excess ratio R measurement, especially where R is significantly above 1.0. The measured v_2 ratio as a function of p_T and centrality is consistent with the conventional relative yield measurement of the direct photon excess ratio R, but has somewhat larger errors.

In conclusion, the v_2 of identified π^0 and inclusive photons as a function of p_T and centrality are measured with the PHENIX central arm spectrometer at $|\eta| < 0.35$ with respect to the event plane defined at $|\eta| = 3.1 \sim 3.9$ in 200 GeV Au + Au collisions at RHIC. The v_2 of identified π^0 shows a similar trend as a function of p_T and centrality compared with other mesons and has values significantly above zero up to the highest p_T point. The measured v_2 of the inclusive photons is consistent with the v_2 of photons from hadronic decays, which is furthermore consistent with the absence of direct photon signal over the measured p_T range. However, the measurement indicates a small direct photon v_2 for the highest p_T (4–6 GeV/c) range in central Au + Au collisions. The ratio of the estimated photon v_2 from the hadronic decay over the measured inclusive photon v_2 is also consistent with the

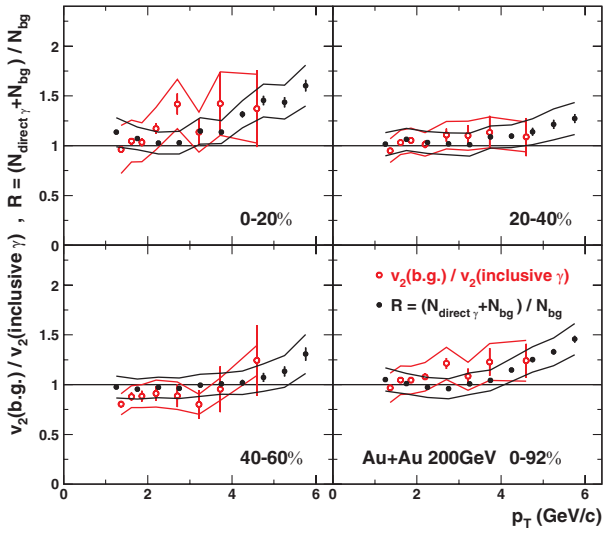

FIG. 3 (color online). The ratio of the hadronic decay photon v_2 over inclusive photon v_2 ($v_2^{\text{bg}}/v_2^{\text{inclusive}\gamma}$, open circles) compared with the direct photon excess ratio $R = (N_{\text{direct}\gamma} + N_{\text{bg}})/N_{\text{bg}}$, (solid circles).

direct photon excess ratio measured via conventional yields ratio. This should also imply that the v_2 of direct photons is zero where the measured direct photon excess ratio R is significantly above 1.0. The present statistics and systematic accuracy of the data from the second year of RHIC running do not allow us to explicitly state the magnitude of direct photon v_2. However, the indication of small v_2 for direct photons would favor the naive scenario of direct photon production from initial hard scattering and its small interaction with produced matter in high-energy Au + Au collisions.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 15 August 2005; published 26 January 2006)

The invariant differential cross section for inclusive electron production in $p + p$ collisions at $\sqrt{s} = 200$ GeV has been measured by the PHENIX experiment at the BNL Relativistic Heavy Ion Collider over the transverse momentum range $0.4 \leq p_T \leq 5.0$ GeV/c in the central rapidity region ($|\eta| \leq 0.35$). The contribution to the inclusive electron spectrum from semileptonic decays of hadrons carrying heavy flavor, i.e., charm quarks or, at high p_T, bottom quarks, is determined via three independent methods. The resulting electron spectrum from heavy-flavor decays is compared to recent leading and next-to-leading order perturbative QCD calculations. The total cross section of charm quark-antiquark pair production is determined to be $\sigma_{c\bar{c}} = 0.92 \pm 0.15(\text{stat}) \pm 0.54(\text{syst})$ mb.

DOI: 10.1103/PhysRevLett.96.032001 PACS numbers: 13.85.Qk, 13.20.Fc, 13.20.He, 25.75.Dw

The production of hadrons carrying heavy quarks, i.e., charm or bottom, serves as a crucial proving ground for quantum chromodynamics (QCD), the theory of the strong interaction. Because of the large quark masses, charm and bottom production can be treated by perturbative QCD (pQCD) even at small momenta without being significantly affected by additional soft processes [1]. This is in distinct contrast to the production of particles composed solely of light quarks, which can be evaluated perturbatively only for sufficiently large momenta. Consequently, pQCD calculations of heavy quark production are expected to be reliable over the full momentum range experimentally accessible at collider energies.

For bottom production, next-to-leading order (NLO) calculations are in reasonable agreement with data [2]. Charm measurements at $\sqrt{s} = 1.96$ TeV exist for high transverse momentum (p_T) only [3], where the cross section is higher than NLO predictions by $\geq 50\%$. However, these discrepancies are within the substantial experimental and theoretical uncertainties [3]. At the Relativistic Heavy Ion Collider (RHIC), charm yields have been measured for $p + p$ and $d + \mathrm{Au}$ collisions at $\sqrt{s_{\mathrm{NN}}} = 200$ GeV [4,5] as well as for Au + Au collisions at 130 and 200 GeV [6,7]. Further measurements are crucial for a better understanding of heavy-flavor production at RHIC. In particular, the relevance of higher order processes and other production mechanisms like jet fragmentation is unclear.

We report on the central rapidity production ($|\eta| \leq 0.35$) of inclusive electrons, $(e^+ + e^-)/2$, in $p + p$ collisions at $\sqrt{s} = 200$ GeV measured by the PHENIX experiment [8] at RHIC. Contributions from semileptonic heavy-flavor decays are extracted in the electron p_T range $0.4 \leq p_T \leq 5.0$ GeV/c. The resulting invariant differential cross section is an important benchmark for pQCD calculations of heavy quark production. Furthermore, it provides a crucial baseline for measurements in nuclear collisions at RHIC. Since hadronic heavy-flavor production is expected to be dominated by initial parton scattering, systematic studies in $p + p$ and $d + \mathrm{Au}$ collisions should be sensitive to the nucleon parton distribution functions as well as to their nuclear modifications such as shadowing [9]. In Au + Au collisions, heavy quarks constitute a unique and, with the data presented here, calibrated probe for the hot and dense medium created in the collisions. Possible medium modification of heavy-flavor probes include energy loss [10,11], azimuthal asymmetry [12], and quarkonia suppression [13] or enhancement [14,15].

The data used here were recorded by PHENIX during RHIC Run 2. Beam-beam counters (BBCs), positioned at pseudorapidities $3.1 < |\eta| < 3.9$, measured the collision vertex and provided the minimum bias (MB) interaction trigger defined by at least one hit on each side of the vertex. Events containing high p_T electrons were selected by an additional level 1 trigger in coincidence with the MB trigger. This level 1 trigger required a minimum energy deposit of 0.75 GeV in a 2×2 tile of towers in the electromagnetic calorimeter (EMC) [16]. After a vertex cut of $|z_{\mathrm{vtx}}| < 20$ cm, an equivalent of 465×10^6 MB events sampled by the EMC trigger was analyzed in addition to the 15×10^6 events recorded with the MB trigger itself.

The PHENIX east arm spectrometer ($|\eta| < 0.35$, $\Delta\phi = \pi/2$) includes a drift chamber and a pad chamber layer for charged particle tracking. Tracks were confirmed by hits in the EMC matching in position with the track projection within 3σ. Electron candidates required at least two associated hits in the ring imaging Čerenkov detector (RICH) in the projected ring area. Random coincidences of hadron tracks and hits in the RICH occurred with a probability of $(3.0 \pm 1.5) \times 10^{-4}$. For electrons the energy E deposited in the EMC must be consistent with the momentum p. Requiring $|(E - p)/p| < 3\sigma$, a total charged hadron rejection factor of about 10^4 (10^5) was achieved for $p_T = 0.4\,(\geq 2.0)$ GeV/c. Remaining background ($<1\%$) was measured via event mixing and subtracted statistically.

The differential cross section for electron production was calculated as

$$E\frac{d^3\sigma}{dp^3} = \frac{1}{\epsilon_{\mathrm{bias}} \int \mathcal{L}dt} \frac{N_e}{2\pi p_T \Delta y \Delta p_T} \frac{1}{A\epsilon_{\mathrm{rec}}}, \qquad (1)$$

where $\int \mathcal{L}dt$ is the integrated luminosity measured with the MB trigger or sampled with the EMC trigger, respectively; ϵ_{bias} is the probability for an electron event to fulfill the MB trigger condition; N_e is the measured electron yield; and $A\epsilon_{\mathrm{rec}}$ is the product of geometrical acceptance and reconstruction efficiency. For the EMC triggered sample, ϵ_{rec} includes the trigger efficiency ϵ_{lvl1}.

$\int \mathcal{L}dt$ is calculated as $N_{\mathrm{MB}}/\sigma_{\mathrm{BBC}}$, where N_{MB} is the number of MB triggers or, for the EMC triggered sample, the number of EMC triggers divided by the measured fraction of MB events which simultaneously fulfill the EMC trigger criterion. With the MB trigger cross section $\sigma_{\mathrm{BBC}} = 21.8 \pm 2.1$ mb [16], the analyzed data samples correspond to integrated luminosities of 0.7 nb^{-1} (MB trigger) and 21 nb^{-1} (EMC trigger), respectively. The p_T independent trigger bias $\epsilon_{\mathrm{bias}} = 0.75 \pm 0.02$ was measured for events containing a π^0 with $p_T > 1.5$ GeV/c [16] and confirmed for charged hadrons with $p_T > 0.2$ GeV/c [17], indicating a universal bias both for hard and soft processes. $A\epsilon_{\mathrm{rec}}$ was calculated as a function of p_T ($< 10\%$ variation over the full p_T range) in a GEANT [18] simulation of electrons with flat distributions in rapidity ($|y| < 0.6$), azimuth ($0 < \phi < 2\pi$), and event vertex ($|z| < 30$ cm) as input. The simulated detector response was carefully tuned to match the real detector. Rigorous fiducial cuts were applied to eliminate active area mismatches between data and simulation as well as run-by-run variations. The trigger efficiency ϵ_{lvl1}, evaluated for single electrons in the fiducial area, rises from zero at low p_T to $95 \pm 5\%$ for $p_T > 2$ GeV/c. Finally, we appropriately corrected for the effect of finite bin width in p_T.

The corrected electron spectra from the MB and EMC triggered samples cover p_T ranges of $0.4 < p_T < 2.0$ GeV/c and $0.6 < p_T < 5.0$ GeV/c, respectively. They are consistent with each other within the statistical uncertainties in the p_T region of overlap. The weighted average of both measurements is shown in Fig. 1(a).

The systematic uncertainty of the inclusive electron spectrum is about 12%, almost p_T independent, calculated as the sum in quadrature of contributions from the acceptance calculation (7%), electron identification cuts (5.2%), run-by-run variations (4%), tracking efficiency (3%), momentum scale (1–5%), and other smaller uncertainties (more details on the uncertainty estimations can be found in Ref. [19]). The value of 12% does not include the 9.6% uncertainty of the absolute normalization.

The invariant cross section of electrons from heavy-flavor decays was determined by subtracting a *cocktail* of contributions from other sources from the inclusive data. The most important background is the π^0 Dalitz decay which was calculated with a hadron decay generator using a parameterization of measured π^0 [16] and $\pi^{\pm}$ [20] spectra as input. The spectral shapes of other light hadrons h were obtained from the pion spectra by m_T scaling.

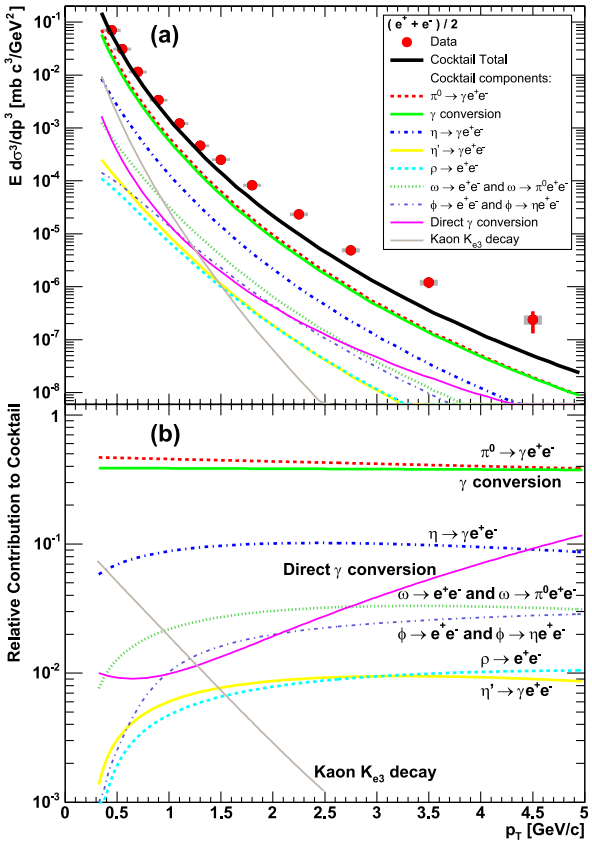

FIG. 1 (color online). (a) Inclusive electron invariant differential cross section, measured in $p + p$ collisions at $\sqrt{s} =$ 200 GeV, compared with all contributions from electron sources included in the background *cocktail*. Error bars (boxes) correspond to statistical (systematic) uncertainties. (b) Relative contributions of all electron sources to the background *cocktail*.

Within this approach the ratios h/π^0 are constant at high p_T and for the relative normalization we used: $\eta/\pi^0 = 0.45 \pm 0.10$ [21], $\rho/\pi^0 = 1.0 \pm 0.3$, $\omega/\pi^0 = 1.0 \pm 0.3$, $\eta'/\pi^0 = 0.25 \pm 0.08$, and $\phi/\pi^0 = 0.40 \pm 0.12$. Only the η contribution is of any practical relevance. Another major electron source is the conversion of photons, mainly from $\pi^0 \to \gamma\gamma$ decays, in material within the acceptance. The spectra of electrons from conversions and Dalitz decays are very similar. In a GEANT simulation of π^0 decays, the ratio of electrons from conversions to electrons from Dalitz decays was determined to be 0.73 ± 0.07, essentially p_T independent. Contributions from photon conversions from other sources were taken into account as well. In addition, electrons from kaon decays (K_{e3}), determined in a GEANT simulation based on measured kaon spectra [20], and electrons from external as well as internal conversions of direct photons [22,23] were considered in the cocktail. All background sources are compared with the inclusive data in Fig. 1(a) with the relative contributions shown in Fig. 1(b). The total systematic uncertainty of the cocktail is about 12%, essentially p_T independent. This uncertainty is dominated by the systematic error of the pion parameterization ($\approx$10%). Other systematic uncertainties, mainly the η/π^0 normalization and, at high p_T, the contribution from direct radiation, are much smaller.

Given the small amount of material within the acceptance (Be beam pipe: 0.29% X_0; air: 0.28% X_0) the ratio R_{NP} of nonphotonic electrons from heavy-flavor decays to background from photonic sources is large ($R_{\mathrm{NP}} > 1$ for $p_T > 1.5$ GeV/c) as shown in Fig. 2. Two complementary analysis methods confirm the *cocktail* result:

The *converter* technique [7] compares electron spectra measured with an additional photon converter $X_C = 1.67\% X_0$ introduced into the acceptance to measurements without converter. The converter increases the contribution from conversions and Dalitz decays by a fixed factor, which was determined precisely via GEANT simulations. Thus, the electron spectra from photonic and nonphotonic sources can be deduced (Fig. 2). The drawbacks of the *converter* method are the limitation in statistics of the converter run period and the fact that the photonic contribution is small at high p_T.

The *$e\gamma$ coincidence* technique evaluates the correlation of electrons and photons via their invariant mass. Electrons from π^0 Dalitz decays or the conversion of one of the photons from $\pi^0 \to \gamma\gamma$ decays are correlated with a photon, in contrast to electrons from semileptonic heavy-flavor decays. Comparing the measured $e\gamma$ coincidence rate with the simulated rate for single π^0 events allows R_{NP} to be deduced as shown in Fig. 2, once corrections for contributions from other photonic sources are applied.

After subtracting the background cocktail from the inclusive electron spectrum the invariant differential cross section of electrons from heavy-flavor decays is shown in Fig. 3 compared with two theoretical predictions. A leading order (LO) PYTHIA calculation, tuned to existing charm and bottom hadroproduction measurements [24,25], is in

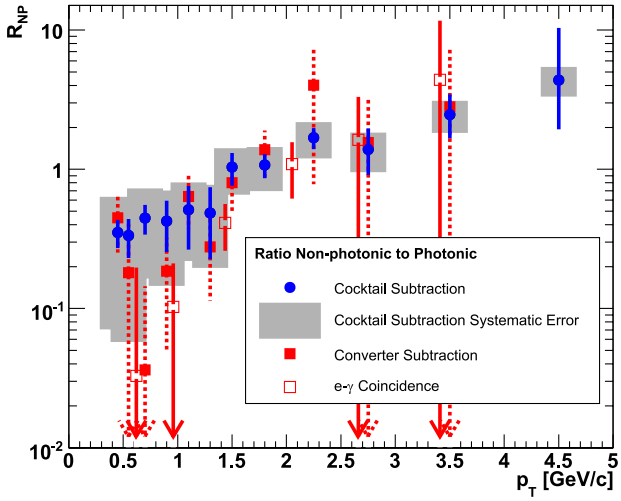

FIG. 2 (color online). Ratio of electrons from heavy-flavor decays (nonphotonic) and other sources (photonic), R_{NP}, for three independent analysis methods. Error bars (boxes) are statistical (*cocktail* systematic) uncertainties.

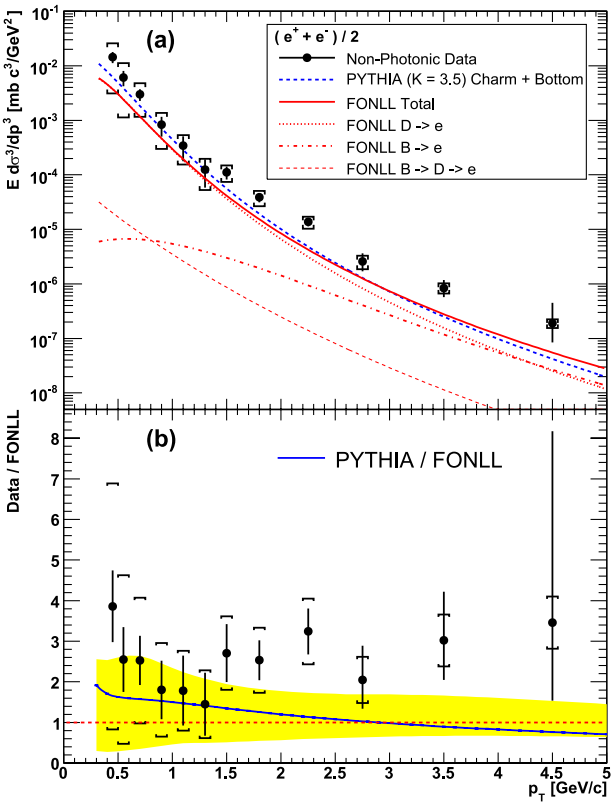

FIG. 3 (color online). (a) Invariant differential cross section of electrons from heavy-flavor decays compared with PYTHIA LO (with $K = 3.5$) and FONLL pQCD calculations. Error bars (brackets) show statistical (systematic) uncertainties. For the FONLL calculation contributions from charm, bottom and bottom cascade decays are shown separately. (b) Ratio of data and FONLL calculations with experimental statistical (error bars) and systematic (brackets) uncertainties as well as the theoretical uncertainty (shaded band). The solid line corresponds to the ratio of PYTHIA and FONLL.

reasonable agreement with the data for $p_T < 1.5$ GeV/c, but underestimates the cross section at higher p_T. It is important to note that this calculation includes a scale factor $K = 3.5$ to accommodate neglected NLO contributions. A *Fixed-Order plus Next-to-Leading-Log* (FONLL) pQCD calculation [26] still leaves room for further contributions beyond the included NLO processes. The predicted contribution from bottom decays is irrelevant for the electron cross section at $p_T < 3$ GeV/c and becomes significant only for $p_T > 4$ GeV/c.

The charm production cross section was derived from the integrated electron cross section for $p_T > p_{T,\mathrm{low}} = 0.6(0.8)$ GeV/c ($d\sigma_e^{p_{T,\mathrm{low}}}/dy = 4.78(2.15) \pm 0.78(0.46) \times$ (stat) $\pm$ 1.74(0.68)(syst) $\times 10^{-3}$ mb). Since in the low p_T region, which dominates the total cross section, PYTHIA describes the measured spectrum reasonably well, the total charm cross section was determined by extrapolating the properly scaled PYTHIA spectrum to $p_T = 0$ GeV/c. First the PYTHIA spectra for electrons from charm and bottom decays were fitted to the data for $p_T > 0.6$ GeV/c, with only the normalizations as free parameters. The resulting central rapidity charm production cross section was determined to be $d\sigma_{c\bar{c}}/dy = 0.20 \pm 0.03(\mathrm{stat}) \pm 0.11(\mathrm{syst})$ mb, where the systematic error is dominated by the uncertainty of the electron spectrum itself ($\approx$56%), evaluated by refitting PYTHIA to the data at the minimum and maximum of the 1σ systematic error band. Additional uncertainties from the relative ratios of different charmed hadron species and their branching ratios into electrons ($\approx$9%) and the variation of the PYTHIA spectral shape ($\approx$11%) [7] were added in quadrature. The rapidity integrated cross section was determined to be $\sigma_{c\bar{c}} = 0.92 \pm 0.15(\mathrm{stat}) \pm 0.54(\mathrm{syst})$ mb, where various parton distribution functions [GRV98LO and MRST(cg) [27] in addition to the default CTEQ5L [25]] were used for the extrapolation, with an associated extra systematic error of $\approx$6% [7] added in quadrature.

Within errors the integrated charm cross section is compatible with data from Au + Au collisions [7] (minimum bias value: $0.622 \pm 0.057 \pm 0.160$ mb per NN collision) and from d + Au collisions [4] ($1.3 \pm 0.2 \pm 0.4$ mb) at the same $\sqrt{s_{\mathrm{NN}}} = 200$ GeV. The FONLL cross section is smaller ($\sigma_{c\bar{c}}^{\mathrm{FONLL}} = 0.256^{+0.400}_{-0.146}$ mb) but it is still compatible with the data. Our measurement does not allow a bottom cross section to be deduced, which is predicted by FONLL to be $\sigma_{b\bar{b}}^{\mathrm{FONLL}} = 1.87^{+0.99}_{-0.67}$ μb.

In conclusion, we have measured single electrons from heavy-flavor decays in $p + p$ collisions at $\sqrt{s} = 200$ GeV. These data provide a crucial benchmark for pQCD heavy quark calculations. We observe that above $p_T \approx 2$ GeV/c the electron spectrum is significantly harder than predicted by a LO PYTHIA charm and bottom calculation. Contributions to the charm production cross section in excess of the considered FONLL calculation, e.g., from jet fragmentation, cannot be excluded. Similar excess at high p_T was ob-

served by Fermilab experiments (CDF and D0) at $\sqrt{s} = 1.96$ TeV [3]. The new data reported here provide an important baseline for the study of possible medium modification of heavy quark production at RHIC.

(Received 28 July 2005; published 10 January 2006)

J/ψ production in d + Au and $p + p$ collisions at $\sqrt{s_{NN}} = 200$ GeV has been measured by the PHENIX experiment at rapidities $-2.2 < y < +2.4$. The cross sections and nuclear dependence of J/ψ production versus rapidity, transverse momentum, and centrality are obtained and compared to lower energy $p + A$ results and to theoretical models. The observed nuclear dependence in d + Au collisions is found to be modest, suggesting that the absorption in the final state is weak and the shadowing of the gluon distributions is small and consistent with Dokshitzer-Gribov-Lipatov-Altarelli-Parisi-based parametrizations that fit deep-inelastic scattering and Drell-Yan data at lower energies.

DOI: 10.1103/PhysRevLett.96.012304 PACS numbers: 25.75.Dw

J/ψ production in hadron collisions, since it proceeds predominantly through diagrams involving gluons (e.g., gluon fusion) [1], is a sensitive probe of the gluon structure function in the nucleon and its modification in nuclei. It is also a leading signal for the creation of hot-dense matter in heavy-ion collisions [2]. Shadowing of partons (quarks or gluons) in nuclei is a depletion of their population at small momentum fraction of the nucleon, x, compared to that in a free nucleon, with a corresponding enhancement at moderate x (antishadowing). In $\sqrt{s_{NN}} = 200$ GeV deuteron-gold ($d + \mathrm{Au}$) collisions at the Relativistic Heavy-Ion Collider (RHIC), for positive (deuteron direction) rapidities, gluons are probed that lie well into the shadowing region with momentum fractions in Au, $x_2 \sim 3 \times 10^{-3}$. Models of gluon shadowing predict suppressions of J/ψ production in nuclei that differ by as much as a factor of 3 [3–5]. Recent theoretical developments, e.g., the color glass condensate model [6], suggest that at very low x nonlinear gluon saturation effects become important and cause substantial modifications of the gluon densities.

The connection of the observed J/ψ suppression to the modified gluon distribution in nuclei can be clouded by the absorption of the final-state $c\bar{c}$ [7] which depends on the poorly known production mechanism [1] and by the energy loss of the intial-state gluon—although the latter is thought to be small at RHIC energies [5]. This connection is also distorted by the fact that approximately a third of the J/ψ's come from decays of higher-mass resonances [8].

Here we present measurements made by the PHENIX experiment at RHIC for the production of J/ψ's in $\sqrt{s_{NN}} = 200$ GeV $d + \mathrm{Au}$ and proton-proton ($p + p$) collisions. These data provide the first measurement of the nuclear dependence of J/ψ production at this energy, a much higher energy than previous $p + A$ measurements from fixed-target experiments at $\sqrt{s_{NN}} \lesssim 40$ GeV [9–13]. Although our measurements are for $d + A$, the nuclear effects on the J/ψ in deuterium were found to be small at lower energies [14]. Besides the shadowing region at small x, these data also probe larger gluon momentum fractions (at negative rapidity) nearer the rest frame of the residual nucleus. Finally, these measurements also serve as a baseline for the upcoming results from the high-luminosity Au + Au and Cu + Cu runs and must be understood in order to look for effects beyond what is expected from cold nuclear matter.

The measurements described here are similar to earlier ones with PHENIX [15] for $p + p$ [16] and Au + Au [17] collisions, but with a second muon spectrometer added and higher luminosity. The two muon spectrometers are especially valuable for asymmetric collisions such as $d + \mathrm{Au}$ where simultaneous measurements at positive ($1.2 < y < 2.4$) and negative ($-2.2 < y < -1.2$) rapidities, along with central ($|y| \leq 0.35$) rapidity from e^+e^-, are then available. Electrons in the central arms are identified by matching charged particle tracks to clusters in an electromagnetic calorimeter (EMC) and to rings in a ring imaging Čerenkov (RICH) detector. Muons are identified by their detection in Iarocci tubes after their penetration through 8 to 11 interaction lengths of copper and steel absorber.

The data used in this analysis were recorded in 2003 using a trigger that required hits in each of the two beam-beam counters located at negative and positive rapidity ($3 < |\eta| < 3.9$). In addition, for the di-muons at least two tracks in the muon identifier of appropriate absorber depth were required, while for the di-electrons a one-track trigger with a signal above threshold in the EMC with a matching hit in the RICH was required. After quality and vertex cuts, the samples for the three arms correspond to integrated luminosities from 180 to 250 nb^{-1} ($p + p$) and 1.4 to 1.7 nb^{-1} ($d + \mathrm{Au}$).

For the di-muons the J/ψ yield is obtained after subtraction of the combinatoric background using like-sign muon pairs ($2\sqrt{N_{++}N_{--}}$) and by fitting the resulting mass peak with a Gaussian plus an exponential to represent the small remaining continuum background underneath the peak. A variety of continuum shapes were checked for each fit in order to establish the uncertainty due to the low-statistics background. For the di-electrons the combinatoric background was subtracted using the sum of like-sign pairs and the J/ψ yield was taken as all remaining events in the mass range 2.6 to 3.6 GeV/c^2. A total ($p + p$ plus $d + \mathrm{Au}$) of about 2100 and 500 J/ψ's were obtained in the $\mu\mu$ and ee channels, respectively.

The differential cross sections are calculated as

$$B_{ll}\frac{d\sigma_{J/\psi}}{dy} = \frac{N_{J/\psi}}{A\epsilon_{\mathrm{rec}}\epsilon_{\mathrm{trig}}\epsilon^{\mathrm{BBC}}_{J/\psi}(N_{\mathrm{evt}}/(\sigma^{\mathrm{tot}}_{\mathrm{MB}}\cdot\epsilon^{BBC}_{\mathrm{MB}}))}\frac{1}{\Delta y} \quad (1)$$

and the nuclear modification factor, R_{dA}, is

$$R_{dA} = \frac{d\sigma^{d\mathrm{Au}}_{J/\psi}/dy}{(2\times 197)\times d\sigma^{pp}_{J/\psi}/dy}. \quad (2)$$

In the above expressions B_{ll} is the J/ψ branching ratio to di-leptons, $N_{J/\psi}$ is the measured J/ψ yield, A is the geometrical acceptance, ϵ_{rec} is the di-lepton reconstruction efficiency, ϵ_{trig} is the trigger efficiency, N_{evt} is the number of minimum-bias triggers sampled, $\sigma^{\mathrm{tot}}_{\mathrm{MB}}$ is the total minimum-bias (MB) cross section, Δy is the rapidity bin width, and $\epsilon^{\mathrm{BBC}}_{\mathrm{MB}}$ and $\epsilon^{\mathrm{BBC}}_{J/\psi}$ are the beam-beam trigger efficiencies for minimum-bias and J/ψ events, respectively. The factor of 2×197 causes R_{dA} to be one if the $d + A$ cross section is just additive from $p + p$, i.e., if there are no nuclear modifications.

For $p + p$ we use the cross section for our beam-beam trigger, $\sigma^{\mathrm{tot}}_{\mathrm{MB}}(pp)\epsilon^{\mathrm{BBC}}_{\mathrm{MB}}(pp) = 23.0 \pm 2.2$ mb, and the efficiency for events with a J/ψ, $\epsilon^{\mathrm{BBC}}_{J/\psi}(pp) = 0.79 \pm 0.02$.

For d + Au collisions we use a beam-beam trigger cross section of $\sigma_{\rm MB}^{\rm tot}(d{\rm Au})\epsilon_{\rm MB}^{\rm BBC}(d{\rm Au}) = 1.99 \pm 0.10$ b from our measurement [18] using photodissociation of the deuteron as a reference [19], which is consistent with our calculated Glauber result of 1.92 ± 0.18 b. For the J/ψ we use $\epsilon_{J/\psi}^{\rm BBC}(d{\rm Au}) = 0.94 \pm 0.02$ [20].

For d + Au collisions, the centrality of the collision can be characterized by measuring the charge deposited in the beam-beam counter in the Au beam direction [20]. An approximate number of nucleon + nucleon collisions $\langle N_{\rm coll}\rangle$ can be obtained through a Glauber calculation that relates this $\langle N_{\rm coll}\rangle$ to the observed charge. In this case $R_{dA}(N_{\rm coll})$ is calculated as

$$R_{dA}(\langle N_{\rm coll}\rangle) = \frac{N_{\rm inv}^{d{\rm Au}}(\langle N_{\rm coll}\rangle)}{\langle N_{\rm coll}\rangle \times N_{\rm inv}^{pp}}, \quad (3)$$

where the invariant yield $N_{\rm inv}$ is

$$N_{\rm inv}(\langle N_{\rm coll}\rangle) = \frac{N_{J/\psi} C_{\rm bias}(\langle N_{\rm coll}\rangle)}{A\epsilon_{\rm rec}\epsilon_{\rm trig}[N_{\rm evt}(\Delta w/w)]} \quad (4)$$

with $\langle N_{\rm coll}\rangle$ being the average number of binary collisions for a particular d + Au centrality bin and $N_{\rm evt}(\Delta w/w)$ the number of d + Au minimum-bias triggers sampled that lie in this fraction, Δw, of the total minimum-bias centrality range, w. This prescription is equivalent to that of Eq. (1) and (2) for minimum bias. For p + p collisions $\Delta w/w$ is one. $C_{\rm bias} = \epsilon_{\rm MB}^{\rm BBC}/\epsilon_{J/\psi}^{\rm BBC}$ is a correction for the smaller trigger efficiency in minimum-bias events compared to those with a J/ψ. For d + Au, $C_{\rm bias}$ depends on $\langle N_{\rm coll}\rangle$ and takes into account the effect of the underlying event multiplicity on both the trigger efficiency and the centrality measurement [20]. Its variation with centrality is up to 7% from unity.

For the electron analysis, $A\epsilon_{\rm rec}$ and $\epsilon_{\rm trig}$ were determined using a GEANT [21] simulation of the central arms and a trigger response software emulation [16]. $\epsilon_{\rm rec}$ was confirmed by studying pairs identified as photon conversions in the data. The systematic uncertainty of 10.4% is dominated by run-to-run efficiencies (5%), yield extraction (5%), and the occupancy dependence of the efficiency (4.4%).

For the muon arms, $A\epsilon_{\rm rec}\epsilon_{\rm trig}$ was determined within each rapidity and p_T bin, using a GEANT simulation with J/ψ events generated by PYTHIA [22]. The dominant systematic uncertainties in our result are $+6/-9\%$ from the muon identifier efficiency and up to 10% (for the most central negative rapidity d + Au data) from the combinatoric background.

Figure 1(a) shows the measured p + p differential cross section times branching ratio versus rapidity with a di-electron point at midrapidity and two di-muon points at negative and positive rapidities. A fit to a shape generated with PYTHIA is performed and, using a di-lepton branching ratio of 5.9% [23], gives a total cross section $\sigma_{pp}^{J/\psi} = 2.61 \pm 0.20({\rm fit}) \pm 0.26({\rm abs})$ μb. Variations in the parton distribution functions and models used to determine the shape are negligible compared to the fit errors. This result is smaller by about two sigma than our previous lower statistics result [16].

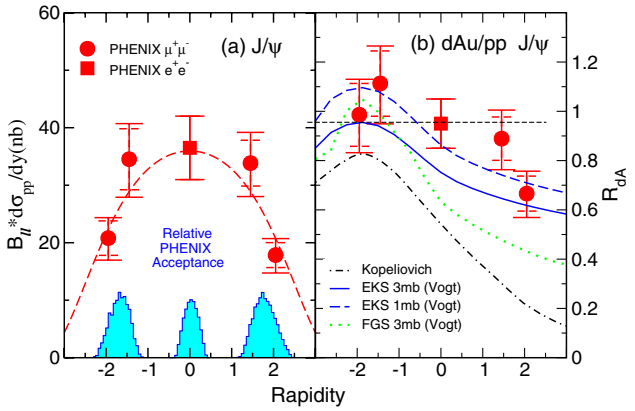

FIG. 1 (color online). (a) The 200 GeV J/ψ p + p differential cross section times di-lepton branching ratio versus rapidity (10% overall normalization uncertainty is not included). (b) The minimum-bias R_{dA} vs rapidity (12% overall normalization uncertainty not included). For both panels the dashed error bars represent systematic uncertainties relevant for comparing the two rapidity bins in each muon arm, while the solid error bars represent the overall uncertainties relevant for comparing points at negative, central, or positive rapidity. The curve in (a) represents a fit as described in the text while the curves in (b) are theoretical calculations [5,24,25] as described in the text.

Figure 1(b) shows the nuclear modification factor R_{dA} [Eq. (2)] versus rapidity, where a value of one would correspond to no nuclear modification. While this ratio is consistent with unity at negative rapidity, it is significantly lower at the most positive rapidity where gluons are expected to be shadowed in a heavy nucleus. Theoretical predictions [5,24,25] that include the effects of absorption and shadowing are shown for comparison in Fig. 1(b). The data favor a relatively modest shadowing in agreement with the parametrization of Eskola-Kolhinen-Salgado (EKS) [3] based on a leading-twist Dokshitzer-Gribov-Lipatov-Altarelli-Parisi-evolved parametrization of nuclear deep-inelastic scattering and Drell-Yan data at lower energies, rather than the stronger gluon shadowing of Kopeliovich [5] or Frankfurt-Guzey-Strikman (FGS) [4] based on models involving coherence for a $q\bar{q}$ dipole in the nucleus. The $c\bar{c}$ absorption cross section is not well determined by our data, but is probably nearer to 1 mb and is certainly smaller than the 4.1 ± 0.4 mb found at lower energy [26].

Lower energy $p + A$ measurements showed that J/ψ suppression did not follow a universal behavior versus x_2 [27], the momentum fraction in the heavy nucleus, as would be expected if the suppression was dominated by shadowing [10]. As shown in Fig. 2(a), our data confirm this x_2 scaling violation with the addition of a smaller x_2

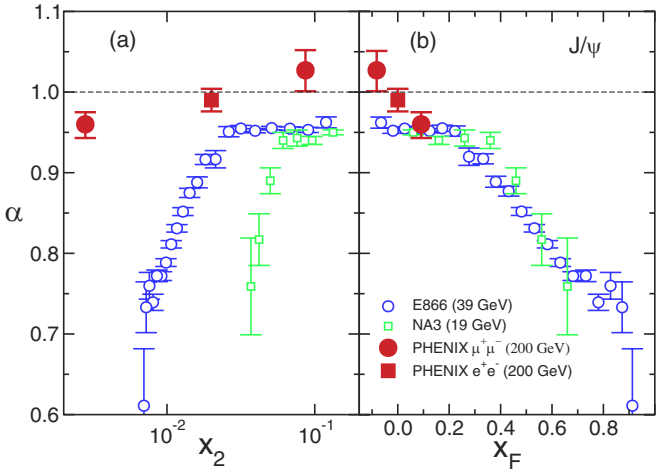

FIG. 2 (color online). α vs (a) x_2 and (b) x_F with present 200 GeV J/ψ results compared to lower energy results [10,13]. An additional overall uncertainty of 0.02 in our α values is not shown.

point, but with our small range in x_F have little to add to the approximate x_F scaling observed in these lower energy measurements [Fig. 2(b)]. Here α is defined by $\sigma_{dA} = \sigma_{pp} \times (2A)^{\alpha}$ and $x_F = x_1 - x_2$, where x_1 is the momentum fraction of the gluon in the deuteron. This x_F scaling may be caused by energy loss of the gluon in the initial state [7], or by an energy conservation effect ("Sudakov suppression") [28] which causes a universal suppression that increases with x_F for production of J/ψ's and other hadrons. It is also similar to that observed for more positive rapidity hadron production in the d + Au "limiting fragmentation" region [29].

Invariant cross sections versus transverse momentum, $(d^2\sigma/dydp_T)/(2\pi p_T)$, have been fit to the form $A \times (1 + (p_T/B)^2)^{-6}$ [30]. Average p_T^2 values resulting from these fits are 4.28 ± 0.31, 3.03 ± 0.40, and 3.63 ± 0.25 GeV$/c^2$ for d + Au collisions at negative, zero, and positive x_F, respectively; compared with 2.51 ± 0.21 and 4.31 ± 0.85 GeV$/c^2$ for negative/positive and zero x_F $p + p$ collisions, respectively. The observed p_T broadening is shown in Fig. 3(a). For negative x_F it is consistent with that of the lower energy ($\sqrt{s_{NN}} = 39$ GeV) measurements from E866/NuSea [10], but may be flatter at positive x_F. At zero x_F no p_T broadening is seen within errors.

R_{dA} [Eq. (3)] is shown in Fig. 3(b) for four centrality classes and for minimum-bias collisions. This classification into centrality bins for these results can only be approximate, as indicated by the overlapping histograms of $N_{\rm coll}$. At positive rapidity (small x_2, or the shadowing region), a weak drop for more central collisions is observed, while no significant centrality dependence is seen

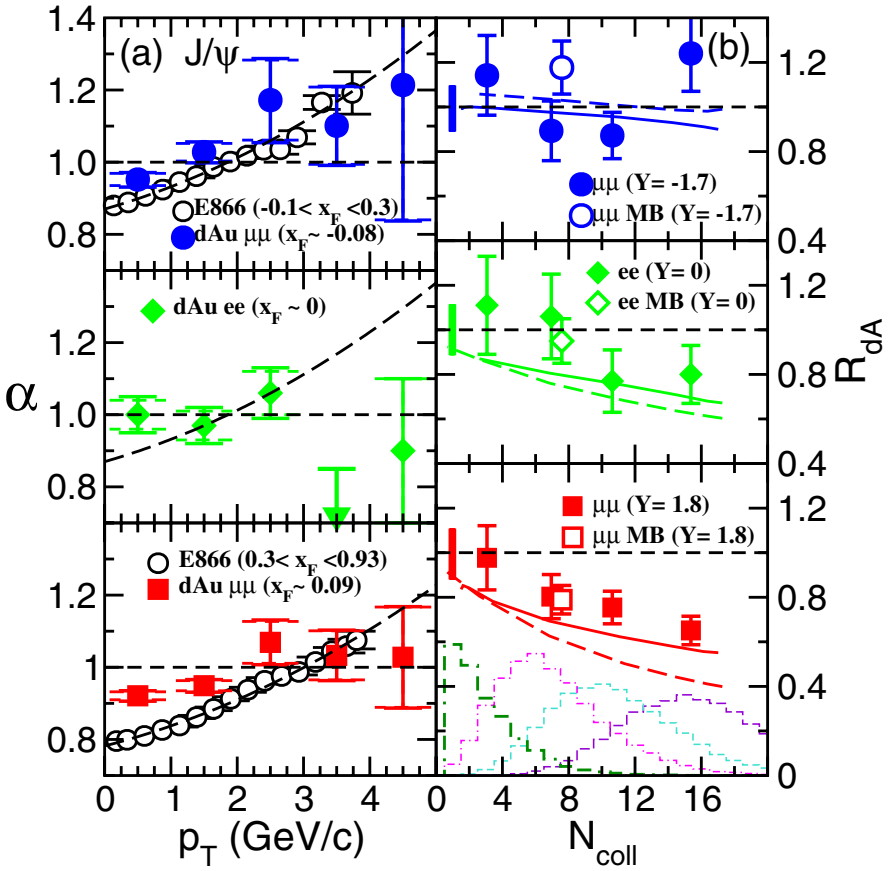

FIG. 3 (color online). (a) α vs p_T compared to lower energy measurements, shown for three different x_F ranges. The error bars have the same meaning as in Fig. 1. An additional 0.02 overall uncertainty is not shown. The dashed curves are simple fits [10] to the lower energy results. (b) Nuclear modification factor vs centrality as given by the number of nucleon + nucleon collisions shown for three different rapidity ranges, compared to theoretical calculations [24,25] including final-state absorption and EKS (solid) or FGS (dashed) shadowing. The bars at the low end of each plot represent the systematic errors between different rapidity ranges. An additional 12% global error bar is not shown. The histograms at the bottom of the lower panel indicate the distribution of the number of collisions for each of the four centrality bins.

for negative rapidity or for central rapidity. The theoretical curves on Fig. 3(b) correspond to different amounts of density dependent shadowing and antishadowing [24,25] and also include absorption. They are consistent with our data except at positive rapidity where the EKS shadowing curve is closest to our results, although slightly lower perhaps due to the amount of absorption that is included.

In summary, during the RHIC 2003 run, the PHENIX experiment measured nuclear effects on J/ψ production for $d + \mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV. Increasing suppression for larger rapidity (smaller x_2) and for more central collisions (higher nuclear densities sampled) both are consistent with models containing a small amount of impact-parameter dependent shadowing and with weak absorption. Theoretical calculations which include EKS shadowing seem most consistent with the data. However, comparisons with other measurements at lower energies show that shadowing cannot be the dominant effect, at least not for the lower energy measurements. We also see some transverse momentum broadening which is consistent with that seen at lower energy. Higher luminosity $d + \mathrm{Au}$ running in the future yielding higher numbers of J/ψ's will be necessary to quantify these nuclear effects and to more clearly distinguish between various theoretical models of shadowing, absorption, and other cold nuclear matter effects.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We acknowledge support from the Department of Energy and NSF (USA), MEXT and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), IN2P3/CNRS, CEA, and ARMINES (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE and DST (India), ISF (Israel), KRF and CHEP (Korea), RMIST, RAS, and RMAE (Russia), VR and KAW (Sweden), US CRDF for the FSU, US-Hungarian NSF-OTKA-MTA, and US-Israel BSF.

(Received 17 July 2005; published 11 November 2005)

Transverse single-spin asymmetries to probe the transverse-spin structure of the proton have been measured for neutral pions and nonidentified charged hadrons from polarized proton-proton collisions at midrapidity and $\sqrt{s} = 200$ GeV. The data cover a transverse momentum (p_T) range 1.0–5.0 GeV/c for neutral pions and 0.5–5.0 GeV/c for charged hadrons, at a Feynman-x value of approximately zero. The asymmetries seen in this previously unexplored kinematic region are consistent with zero within errors of a few percent. In addition, the inclusive charged hadron cross section at midrapidity from $0.5 < p_T < 7.0$ GeV/c is presented and compared to next-to-leading order perturbative QCD (pQCD) calculations.

Successful description of the unpolarized cross section above ~ 2 GeV/c suggests that pQCD is applicable in the interpretation of the asymmetry results in the relevant kinematic range.

DOI: 10.1103/PhysRevLett.95.202001 PACS numbers: 14.20.Dh, 13.85.Ni, 13.88.+e, 25.40.Ep

The spin structure of the proton persists as an intricate problem in quantum chromodynamics (QCD). In particular, its transverse-spin structure remains poorly understood. The measurement of transverse single-spin asymmetries (SSAs) in proton-proton collisions and lepton-nucleon deep-inelastic scattering (DIS) probes the quark and gluon structure of transversely polarized nucleons. Interest in these measurements is heightened by the large transverse SSAs observed in spin-dependent proton-proton scattering experiments spanning a wide range of energies. At $\sqrt{s} = 5$–10 GeV, asymmetries approaching 30% were seen in forward inclusive pion production [1,2]. At midrapidity, asymmetries were also observed in inclusive π^0 and π^+ but not π^- production [3–5]. At higher center-of-mass energies of 20 and 200 GeV, π^+, π^-, and π^0 asymmetries were found to persist at large Feynman-x (x_F) [6–8] while the asymmetry in π^0 production at midrapidity was found to be consistent with zero at $\sqrt{s} = 20$ GeV [9]. Nonzero transverse asymmetries have also been observed in semi-inclusive DIS experiments [10–12].

Three different mechanisms have been studied as the possible origin of transverse SSAs in hadron collisions at high energies: (1) Transversity distributions, the quark spin distributions in a transversely polarized proton, can give rise to SSAs in combination with spin-dependent fragmentation functions (FFs), e.g., the Collins function [13]. Spin-dependent FFs serve as analyzers for the transverse spin of the struck quark. (2) Quark and gluon distributions that are asymmetric in the transverse intrinsic parton momentum, k_T, first suggested by Sivers [14], can lead to SSAs. (3) Alternatively, interference between quark and gluon fields in the initial or final state can also generate SSAs [15,16]. Sivers parton distributions can exist for both quarks and gluons, and a possible connection to orbital angular momentum of partons in the nucleon has been suggested [14,17].

It is expected that SSAs measured at the Relativistic Heavy Ion Collider (RHIC) result from a combination of these three effects (see [8], and references therein). Model calculations leading to predictions for the Sivers and transversity distributions have been performed to describe existing data at forward rapidities. Precision measurements of SSAs in different regions of x_F and transverse momentum (p_T) and their QCD analysis may serve to quantify contributions from the competing mechanisms. In this Letter, we present first measurements of transverse single-spin asymmetries at midrapidity and collider energies.

These data were collected during the 2001–2002 polarized proton run at RHIC, in which approximately 0.15 pb^{-1} of integrated luminosity were collected using the PHENIX detector. Two beams of 55 bunches of polarized protons, with approximately 5×10^{10} protons per bunch, were injected into RHIC and accelerated to 100 GeV each.

Measurements of the unpolarized production of charged hadrons and of the spin-dependent production of neutral pions and charged hadrons were made in the central arms of the PHENIX detector. These cover a pseudorapidity range $|\eta| < 0.35$ and two azimuthal angle intervals of 90°, offset 33.75° from vertical [18].

A minimum-bias (MB) collision trigger and the vertex position in the beam direction are provided by two beam-beam counters (BBCs) [19]. The BBCs, which cover 2π in azimuth and $3.0 < |\eta| < 3.9$, are sensitive to charged particles and select approximately half of the total inelastic proton-proton cross section. A ± 30 cm event vertex cut was applied for all analyses, corresponding to the central arm acceptance. The approximate vertex resolution was 2 cm in the beam direction.

Charged-particle tracks from MB events were reconstructed using a drift chamber and pad chambers [20] as well as the collision vertex, which is the assumed point of origin because the tracking chambers are placed outside the magnetic field. Thus charged particles that do not originate at the vertex have incorrectly reconstructed momentum, leading to low-momentum, long-lived particle decays (e.g., $K^{\pm}$, K^0_L) and conversion electrons as the two main sources of background.

For the charged hadron cross section, approximately 17×10^6 MB events were analyzed. The luminosity was measured as $N_{\mathrm{BBC}}/\sigma_{\mathrm{BBC}}$ with $\sigma_{\mathrm{BBC}} = 21.8$ mb [21], accounting for the fraction of the yield for which the MB condition was satisfied. Backgrounds were estimated and subtracted statistically following the method of [22]: Conversion electrons were estimated using the different response of the ring-imaging Čerenkov detector (RICH) [23] to electrons and charged pions, and decay particles were estimated using the track bend in the residual magnetic field in the tracking detectors. Weak decays of short-lived particles, mainly K^0_S, Λ, and $\bar{\Lambda}$, remain, especially when they decay close to the vertex. Based on a Monte Carlo simulation, the reported cross section was reduced by 7% over the entire p_T range to correct for these decays.

The unpolarized cross section for inclusive charged hadron production at midrapidity is presented in Fig. 1 and Table I. The dominant systematic uncertainty for $p_T > 5$ GeV/c is from the background subtraction, while for $p_T < 5$ GeV/c it is due to the weak-decay correction.

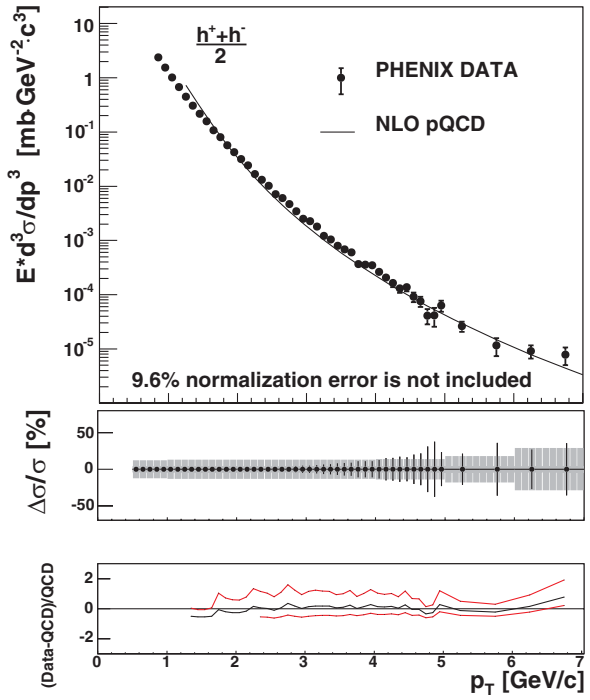

FIG. 1 (color online). Top panel: Invariant cross section vs p_T for the production of charged hadrons at midrapidity, averaged over sign. A 9.6% normalization uncertainty is not shown. The curve represents a NLO pQCD calculation at a renormalization scale of p_T [26]. Middle panel: The relative statistical (points) and point-to-point systematic (band) errors. Bottom panel: The relative difference between the data and the theory with scales of $p_T/2$ (lower curve), p_T, and $2p_T$ (upper curve).

There is a 9.6% normalization uncertainty due to the luminosity measurement. In Fig. 1 the cross section is compared to a next-to-leading-order (NLO) perturbative QCD (pQCD) calculation using the CTEQ6M [24] parton distribution functions and Kniel-Kramer-Pötter FFs [25] and found to be consistent above $p_T \sim 2$ GeV/c. The unpolarized cross sections for midrapidity and forward production of neutral pions have also been measured in 200 GeV proton-proton collisions at RHIC [8,21] and have been found to agree well with NLO pQCD calculations [26–28]. This agreement between all of these unpolarized measurements and theory indicates that NLO pQCD is applicable in interpreting polarized data at $\sqrt{s} =$ 200 GeV and provides a solid theoretical foundation for the study of the spin structure of the proton at RHIC.

The stable spin direction of the protons through acceleration and storage is vertical, and there is an approximately equal number of bunches filled with the spin of the protons up as there is down. With both beams polarized, single-spin analyses were performed by taking into account the spin states of one beam, averaging over those of the other. The beam polarization at 100 GeV was obtained using the same analyzing power (A_N^{pC}) in proton-carbon elastic scattering in the Coulomb-nuclear interference region measured at 22 GeV (see [29], and references therein), near RHIC injection energy. The average beam polarization was $15 \pm 5\%$.

TABLE I. Selected invariant cross section values for $(h^+ + h^-)/2$ corresponding to Fig. 1. A 9.6% normalization uncertainty is not included.

p_T (GeV/c)	Invariant cross section (mb/GeV^2)	Statistical error (%)	Systematic error (%)
0.55	1.06×10^{1}	0.2	8
1.05	1.02×10^{0}	0.4	8.5
1.55	1.58×10^{-1}	0.9	8.5
2.05	3.16×10^{-2}	1.7	9
2.55	7.14×10^{-3}	3.2	9
3.05	2.28×10^{-3}	5.1	9
3.55	6.86×10^{-4}	8.5	9
4.05	2.63×10^{-4}	12.8	9.5
4.55	9.12×10^{-5}	20.2	9.5
5.25	2.61×10^{-5}	21.2	16
5.75	1.16×10^{-5}	36.3	16
6.25	9.12×10^{-6}	27.2	28
6.75	7.82×10^{-6}	35.7	28

The left-right transverse single-spin asymmetry, A_N, can be extracted using

$$A_N = \frac{1}{P_{\mathrm{b}}}\left(\frac{\sigma^{\uparrow} - \sigma^{\downarrow}}{\sigma^{\uparrow} + \sigma^{\downarrow}}\right) = \frac{1}{P_{\mathrm{b}}}\frac{1}{\langle|\cos\phi|\rangle}\left(\frac{N^{\uparrow} - \mathcal{R}N^{\downarrow}}{N^{\uparrow} + \mathcal{R}N^{\downarrow}}\right), \quad (1)$$

where P_{b} is the beam polarization, $\sigma^{\uparrow}$ ($\sigma^{\downarrow}$) the production cross section when the protons in the bunch are polarized up (down), $N^{\uparrow}$ ($N^{\downarrow}$) the experimental yield from up- (down-) polarized bunches, and $\mathcal{R} = \mathcal{L}^{\uparrow}/\mathcal{L}^{\downarrow}$ the relative integrated luminosity of bunches of opposite polarization sign. The azimuthal term accounts for the coverage of the central arms. The above formula as written applies to yields observed to the left of the polarized beam. An overall minus sign is required for yields observed to the right of the polarized beam. Alternatively, we derive the asymmetry using

$$A_N = \frac{1}{P_{\mathrm{b}}}\frac{1}{\langle|\cos\phi|\rangle}\left(\frac{\sqrt{N_L^{\uparrow}N_R^{\downarrow}} - \sqrt{N_L^{\downarrow}N_R^{\uparrow}}}{\sqrt{N_L^{\uparrow}N_R^{\downarrow}} + \sqrt{N_L^{\downarrow}N_R^{\uparrow}}}\right), \quad (2)$$

which calculates a single value for the asymmetry taking into account yields from both the left (N_L) and right (N_R) sides of the polarized beam and provides a consistency check on the relative luminosity [30].

The BBCs were used to determine the relative luminosity [$\mathcal{R}$ in Eq. (1)] between bunches of opposite polarization sign fill-by-fill. A typical $\mathcal{R}$ for the data sample analyzed here was approximately 1.09, measured to better than 10^{-3}. In the asymmetry analysis of charged hadrons, which utilized ~13 M minimum-bias events, it was required that

TABLE II. Neutral pion transverse single-spin asymmetry values and statistical uncertainties for all photon pairs falling within the π^0 mass peak, for the background (bg), and for the π^0 background corrected. The third column (r) indicates the background contribution under the π^0 peak. An A_N scale uncertainty of $\pm 35\%$ is not included.

p_T (GeV/c)	$\langle p_T \rangle$ (GeV/c)	r (%)	A_N^{peak} (%)	A_N^{bg} (%)	$A_N^{\pi^0}$ (%)
1–2	1.45	34	-0.6 ± 0.8	-0.7 ± 0.9	-0.5 ± 1.2
2–3	2.34	12	-1.4 ± 1.7	-3.1 ± 3.4	-1.2 ± 2.0
3–4	3.36	6	-1.3 ± 4.2	3.6 ± 12.2	-1.6 ± 4.7
4–5	4.38	5	7.0 ± 10.1	42 ± 39	5.2 ± 10.9

there be no hits in the RICH in order to eliminate electrons from photon conversions which mimic high-p_T charged tracks. The momentum threshold for production of Čerenkov radiation by pions was 4.7 GeV/c, allowing the RICH veto to preserve nearly all charged pions. The electron contamination in the final data sample was less than 1%. The decay background from long-lived particles was less than 5%.

Neutral pions were reconstructed via their decay to two photons using finely segmented ($\Delta\phi \times \Delta\eta \approx 0.01 \times 0.01$) electromagnetic calorimeters (EMCal) [31]. Photon clusters were selected by their shower shape and a charged track veto. Approximately 18 M events recorded by an EMCal–based high-energy photon trigger in coincidence with the BBC collision trigger were analyzed [21]. The trigger efficiency for neutral pions varied from ~24% in the 1–2 GeV/c bin to ~78% in the 4–5 GeV/c bin. Only triggered events were used in this analysis. The π^0 peak widths varied from 13.2 MeV/c^2 in the 1–2 GeV/c bin to 10.6 MeV/c^2 in the 4–5 GeV/c bin. The contribution from combinatorial background ranged from 34% to 5% across these bins; in order to avoid errors associated with peak extraction it was not subtracted.

The asymmetry for neutral pions and charged hadrons was determined for each fill using Eq. (1), then averaged over all fills. The contribution to the π^0 asymmetry by the background under the peak was estimated by calculating the asymmetry of 50 MeV/c^2 regions on both sides of the signal, from 60–110 MeV/c^2 and 170–220 MeV/c^2 (see Table II). The asymmetry of the signal region and its uncertainty were then corrected using

$$A_N^{\pi^0} = \frac{A_N^{\text{peak}} - r A_N^{\text{bg}}}{1 - r}, \qquad \sigma_{A_N^{\pi^0}} = \frac{\sqrt{\sigma^2_{A_N^{\text{peak}}} + r^2 \sigma^2_{A_N^{\text{bg}}}}}{1 - r}, \quad (3)$$

where r is the fraction of background under the peak.

As the dominant systematic uncertainty is expected to be from the determination of the relative luminosity, systematic errors were evaluated by direct comparison of the asymmetry values calculated using Eqs. (1) and (2). Any potential effect should be the same for both the charged hadron and neutral pion analyses. No p_T dependence was expected or observed; therefore, we take the weighted average of the systematic uncertainties calculated for each bin, 0.002, as the overall, uniform systematic uncertainty.

The asymmetries are plotted vs p_T in Fig. 2 and shown in Tables II and III. The asymmetries are consistent with zero over the entire transverse momentum range.

In this Letter we have presented the first measurement of transverse-spin asymmetries A_N at midrapidity and high p_T at collider energies and the cross section for inclusive charged hadrons at midrapidity. NLO pQCD calculations have been found to reproduce experimental results for $p_T \gtrsim 2$ GeV/c not only for the cross section presented here but also for inclusive neutral pion production, indicating that pQCD can be used to interpret the high-p_T asymmetries. The transverse SSAs observed for midrapidity production of both neutral pions and charged hadrons are consistent with zero within statistical errors of a few percent, measured over $0.5 < p_T < 5$ GeV/c. The result is consistent with the midrapidity results for neutral pions at $\sqrt{s} = 20$ GeV [9]. The present measurement is complementary to that of [8]. The large asymmetries observed in neutral pion production at forward rapidity at $\sqrt{s} = 200$ GeV [8] are expected to originate from partonic processes involving valence quarks ($x > 0.1$), whereas the

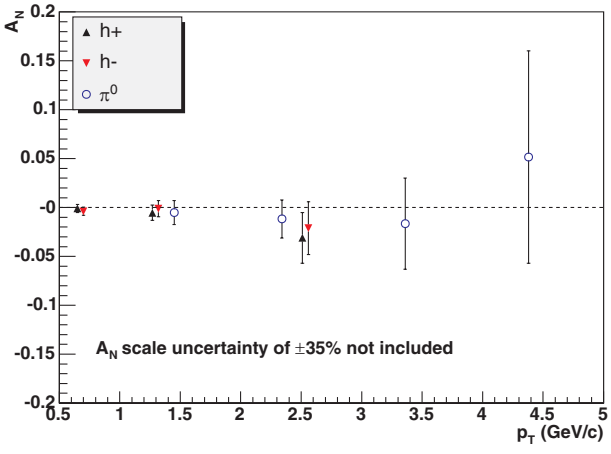

FIG. 2 (color online). Midrapidity neutral pion and charged hadron transverse single-spin asymmetry A_N vs transverse momentum. Points for positive hadrons have been shifted down by 50 MeV/c to improve readability. The error bars indicate statistical uncertainties.

TABLE III. Charged hadron transverse single-spin asymmetry values and statistical uncertainties. An A_N scale uncertainty of $\pm 35\%$ is not included.

p_T (GeV/c)	$\langle p_T \rangle$ (GeV/c)	$A_N^{h^-}$ (%)	$A_N^{h^+}$ (%)
0.5–1	0.70	-0.38 ± 0.42	-0.09 ± 0.41
1–2	1.32	-0.12 ± 0.82	-0.54 ± 0.78
2–5	2.56	-2.1 ± 2.7	-3.1 ± 2.6

particle production at midrapidity presented here is dominated by gluon-gluon and quark-gluon processes ($x < 0.1$). Our results are consistent with the pQCD expectation that quark-gluon correlations are suppressed at high p_T and midrapidity [15,32]. A QCD analysis of the presented A_N may lead to constraints on gluon-Sivers contributions to observed transverse-spin phenomena. The present transverse single-spin asymmetries represent an early measurement in a rigorous program to study transverse proton spin structure at hard scales using a pQCD framework at RHIC.

We thank the staff of the Collider-Accelerator Department, Magnet Division, and Physics Department at BNL and the RHIC polarimetry group for their vital contributions. We thank W. Vogelsang for calculations as well as numerous useful discussions. (Received 1 July 2005; published 2 August 2006)

Azimuthal correlations of jet-induced high-p_T charged hadron pairs are studied at midrapidity in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The distribution of jet-associated partner hadrons ($1.0 < p_T < 2.5$ GeV/c) per trigger hadron ($2.5 < p_T < 4.0$ GeV/c) is found to vary with collision centrality, in both shape and yield, indicating a significant effect of the nuclear collision medium on the jet fragmentation process.

DOI: 10.1103/PhysRevLett.97.052301 PACS numbers: 25.75.Dw

Energetic collisions between heavy ions at the Relativistic Heavy Ion Collider (RHIC) have been shown to produce matter with extremely high energy density [1]. This matter has been observed to strongly suppress the yield of hadrons with large transverse momenta in central Au + Au collisions, compared to yields in $p + p$ collisions scaled by the number of binary nucleon-nucleon collisions [2–5]. Such a suppression was predicted to result from energy loss of hard-scattered partons (light quarks and gluons) traversing the dense matter prior to forming the observed hadrons [6,7]. If the parton encounters a sufficient amount of dense matter, the energy loss could strongly modify its fragmentation into jets of hadrons.

Strong suppression of the awayside jet has been observed at RHIC [8]. However, it is unclear at present how the lost energy is transported by the dense medium, and how the parton-medium interaction affects the fragmentation process. Recently, there have been predictions that the coupling of jets to a strongly interacting medium may modify the angular distribution and number of jet fragments [9–16]. Quarks from hard scattering processes may recombine with thermal quarks from the dense medium [9,10]. Comoving radiated gluons may produce a ''wake'' in the medium, further increasing the number of quarks available for building hadrons in the jet fragmentation process [11,13]. It has even been proposed that the energy deposited in the medium creates a shock wave around the propagating parton, thereby creating a ''conical flow'' akin to a sonic boom in a fluid [14–16]. To investigate the transport of lost parton energy, the PHENIX experiment at RHIC measures azimuthally correlated hadrons arising from jet fragmentation as a function of centrality in Au + Au collisions. Such studies, in effect, use hard-scattered partons as short-wavelength probes of the produced medium.

The analysis presented in this Letter uses data from $\sqrt{s_{NN}} = 200$ GeV Au + Au collisions in the PHENIX 2002 data set. Charged particles are reconstructed in the central arms of PHENIX using drift chambers, each with azimuthal coverage of $\pi/2$, and two layers of multiwire proportional chambers with pad readout (PC1, PC3) [17]. Pattern recognition is based on a combinatorial Hough transform in the track bend plane, with the polar angle determined by PC1 and the collision vertex along the beam direction [18]. Particle momenta are measured with a resolution $\delta p/p = 0.7\% \oplus 1.0\% p$ (GeV/c). To reject most background from albedo, conversions, and decays, a confirmation hit is required within a 2σ matching window in PC3 [2]. The Au + Au event centrality is determined using the PHENIX beam-beam counters (BBC) and zero-degree calorimeters [19].

The traditional identification of jets through hadronic calorimetry and cluster algorithms is problematic in Au + Au collisions at RHIC, since low-energy jets (<10–20 GeV) are overwhelmed by other produced particles in the underlying event and high-energy jets are relatively rare at $\sqrt{s_{NN}} = 200$ GeV. Instead, we study hard-scattered single partons and parton pairs through angular correlations of high-p_T hadron pairs. We examine the distribution of pairs over relative azimuthal angle $dN^{AB}/d(\Delta\phi)$, where A and B denote charged particles in the PHENIX pseudorapidity acceptance ($|\eta| < 0.35$) and in p_T bins $2.5\ \text{GeV}/c < p_T^A < 4.0\ \text{GeV}/c$ (''trigger'') and $1.0\ \text{GeV}/c < p_T^B < 2.5\ \text{GeV}/c$ (''partner''). Pairs from fragments of the same jet are expected to appear near $\Delta\phi \sim 0$, while $\Delta\phi \sim \pi$ indicates one hadron each from the outgoing hard-scattered parton pair (hereafter ''dijet'').

The PHENIX acceptance at central rapidity is nonuniform in azimuth. We correct for the shape of the acceptance in $\Delta\phi$ through the standard approach of constructing a correlation function, area normalized, utilizing pairs from mixed events:

$$C(\Delta\phi) \equiv \frac{Y^{AB}_{\text{same}}(\Delta\phi)}{Y^{AB}_{\text{mixed}}(\Delta\phi)} \frac{\int Y^{AB}_{\text{mixed}}(\Delta\phi)d(\Delta\phi)}{\int Y^{AB}_{\text{same}}(\Delta\phi)d(\Delta\phi)} \propto \frac{dN^{AB}}{d(\Delta\phi)}, \quad (1)$$

where $Y^{AB}_{\text{same}}(\Delta\phi)$ and $Y^{AB}_{\text{mixed}}(\Delta\phi)$ are, respectively, the uncorrected yields of pairs in the same event and in mixed events, each of which are chosen uniformly within each data sample.

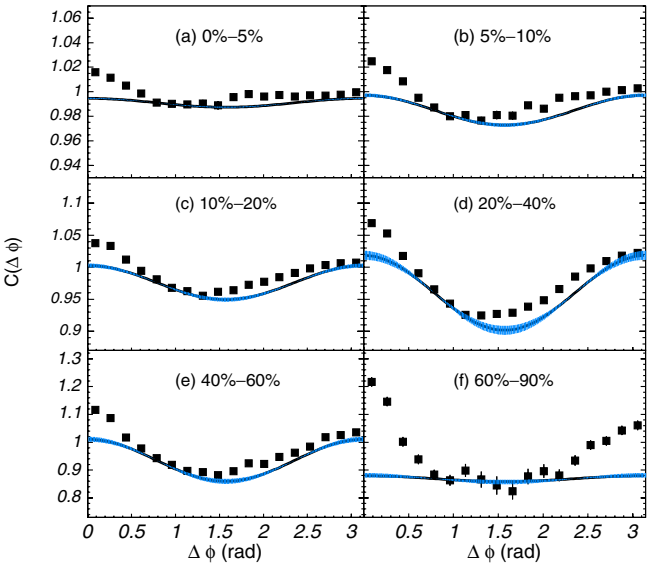

FIG. 1 (color online). Correlation functions, $C(\Delta\phi)$, for pairs of charged hadrons with $2.5\ \text{GeV}/c < p_T^A < 4.0\ \text{GeV}/c$ and $1.0\ \text{GeV}/c < p_T^B < 2.5\ \text{GeV}/c$ in different bins of collision centrality from the most central (a) 0%–5% to the most peripheral (f) 60%–90%. The solid bands indicate the estimate of the background pair component (see text) within one unit of its systematic error.

The correlation functions are shown in Fig. 1, folded into the range $0 < \Delta\phi < \pi$. For the most peripheral collisions [cf. Fig. 1(f)], the correlation function shows two well-defined peaks centered at $\Delta\phi = 0$ and $\Delta\phi = \pi$, which we can attribute to (di)jet pairs. For more central collisions, there is a similar peak at $\Delta\phi = 0$, a broader peak at $\Delta\phi = \pi$, and the apparent minima appear at $\Delta\phi < \pi/2$. These features reflect a mixture of (di)jet pairs and underlying events with particle flow along the reaction plane [20].

In order to extract and examine the jet-induced pairs, we analyze the pair distribution in the context of a *two-source model*, assuming that each hadron can be attributed to either (i) a jet fragmentation source or (ii) the underlying event. Additionally, we assume that the ϕ distributions for A or B inclusive single particles, summed over both sources, have a shape proportional to $\{1 + 2\langle v_2^{A\text{ or }B}\rangle \times \cos[2(\phi - \Phi_{\mathrm{RP}})]\}$ relative to azimuthal angle Φ_{RP} of the reaction plane of each event. All pairs which are not from the same jet or dijet fragmentation are termed *background pairs*, and are taken to have no angular correlation beyond having their distributions respect the same reaction plane. In principle, contributions from resonance decays and global transverse momentum conservation can also affect the distribution of background pairs, but we estimate these effects to be negligible for these p_T ranges and the PHENIX η acceptance. The distribution of background pairs over $\Delta\phi$ is then proportional to $[1 + 2\langle v_2^A v_2^B\rangle \times \cos(2\Delta\phi)]$ [20].

Given a normalization, $C(\Delta\phi)$ can then be decomposed into two pieces, one proportional to the distribution of background pairs and another $J(\Delta\phi)$ proportional to that of the (di)jet pairs:

$$C(\Delta\phi) = b_0[1 + 2\langle v_2^A v_2^B\rangle \cos(2\Delta\phi)] + J(\Delta\phi). \quad (2)$$

We approximate $\langle v_2^A v_2^B\rangle = \langle v_2^A\rangle\langle v_2^B\rangle$, and we measure $\langle v_2^A\rangle$ and $\langle v_2^B\rangle$ for each centrality and particle p_T bin through a standard reaction-plane analysis using the PHENIX BBC to reconstruct the reaction plane event by event. The large rapidity gap, $\Delta\eta > 2.75$, between the central arm acceptance and the BBC acceptance substantially reduces nonflow contributions to the measured v_2 values, particularly those arising from (di)jets. The results are shown in Table I; they are consistent with prior PHENIX v_2 measurements [21], where available.

The average level of the background b_0 can, in principle, be fixed by making an assumption about the shape of the (di)jet-pair distribution. However, since we wish to measure the shape of the (di)jet azimuthal correlations, we use a technique that requires no such *a priori* assumptions. The simplest assumption allowing b_0 to be fixed is that $dN^{AB}_{(\mathrm{di})\mathrm{jet}}/d(\Delta\phi)$ is zero for at least one value of $\Delta\phi$ (i.e., $\Delta\phi_{\mathrm{min}}$). We refer to this as the ZYAM ("zero yield at minimum") assumption for the (di)jet-pair distribution. The ZYAM condition is met by varying b_0 until the background component matches a functional fit to the correlation function at one point $\Delta\phi_{\mathrm{min}}$, as illustrated by the solid bands in Fig. 1. The systematic error on b_0 associated with this procedure (see Fig. 2) was estimated by using a variety of functional forms that matched the data.

TABLE I. Anisotropy values for bins A ($2.5 < p_T < 4.0$ GeV/c) and B ($1.0 < p_T < 2.5$ GeV/c), shown with statistical errors, and values of ϕ_{min} (see text). The relative systematic errors on the anisotropies are estimated to be $\pm 6\%$ for the five most central samples and $\pm 40\%$ for the most peripheral sample. The systematic errors on the v_2's are dominated by the uncertainty in the correction for reaction plane resolution [21], and we assume them to be completely correlated between the two p_T bins in each centrality sample.

Centrality (%)	$\langle v_2^B\rangle$	$\langle v_2^A\rangle$	ϕ_{min} (rad)
0–5	0.035 ± 0.001	0.052 ± 0.007	0.94
5–10	0.062 ± 0.001	0.100 ± 0.005	0.96
10–20	0.095 ± 0.0005	0.144 ± 0.003	0.98
20–40	0.146 ± 0.0004	0.208 ± 0.003	0.91
40–60	0.171 ± 0.001	0.236 ± 0.006	0.86
60–90	0.066 ± 0.001	0.091 ± 0.004	1.06

A nonzero yield of (di)jet pairs at $\Delta\phi_{\mathrm{min}}$ would invalidate the ZYAM assumption and result in an overestimate of the value of b_0. To verify that we are not making a significant error in the normalization of the background, we have independently estimated the b_0 values using the AB pair combinatorial rate, corrected for a slight bias

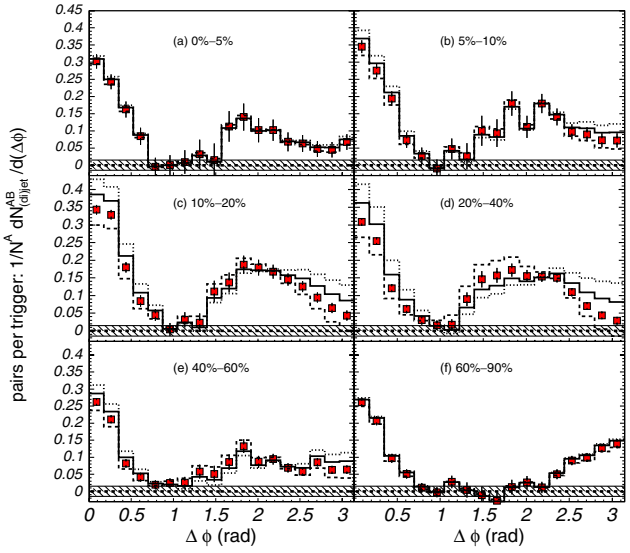

FIG. 2 (color online). Jet-pair distributions $dN^{AB}_{(\mathrm{di})\mathrm{jet}}/d(\Delta\phi)$ for different centralities, normalized per trigger particle. The shaded bands indicate the systematic error associated with the determination of $\Delta\phi_{\mathrm{min}}$. The dashed (solid) curves are the distributions that would result from increasing (decreasing) $\langle v_2^A v_2^B\rangle$ by one unit of the systematic error; the dotted curve would result from decreasing by two units.

introduced by mixing events of different multiplicity within the same centrality class [22]. These independent estimates are consistent with the ZYAM-determined values for b_0, confirming that we are not significantly overestimating the background levels.

Once $\langle v_2^A v_2^B \rangle$ and b_0 are fixed, we can extract $J(\Delta\phi)$ and the fully corrected (di)jet pairs distribution $dN^{AB}_{(\mathrm{di})\mathrm{jet}}/d(\Delta\phi)$. We construct the conditional yield distribution of jet-associated partners per trigger:

$$\frac{1}{N^A}\frac{dN^{AB}_{(\mathrm{di})\mathrm{jet}}}{d(\Delta\phi)} = \frac{J(\Delta\phi)}{\int C(\Delta\phi')d(\Delta\phi')}\frac{N^{AB}}{N^A}. \quad (3)$$

Here, N^A is the number of triggers and N^{AB} is the total number of AB pairs in the event sample. Assuming that the pair efficiency is the product of the single particle efficiencies, the trigger (A) efficiency cancels in Eq. (3). Thus, the ratio is corrected for acceptance and reconstruction efficiency [5] of the lower-p_T B particles; the systematic error on this correction leads to a 10% uncertainty on the associated yields.

The conditional yields of (di)jet-induced partners per trigger are shown in Fig. 2. For the most peripheral event sample the (di)jet-associated yield distribution has an appearance we might expect from a normal (di)jet fragmentation process [23]: a well-defined nearside peak around $\Delta\phi = 0$ and a somewhat wider awayside peak around $\Delta\phi = \pi$. For more central event samples the shape of the nearside peak is essentially unchanged while the associated yield in the nearside peak increases, indicating some change in the fragmentation process.

The much more dramatic change, however, is in the awayside peak, which is considerably broader in all the event samples more central than 60%. In midcentral and central collisions there is a local minimum at $\Delta\phi = \pi$. The existence of these local minima *per se* is not significant once we take the systematic errors on $\langle v_2^A v_2^B \rangle$ into account (see below), but it is clear that the awayside peaks in all the more central samples have a very different shape than in the most peripheral sample.

Given the dramatic results for the awayside peaks seen in Fig. 2, it is important to establish that they are not simply artifacts created by our method for background pair subtraction. If we relax the ZYAM assumption and lower b_0 slightly, the effect on any (di)jet-pair distribution would essentially be to raise it by a constant, which would not change the presence of the local minima at $\Delta\phi = \pi$, but would increase the per trigger yields. ZYAM derived yields are lower limit yields [20].

Changes to our estimate for $\langle v_2^A v_2^B \rangle$ can alter the shape of the (di)jet distribution for some centrality samples, but the result of awayside broadening with centrality remains robust. The curves in Fig. 2 show the distributions that would result if the $\langle v_2^A v_2^B \rangle$ products were arbitrarily lowered by one and two units of their systematic error. With a two-unit shift the shape in the midcentral would no longer show significant local minima at $\Delta\phi = \pi$. However, the widths of the awayside peaks are clearly still much greater than in the peripheral sample and the distributions in the two most central samples are hardly changed at all in shape. Even lower values of $\langle v_2^A v_2^B \rangle$ could be contemplated, but they would still not change the qualitative result of awayside broadening. And, such low $\langle v_2^A v_2^B \rangle$ values would also require a severe breakdown of the assumption $\langle v_2^A v_2^B \rangle = \langle v_2^A \rangle \langle v_2^B \rangle$, indicating that these background pairs have a large, hitherto-unknown source of azimuthal anticorrelation.

Convoluting the jet fragments' angles with respect to their parent partons and the acoplanarity between the two partons [23] would yield a Gaussian-like shape in $\Delta\phi$, possibly broadened through jet quenching [13,24]. The observed shapes in the awayside peaks cannot result from such a convolution.

We define the part of the $\Delta\phi$ distribution in $|\Delta\phi| < \Delta\phi_{\mathrm{min}}$ as the "nearside" peak and $|\Delta\phi| > \Delta\phi_{\mathrm{min}}$ as the "awayside" peak. Each peak is characterized by its yield of associated partners per trigger and by its rms width. We measure these for the full peak in the distribution over all values of $\Delta\phi$; the folded distributions over $0 < \Delta\phi < \pi$ shown here contain only half of each full peak's shape. These yields and widths are plotted in Fig. 3 for the different Au + Au centrality samples, along with the same quantities for 0%–20% central d + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [23]. The yields and widths for the near- and awayside peaks in peripheral Au + Au collisions are consistent with those in d + Au collisions. The yields of both the near- and awayside peaks increase from peripheral to midcentral collisions, and then decrease for the most central collisions. The nearside width is unchanged with centrality, while the awayside width in-

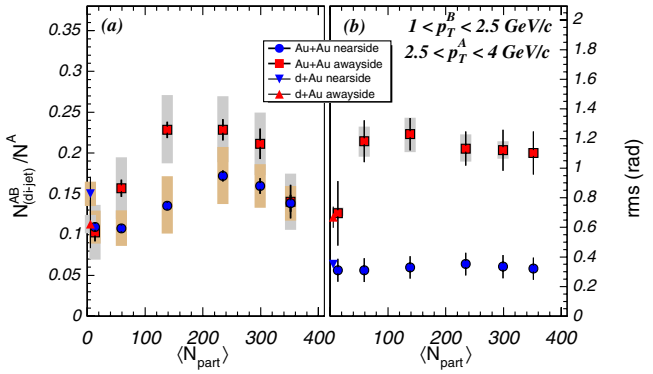

FIG. 3 (color online). (a) Associated yields for near- and awayside peaks in the jet-pair distribution, and (b) widths (rms) of the peaks in the full 0–2π distributions; plotted versus the mean number of participating nucleons for each event sample. Triangles show results from 0%–20% central d + Au collisions at the same $\sqrt{s_{NN}}$ [23]. Bars show statistical errors, shaded bands systematic.

creases substantially from the 60%–90% sample to the 40%–60% sample, and then remains constant with centrality.

In summary, we have presented correlations of high momentum charged hadron pairs as a function of collision centrality in Au + Au collisions. Utilizing a novel technique, we extract the jet-induced hadron pair distributions and show that the dense medium formed in Au + Au collisions at RHIC modifies jet fragmentation. In central and midcentral collisions the awayside angular distribution is significantly broadened relative to peripheral and d + Au collisions, and appears to be non-Gaussian. The shapes of the awayside $\Delta\phi$ distributions for non-peripheral collisions are apparently not consistent with Gaussian broadening of the peripheral Au + Au awayside. However, the broadening and possible changes in shape of the awayside jet are suggestive of recent theoretical predictions of dense-medium effects on fragment distributions [14–16,25]. The broadened shapes of the awayside distributions also imply that integration of the awayside peak in a narrow angular range around $\Delta\phi = \pi$ yields fewer associated partners in central collisions than in peripheral or d + Au collisions, as seen elsewhere [8,22]; but integrating over the entire broadened peak recovers the jet partners in the range $1.0\ \mathrm{GeV}/c < p_T^B < 2.5\ \mathrm{GeV}/c$ used here. Even though two-particle correlations do not allow for full reconstruction of the jet fragmentation function, these data provide an entirely new way to probe the hot, dense medium formed in heavy ion collisions.

(Received 7 March 2005; published 16 June 2005)

The first measurement of direct photons in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV is presented. The direct photon signal is extracted as a function of the Au + Au collision centrality and compared to next-to-leading order perturbative quantum chromodynamics calculations. The direct photon yield is shown to scale with the number of nucleon-nucleon collisions for all centralities.

DOI: 10.1103/PhysRevLett.94.232301 PACS numbers: 25.75.Dw

One of the most exciting observations from experiments at the Relativistic Heavy Ion Collider (RHIC) is the strong suppression of the yield of hadrons at large transverse momenta ($p_T > 2$ GeV/c) in central Au + Au collisions, as compared to measured yields in $p + p$ collisions scaled by the number of binary nucleon-nucleon collisions [1–4].

Such quenching was predicted to result from the energy loss of hard-scattered partons propagating through the high density matter created in heavy ion collisions [5]. It was later proposed that the observed hadron suppression could be an initial-state effect due to saturation of the initial parton distributions in large nuclei [6]. The high-p_T hadron suppression was not observed in d + Au collisions [7,8]. This indicates that the suppression in Au + Au collisions is due to the extended dense matter in the final state that is absent in d + Au collisions.

Measurement of direct photon production allows more definitive discrimination between initial- and final-state suppression due to the fact that photons, once produced, are essentially unaffected by the surrounding matter. Hence photons produced directly in initial parton scatterings are not quenched unless the initial parton distributions are suppressed in the nucleus. In fact, there may be additional direct photon yield in AA collisions [9] due to various processes such as momentum broadening of the incoming partons, additional fragmentation contributions [10,11], or additional scatterings in the thermalizing dense matter of the final state.

This Letter reports on direct photon production in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV with data taken by the PHENIX experiment [12] during the second RHIC run (2001–2002). This analysis used the beam-beam counters (BBC, $3.0 < |\eta| < 3.9$) and the zero degree calorimeter (ZDC) for trigger and event characterization, the electromagnetic calorimeter (EMCal) in the two central arms ($|\eta| \leq 0.35$) to measure the inclusive γ, π^0, and η yields, and the tracking system of the central arms to estimate the charged particle contamination. The EMCal consists of two subsystems: six sectors of lead-scintillator sandwich calorimeter (PbSc) and two sectors of lead-glass Čerenkov calorimeter (PbGl). Located at a radial distance of about 5 m, each sector covers an azimuthal interval of $\Delta\phi \approx 22.5°$. The fine segmentation of the EMCal ($\Delta\phi \times \Delta\eta \sim 0.01 \times 0.01$) ensures that the two photons from a decayed π^0 are well resolved up to transverse momenta of 15–20 GeV/c.

The event centrality was selected by cuts on the correlated distribution of charged particles detected in the BBCs versus energy measured in the ZDC detectors. A Glauber model Monte Carlo combined with a simulation of the BBC and ZDC responses gave an estimate of the associated number of binary collisions ($N_{\rm coll}$) and participating nucleons ($N_{\rm part}$) for each centrality bin (values tabulated in Ref. [3]).

For this analysis a minimum bias trigger sample of 30×10^6 events, also used for the previously published π^0 analysis [3], was combined with a level-2 trigger event sample equivalent to additional 55×10^6 minimum bias events. The level-2 trigger sample was obtained by the use of an EMCal software trigger on highly energetic showers equivalent to the level-1 hardware trigger used in Ref. [13]. The threshold energy of the trigger was set at 3.5 GeV with a resulting trigger efficiency plateau at 100% for single photons above $p_T \approx 5$ GeV/c (6.5 GeV/c) for the PbSc (PbGl). The normalization of the level-2 data sample relative to the minimum bias data sample is accurate to 2%. In the following, the minimum bias result refers to the combined level-2 and minimum bias trigger samples without selection on centrality.

The direct photon yield is extracted on a statistical basis, without isolation cuts, by a comparison of the inclusive photon spectra to the expected background from hadronic decays [14,15] (mainly $\pi^0 \rightarrow 2\gamma$). Photonlike clusters are identified in the EMCal by applying appropriate particle identification (PID) cuts based on time of flight and the shower profile. The consistency of the final results obtained independently with the PbSc and PbGl, and with different PID cuts, including no PID cut, is used to check the systematic error estimates. The π^0 and η yields are determined as described in [3,16] by an invariant mass analysis of photon pairs, with the combinatorial background established by combining uncorrelated photon pairs from different events.

The raw inclusive photon-candidate spectra must be corrected for charged and neutral hadron contaminations not removed by the PID cuts, as well as for photon conversions. Charged contaminants are identified by associating photon candidates in the EMCal with charged hits in the pad chamber (PC3) positioned directly in front of the EMCal. The charged contaminant spectra are subtracted from the photon-candidate spectra. The charged hadron contamination depends strongly on the PID cut and increases significantly for $p_T < 3$ GeV/c with a contribution of 4% above 3 GeV/c for the tightest PID cut. The contamination of neutral hadrons (mainly antineutrons) is determined with a full GEANT simulation of the detector response to neutrons and antineutrons with input spectra based on the proton and antiproton yields measured by PHENIX [4]. The neutral hadron contamination is found to be negligible above $p_T = 5$ GeV/c ($< 1\%$). The neutral photon-candidate spectra are corrected for conversions removed by the charged contaminant subtraction with a p_T-independent factor (5.9%–7.3% for different sectors based on simulation).

The raw spectra are normalized to one unit of rapidity and full azimuth (the purely geometrical acceptance correction is $\sim 1/0.35$). The spectra are further corrected for (i) the detector response (energy resolution, dead areas), (ii) the reconstruction efficiency (PID cuts), and (iii) occupancy effects (cluster overlaps). These corrections are quantified by embedding simulated single γ's, π^0's, or η's from a full PHENIX GEANT simulation into real events and by analyzing the merged events with the same analysis cuts used to obtain the real yields. The overall π^0 yield correction was ~ 2.5 with a centrality dependence of $\lesssim 25\%$. The losses were dominated by fiducial and asym-

metry cuts. The nominal energy resolution was adjusted in the simulation by smearing the energies with a constant term of ~5% for PbSc and ~7% for PbGl to reproduce the measured width of the π^0 peak observed at each p_T. The shape, position, and width of the π^0 peak measured for all centralities were confirmed to be well reproduced by the embedded data.

The energy calibration of the EMCal was corroborated by the position of the π^0 invariant mass peak, by the energy deposit from minimum ionizing charged particles traversing the EMCal (PbSc), and by the correlation between the measured momentum of electron and positron tracks identified by the ring-imaging Čerenkov detector and the associated energy deposit in the EMCal. From these studies it is determined that the accuracy of the energy measurement was better than 1.5%.

The main sources of systematic errors in the PbSc and PbGl measurements are the uncertainties in (i) the yield extraction, (ii) the yield correction, and (iii) the energy scale. The relative contributions of these effects to the total error differ for the PbSc and PbGl (Table I). The weighted average of the two independent measurements reduces the total error. The final systematic errors on the spectra are at the level of ~15%–20% (Table I). A correction for the true mean value of the p_T bin is applied to the steeply falling spectra.

TABLE I. Summary of the dominant sources of systematic errors on the π^0 and inclusive γ yields extracted independently with the PbGl and PbSc electromagnetic calorimeters. The error estimates are quoted at two p_T values in central events for the PbGl and PbSc. For the combined π^0 and inclusive γ spectra and γ/π^0 ratios, the approximate statistical and systematical errors are quoted for the most peripheral and most central reactions.

	PbGl (Central)		PbSc (Central)

The completely corrected and combined PbSc and PbGl inclusive photon yields are compared to the expected yields of background photons from hadronic decays in Fig. 1 for minimum bias Au + Au collisions (0%–92% of the geometric cross section) and for five centrality bins. The decay photon calculations are based on the measured π^0 and η spectra [16] assuming m_T scaling for all other radiative decays (η', K^0_s, ω). The comparison is made as the ratio of measured (inclusive) γ/π^0 and calculated background γ/π^0 since this has the advantage that many uncertainties, such as the energy scale, cancel to a varying extent in the ratio. Since the π^0 spectra of the background calculations are taken to be the same as the measured spectra, we have

$$R_\gamma = \frac{(\gamma/\pi^0)_{\text{Measured}}}{(\gamma/\pi^0)_{\text{Background}}} \approx \frac{\gamma_{\text{Measured}}}{\gamma_{\text{Background}}}, \qquad (1)$$

and any significant deviation of the double ratio above unity indicates a direct photon excess. In Fig. 1 an excess

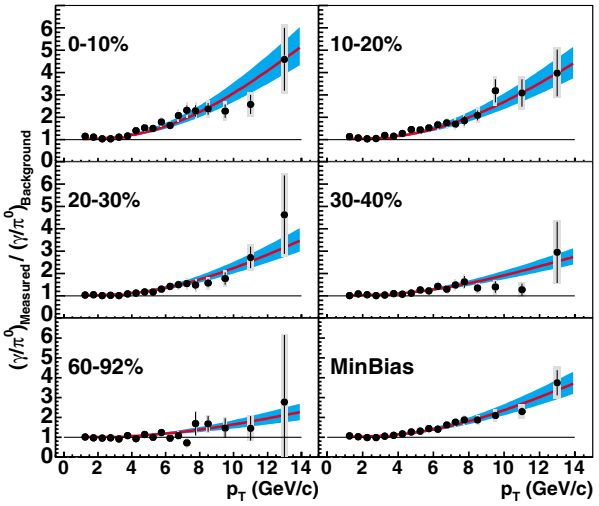

FIG. 1 (color online). Double ratio of measured $(\gamma/\pi^0)_{\text{Measured}}$ invariant yield ratio to the background decay $(\gamma/\pi^0)_{\text{Background}}$ ratio as a function of p_T for minimum bias and for five centralities of Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV (0%–10% is the most central). Statistical and total errors are indicated separately on each data point by the vertical bar and shaded region, respectively. The solid curves are the ratio of pQCD predictions described in the text to the background photon invariant yield based on the measured π^0 yield for each centrality class. The shaded regions around the curves indicate the variation of the pQCD calculation for scale changes from $p_T/2$ to $2p_T$, plus the $\langle N_{\text{coll}} \rangle$ uncertainty.

is observed at high p_T with a magnitude that increases with increasing centrality of the collision.

The measured results are compared to NLO perturbative QCD (pQCD) predictions [17], scaled by the number of binary nucleon collisions for each centrality selection. The same calculations are in agreement with the PHENIX direct photon measurement [15] for $p + p$ collisions at the same $\sqrt{s}$, and similar NLO pQCD calculations provide a good description of the measured π^0 production in $p + p$ collisions [13]. The calculations were performed [15,17] with normalization and factorization scales set equal to p_T, and using the CTEQ6 [18] set of parton distribution functions and the GRV set of fragmentation functions [19]. The direct photon spectra extracted as $\gamma_{\text{Direct}} = (1 - R_\gamma^{-1}) \cdot \gamma_{\text{Measured}}$ are shown in Fig. 2 for all nine centrality selections as well as minimum bias, and compared to the same NLO calculations. The binary collision scaled predictions are seen to provide a good description of the measured direct photon spectra (Fig. 2). The increasing ratio with centrality seen in Fig. 1 is therefore attributed to the decreasing decay background due to π^0 suppression [3].

Medium effects in AA collisions are often presented using the *nuclear modification factor* given as the ratio of the measured AA invariant yields to the NN-collision-scaled $p + p$ invariant yields:

$$R_{AA}(p_T) = \frac{(1/N_{AA}^{\text{evt}}) d^2N_{AA}/dp_T dy}{\langle N_{\text{coll}}\rangle/\sigma_{pp}^{\text{inel}} \times d^2\sigma_{pp}/dp_T dy}, \qquad (2)$$

where the $\langle N_{\text{coll}}\rangle/\sigma_{pp}^{\text{inel}}$ is the average nuclear thickness function, $\langle T_{AA}\rangle$, in the centrality bin under consideration (Ref. [3]). $R_{AA}(p_T)$ measures the deviation of AA data from an incoherent superposition of NN collisions.

The centrality dependence of the high p_T γ production represented as a function of the number of participating nucleons, N_{part}, is shown by the closed circles in Fig. 3. The production in Au + Au collisions relative to $p + p$ is characterized by the $R_{AA}(p_T > 6\ \text{GeV}/c)$ ratio of Eq. (2) as the ratio of Au + Au over the $\langle N_{\text{coll}}\rangle$ scaled $p + p$ yields each integrated above 6 GeV/c. The direct photon $p + p$ yields are taken as the NLO pQCD predictions described above. As noted above, the high p_T direct γ production is well described by the $p + p$ direct γ yield prediction scaled by $\langle N_{\text{coll}}\rangle$ for all centralities. This is in sharp contrast [3] to the centrality dependence of the π^0 $R_{AA}(p_T > 6\ \text{GeV}/c)$ shown by open circles in Fig. 3 where the measured π^0 yield [13] is used as the $p + p$ reference in Eq. (2).

The observed close agreement between the measured yields and NLO calculations is in contrast to observations for central Pb + Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV [14] where the measured photon yield exceeds the scaled NN photon yield by about a factor of 2. The present result constrains modifications of the initial parton distributions, or of the fragmentation contributions [10,11] (in these

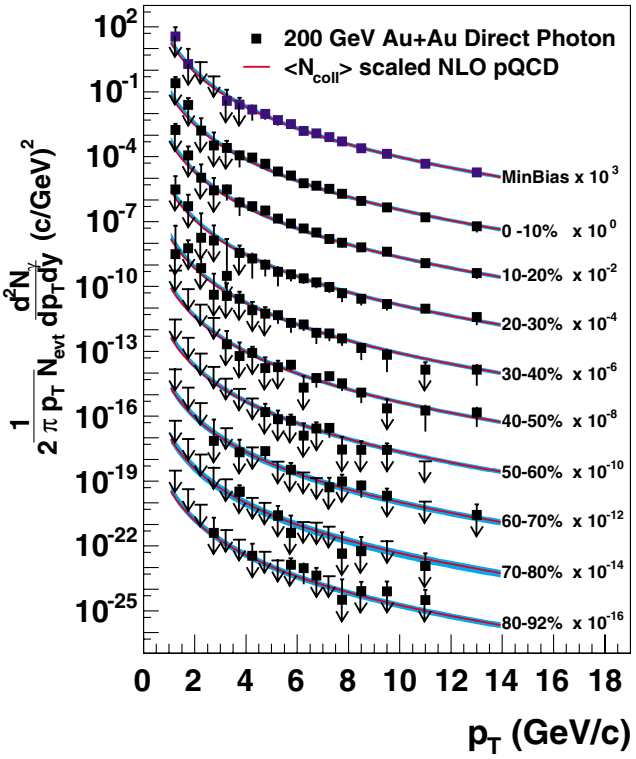

FIG. 2 (color online). Direct γ invariant yields as a function of transverse momentum for 9 centrality selections and minimum bias Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The vertical error bar on each point indicates the total error. Arrows indicate measurements consistent with zero yield with the tail of the arrow indicating the 90% confidence level upper limit. The solid curves are pQCD predictions described in the text.

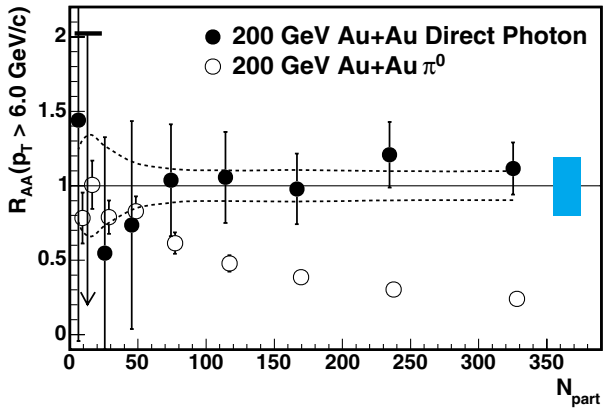

FIG. 3 (color online). Ratio of Au + Au yield to $p + p$ yield normalized by the number of binary nucleon collisions as a function of centrality given by N_{part} for direct γ (closed circles) and π^0 (open circles) yields integrated above 6 GeV/c. The $p + p$ direct photon yield is taken as the NLO pQCD prediction described in the text. The error bars indicate the total error excluding the error on $\langle N_{\text{coll}}\rangle$ shown by the dashed lines and the scale uncertainty of the NLO calculation shown by the shaded region at the right.

NLO calculations the contribution is significant: ~50% at 3.5 GeV/c and ~35% at 10 GeV/c), or additional photon yield from thermal radiation to levels comparable to the present measurement uncertainty.

In summary, the transverse momentum spectra of direct photons have been measured at midrapidity up to $p_T \approx 13$ GeV/c for nine centrality bins of Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The significance of the direct photon signal increases with collision centrality due to the increasingly suppressed π^0 production and associated decrease in the photon background from hadron decays. The direct photon spectral shapes and invariant yields are consistent with NLO pQCD predictions for $p + p$ reactions scaled by the average number of inelastic NN collisions for each centrality class. The close agreement between measurement and the binary scaled pQCD predictions of the direct photon yield suggests that nuclear modifications of the quark and gluon distribution functions in the relevant region of momentum fraction x are minor. The result provides strong confirmation that the observed large suppression of high p_T hadron production in central Au + Au collisions is dominantly a final-state effect due to parton energy loss in the dense produced medium, rather than an initial-state effect.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 4 February 2005; published 10 August 2005)

The transverse momentum dependence of the azimuthal anisotropy parameter v_2, the second harmonic of the azimuthal distribution, for electrons at midrapidity ($|\eta| < 0.35$) has been measured with the PHENIX detector in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The measurement was made with respect to the reaction plane defined at high rapidities ($|\eta| = 3.1$–3.9). From the result we have measured the v_2 of electrons from heavy flavor decay after subtraction of the v_2 of electrons from other sources such as photon conversions and Dalitz decay from light neutral mesons. We observe a nonzero single electron v_2 with a 90% confidence level in the intermediate-p_T region. The precision of the present data set does not permit us to conclude definitively that heavy quarks exhibit thermalization with the transverse flow of the bulk matter.

DOI: 10.1103/PhysRevC.72.024901 PACS number(s): 25.75.Dw

I. INTRODUCTION

The azimuthal anisotropy of particle emission is a powerful tool to study the early stage of ultrarelativistic nuclear collisions. The spatial anisotropy in the initial stage of noncentral nucleus-nucleus collisions is transferred into momentum anisotropy in the final state. The azimuthal anisotropy is defined by

$$\frac{dN}{d\phi} = N_0 \left\{ 1 + \sum_n 2v_n \cos[n(\phi - \Psi_{\mathrm{R.P.}})] \right\}, \qquad (1)$$

*Deceased.
†PHENIX spokesperson: zajc@nevis.columbia.edu

where N_0 is a normalization constant, ϕ is the azimuthal angle of particles, and $\Psi_{\mathrm{R.P.}}$ is the direction of the nuclear impact parameter ("reaction plane") in a given collision. The harmonic coefficients, v_n, indicate the strength of the nth anisotropy. The azimuthal anisotropy parameter v_2 (the second harmonic coefficient of the Fourier expansion of the azimuthal distribution) may be especially sensitive to the early pressure [1]. The transverse momentum (p_T) dependence of v_2 has been measured for identified particles at Brookhaven National Laboratory's Relativistic Heavy Ion Collider (RHIC) [2–5]. Previous measurements are limited to hadrons made of light quarks. These results show a clear mass dependence of v_2, which is well reproduced by a hydrodynamical calculation [6] in the low-p_T region ($p_T < 2$ GeV/c). The agreement is considered as evidence that the collective motion develops in the very early stages of the reaction. It is also observed that v_2 as a function of p_T scales via the coalescence prescription; that is, v_2/n as a function of p_T/n is universal, where n is the number of valence quarks plus valence antiquarks. This scaling behavior is consistent with the prediction of the quark coalescence model, which assumes a finite v_2 of quarks [7]. This suggests that the v_2 already develops in the partonic phase for hadrons made of light quarks. In addition, if the v_2 of heavy quarks is nonzero, it would support partonic level thermalization and very high density at the early stage of the collisions.

Electrons are a useful tool to study the production of heavy quarks such as charm quarks. In the PHENIX experiment at RHIC, transverse momentum spectra of single electrons have been measured in Au+Au collisions at $\sqrt{s_{NN}} = 130$ GeV [8] and 200 GeV [9]. The results are consistent with that expected from semileptonic charm decays in addition to decays of light mesons and photon conversions [8]. However, electrons originating from semileptonic decays of D mesons have a significant angular deviation from the original D meson direction. The effect on v_2 has been shown in [10] and [11]. The results suggest that the effect is not significant for the decay electron v_2, and the electron v_2 reflects the v_2 of the D meson. Therefore the single-electron v_2 measurement is a useful method for studying open charm v_2 [12,13].

Currently the single-electron spectra from PHENIX are consistent with two opposing scenarios: (1) initial perturbative QCD charm production without final-state interactions and (2) complete thermal equilibrium for charmed hadrons [14]. Therefore the measurement of the azimuthal anisotropy of electrons from semileptonic charm decays could give us important new information regarding the charm dynamics in high-energy heavy-ion collisions. The measurement is also important for the quark coalescence model, because of the large difference between the charm quark and light quark masses, and for the prediction of v_2 for the J/ψ and the D meson, those contain charm quarks.

In this paper, we present the first measurement of the single-electron v_2, which is expected to reflect the heavy flavor azimuthal anisotropy, below 4 GeV/c with respect to the reaction plane in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The single-electron v_2 was measured by subtracting from the inclusive electron v_2 the v_2 of electrons from other sources such as photon conversions and Dalitz decays from light neutral mesons.

II. DATA ANALYSIS

About 16 million minimum bias events in RHIC-Run2 (2001) for $\sqrt{s_{NN}} = 200$ GeV are used in this analysis after a vertex cut is applied ($|z_{\mathrm{vertex}}| < 20$ cm). In this section we present a brief overview of the PHENIX detectors [15] used in this analysis and then present details of event selection, electron identification, and reaction-plane determination.

A. Overview of PHENIX detector

PHENIX consists of four spectrometer arms (central arms and muon arms) and a set of global detectors. The central arms are located east and west of the interaction region at midrapidity. The muon arms are located to the north and south at forward rapidity. Figure 1 shows the configuration of the central arms in Run2.

The global detectors consist of the beam-beam-counters (BBCs) and the zero-degree calorimeters (ZDCs). These detectors provide the time of the Au+Au collision, the collision vertex, the event trigger, and the collision centrality. In this analysis the BBCs are also used to determine the reaction plane. The BBCs are installed on the north and south sides of the collision point along the beam axis. Each BBC is placed 144 cm from the center of the interaction region and surrounds the beam pipe. This corresponds to a pseudorapidity range from 3.1 to 3.9 over the full azimuth. Each BBC is composed of 64 elements and a single BBC element consists of a 1-in-diameter mesh dynode photomultiplier tube mounted on a 3-cm-long quartz radiator. The ZDC is a hadron calorimeter and measures the energy of spectator neutrons. The ZDCs are located 18 m downstream and upstream along the beam axis, and each ZDC covers 2 mrad of forward angular cone, corresponding to $\eta > 6.0$.

The central arms are designed to track particles emitted from collisions, identify charged particles, and reconstruct invariant masses. The central arms each cover the pseudorapidity range $|\eta| < 0.35$ and 90° in azimuthal angle. The central arms consist of several subsystems. In this analysis drift chambers (DCs), pad chambers (PCs), ring imaging Cherenkov counters (RICHs), and electromagnetic calorimeters (EMCals) are used. The DCs are located between 2.0 and 2.4 m from the beam axis on each central arm and measure charged particle trajectories in the r-ϕ plane. The central arms have three layers of PCs, which are multiwire proportional chambers. The PCs are located at 2.4 m (PC1), 4.2 m (PC2), and 5.0 m (PC3) from the beam axis. PC1 and PC3 are installed in each central arm, but PC2 is installed only in the west arm. The PC measures three-dimensional space points along the straight-line particle trajectories. A RICH, the primary detector for electron identification, is installed in each central arm. The RICH consists of a gas vessel, a thin reflector, and a photon detector consisting of an array of photomultiplier tubes (PMTs). During Run2 CO_2 was used as the Cherenkov radiator so only pions with $p > 4.7$ GeV/c emit Cherenkov light in the

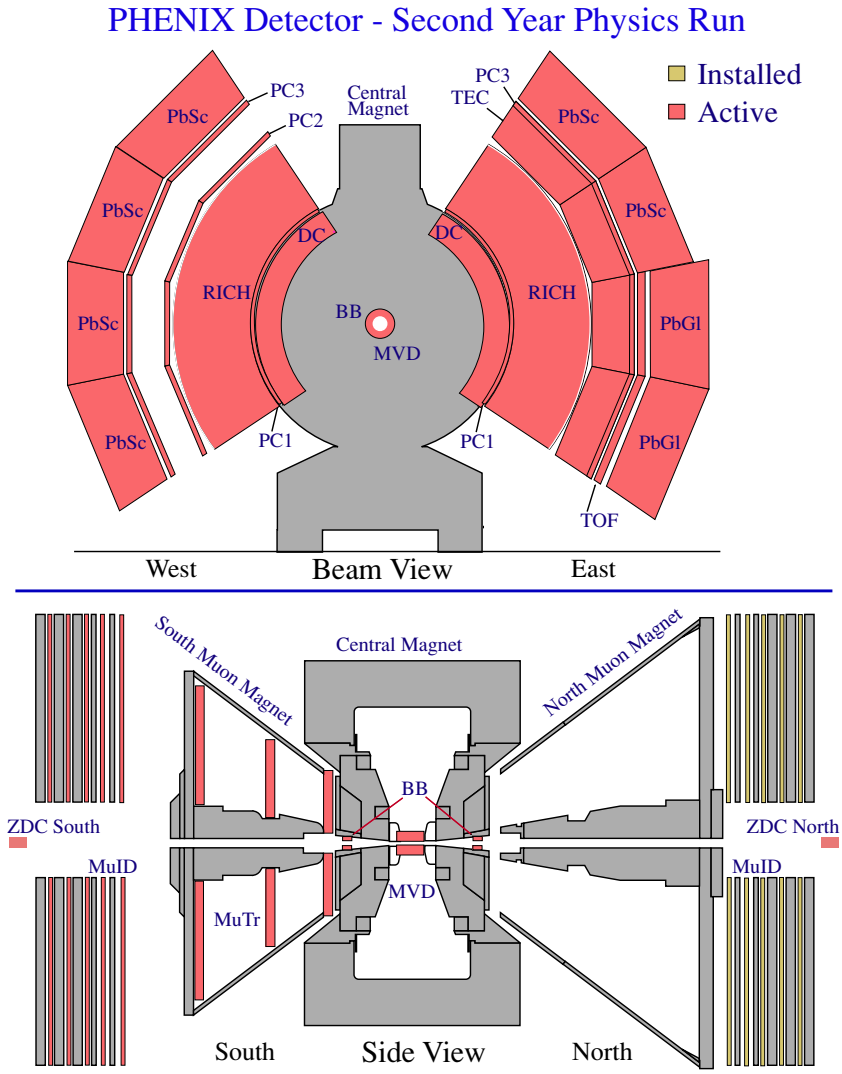

FIG. 1. (Color online) PHENIX experiment configuration in Run2. (Top) Cross section perpendicular to the beam pipe. (Bottom) East side view of the cross section along the beam pipe.

RICH. The EMCal is used to measure the spatial position and energy of electrons and photons. It covers the full central arm acceptance of $70^\circ < \theta < 110^\circ$ with each of the two walls subtending 90° in azimuth. One wall comprises four sectors of Pb-scintillator sampling calorimeter; the other has two sectors of Pb scintillator and two of Pb-glass Cherenkov calorimeter. The central magnet (CM) provides a magnetic field around the interaction vertex that is parallel to the beam. The CM allows momentum analysis of charged particles in the polar angle range $70^\circ < \theta < 110^\circ$ and provides a field integral of about 0.8 T m [16].

B. Event selection

Event selection was done with the BBC and the ZDC in this analysis. The minimum-bias trigger requires a coincidence between north and south BBC signals. The trigger included $92.2^{+2.5}_{-3.0}\%$ of the 6.9-b Au+Au inelastic cross section [17]. The event centrality is determined by combining information on spectator neutrons measured by the ZDC and the charge sum information measured by the BBC. The collision vertex point along the beam line is determined by the timing difference of the two BBCs. We required $|z_{\text{vertex}}| < 20$ cm for this analysis.

C. Charged particle selection and electron identification

Charged particle tracks are reconstructed by the DC and the first pad chamber plane (PC1) installed in each central arm together with the collision vertex determined by the BBC [18]. For a reconstructed track to be selected, the track projection to the EMCal and the position of the associated hit in the EMCal must match within two standard deviations. The electron candidates are required to have at least three associated hits in the RICH that pass a ring-shape cut and are also required to pass a timing cut. To reduce background from hadrons and photon conversions far from the vertex, energy is measured in the EMCal, and momentum matching (E/p) is required. Electrons deposit all of their energy in the EMCal; therefore the E/p is approximately 1.0. In this analysis we require $-2\sigma < (E-p)/p < 3\sigma$ to reduce background. Figure 2 shows the $(E-p)/p/\sigma$ distribution. Here the σ means a standard deviation of $(E-p)/p$. A background of less than 10% remains, caused by accidental association of

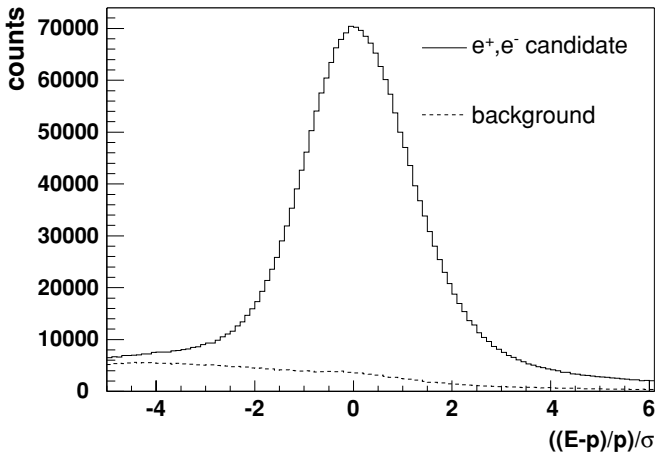

FIG. 2. $(E-p)/p/\sigma$ distribution. We require $-2\sigma < (E-p)/p < 3\sigma$ to reduce background from hadrons and photon conversions far from the vertex.

tracks with RICH hits. The background level is estimated by an event-mixing method and is subtracted when we calculate the electron v_2.

D. Reaction-plane determination

In this analysis the values of v_2 are calculated by the reaction-plane method, which measures the azimuthal angle of the particle emission with respect to the reaction plane [19]. The azimuthal angle of the reaction plane for the nth harmonic is determined by [19]

$$\psi_n^{\text{meas}} = \left[\tan^{-1}\frac{\sum_i w_i \sin(n\phi_i)}{\sum_i w_i \cos(n\phi_i)}\right] \Big/ n, \tag{2}$$

where ϕ_i is the azimuthal angle of each particle used in the reaction-plane determination and w_i is the corresponding weight. The azimuthal angle distribution of the particle emission measured with respect to the reaction plane can be written as Eq. (1). Because of finite reaction-plane resolution, coefficients in the Fourier expansion of the azimuthal distribution with respect to the "measured" reaction plane (v_n^{meas}) are smaller than coefficients measured with respect to the "real" reaction plane (v_n). The resolution correction necessary for v_n^{meas} is given by

$$v_n = v_n^{\text{meas}}/\sigma_{v_n}, \tag{3}$$

where v_n is the real coefficient and σ_{v_n} is the reaction-plane resolution for the nth harmonic. The reaction-plane resolution is defined as $\langle \cos n(\psi_n^{\text{meas}} - \psi_n^{\text{real}})\rangle$ [19]. The value of v_n^{meas} is obtained by fitting the azimuthal distribution (relative to the reaction plane) with

$$\frac{dN}{d\phi} = N_0\left[1 + 2v_n^{\text{meas}}\cos(n\phi)\right], \tag{4}$$

where N_0 and v_n^{meas} are fitting parameters. We can also calculate v_n^{meas} directly by

$$v_n^{\text{meas}} = \langle \cos(n\phi)\rangle. \tag{5}$$

In this analysis the v_2 is estimated by using the reaction plane found from the second harmonic ($n = 2$), since better accuracy of v_n is obtained by using the same harmonic's reaction plane [19]. The reaction planes are determined by using both BBCs. In the PHENIX experiment the reaction plane is also determined by using the central arm detectors. One of the key issues of the reaction-plane determination involves nonflow effects such as jets, resonance decays, and Hanbury-Brown and Twiss (HBT). Since each BBC is roughly three units of pseudorapidity away from the central arms, it is expected that the nonflow effects are smaller there than in the central arm detectors [2].

Using the BBC information the reaction plane is measured by

$$\psi = \left[\tan^{-1}\frac{\sum_{i=1}^{64} q_i \sin(2\phi_i)}{\sum_{i=1}^{64} q_i \cos(2\phi_i)}\right] \Big/ 2, \tag{6}$$

where ϕ_i is the azimuthal angle of each PMT and q_i is the charge information of each PMT. Owing to the random distribution of the impact-parameter direction in collisions, the reaction plane should have an isotropic azimuthal distribution. Because of the possible azimuthal asymmetries in the BBC response, however, the measured reaction-plane distribution is anisotropic. In this paper, we use the following two-step method to correct the reaction plane. First, the distribution of $\sum_{i=1}^{64} q_i \sin(2\phi_i)$ and $\sum_{i=1}^{64} q_i \cos(2\phi_i)$ are recentered by subtracting $\langle\sum_{i=1}^{64} q_i \sin(2\phi_i)\rangle$ and $\langle\sum_{i=1}^{64} q_i \cos(2\phi_i)\rangle$ over all events [19]:

$$\psi = \left[\tan^{-1}\frac{\sum_{i=1}^{64} q_i \sin(2\phi_i) - \left\langle\sum_{i=1}^{64} q_i \sin(2\phi_i)\right\rangle}{\sum_{i=1}^{64} q_i \cos(2\phi_i) - \left\langle\sum_{i=1}^{64} q_i \cos(2\phi_i)\right\rangle}\right] \Big/ 2. \tag{7}$$

This method does not remove higher harmonic components of the determined reaction plane, so we apply an additional correction method [20]. In this method flattening the reaction plane is accomplished by using a shift

$$n\psi^{\text{flat}} = n\psi_{\text{obs}} + \Delta\psi, \tag{8}$$

where $\Delta\psi$ is the correction factor for the reaction plane. $\Delta\psi$ is determined by

$$\Delta\psi = \sum_n A_n \cos(2n\psi_{\text{obs}}) + B_n \sin(2n\psi_{\text{obs}}), \tag{9}$$

where A_n and B_n are defined by requiring the nth Fourier moment of the new reaction plane (ψ^{flat}) to vanish. Hence

$$A_n = -\frac{2}{n}\langle \sin(2n\psi_{\text{obs}})\rangle, \tag{10}$$

$$B_n = \frac{2}{n}\langle \cos(2n\psi_{\text{obs}})\rangle. \tag{11}$$

Since the reaction plane depends on collision centrality and the z vertex, the reaction planes are divided into 40 samples (20 centrality bins and 2 vertex bins), and these corrections are determined independently for each sample. To measure the v_2 in this analysis, use is made of a combined reaction-plane, which is defined by weighted averaging of the

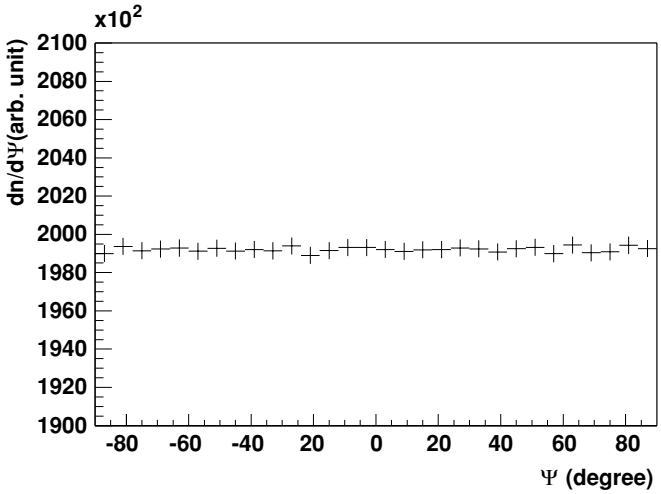

FIG. 3. The azimuthal angle distribution of the combined reaction plane after applying the flattening corrections. (Note that the vertical scale is zero suppressed.) After applying the corrections, the reaction plane has an isotropic azimuthal distribution.

reaction-plane angles obtained by the south-side BBC and the north-side BBC. Figure 3 shows the azimuthal angle distribution of the combined reaction plane after applying the flattening corrections. After applying the corrections, the reaction plane has an isotropic azimuthal distribution. The resolution of the combined reaction plane is estimated by using Eq. 11 in [19]. Figure 4 shows the centrality dependence of the resolution (σ_{v_2}).

III. RESULTS AND DISCUSSION

In this section we present a method to calculate the single-electron v_2 from inclusive electrons and show its transverse momentum dependence.

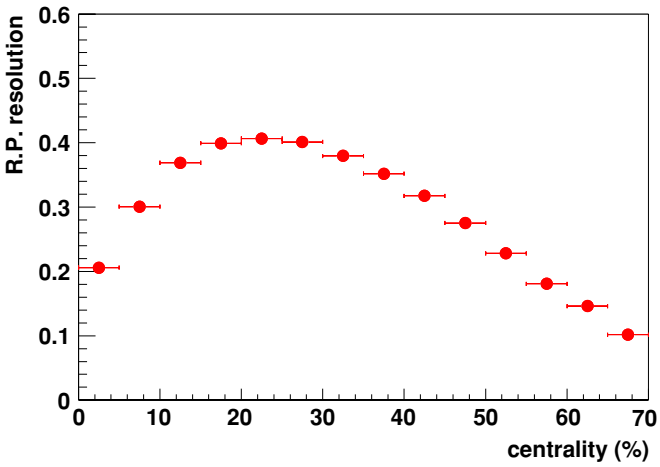

FIG. 4. (Color online) Centrality dependence of the combined reaction plane (R.P.) resolution determined by the BBC. The resolution is estimated by using Eq. 11 in [19].

A. Inclusive electron v_2

The azimuthal distributions of electrons relative to the reaction plane are shown in the middle panel of Fig. 5. The distributions are overlaid by shifting them on the vertical axis such that the spacing between each is equal. Each symbol represents the measured p_T region indicated in the left panel, which shows the raw yields of each distribution with large symbols. As described in Sec. II C, less than 10% background remains from accidental RICH associations. The azimuthal distributions of the background are shown in the right panel, and the yields are shown as small symbols in the left panel. The electron v_2 are measured after subtraction of this background ($dN^{e_{\rm back}}/d\phi$) from electrons that are identified by the RICH ($dN^{e_{\rm cand}}/d\phi$):

$$\frac{dN^e}{d\phi} = \frac{dN^{e_{\rm cand}}}{d\phi} - \frac{dN^{e_{\rm back}}}{d\phi}. \tag{12}$$

The transverse momentum dependence of the electron v_2 for minimum-bias events (centrality 0–92%) after subtracting background is shown in Fig. 6. The statistical errors are shown as vertical lines in the figure. The 1σ systematic uncertainties are shown as vertical bands. The systematic uncertainties include the systematic uncertainty of the reaction-plane determination and electron identification. The systematic uncertainty of the reaction-plane determination is about 5%. The uncertainty was estimated by measuring v_2 with a reaction plane determined by the north-side BBC, the south-side BBC, and a combination of the north and south sides. The systematic uncertainty from electron identification was estimated by measuring electron v_2 with several different sets of electron identification cuts. A comparison with v_2 for a charged pion [2] is also shown in Fig. 6. At low p_T ($p_T < 1.0$ GeV/c), the electron v_2 is larger than the v_2 of the pion. In this region electrons come mainly from π^0 decays, directly from the Dalitz decays, or indirectly from photon conversions. Because the decay angle of the π^0 decay is small, the electron has about the same azimuthal angle as the parent π^0, wheres the electron p_T is smaller than the π^0 p_T. Therefore the electron v_2 at a given p_T corresponds to the larger v_2 of the π^0 at higher p_T. The v_2 of charged pions is consistent with that of neutral pions [12]; therefore the inclusive electron v_2 is higher than the pion v_2. The v_2 at high p_T is thought to reflect parton energy loss in the initial stage of the collisions [21]. As described in Sec. III B, the primary source of electrons at high p_T is semileptonic decays of mesons containing heavy quarks. If these heavy quarks experience energy loss, the trend of the electron v_2 at high p_T might be the same as for pions. However, the electron v_2 at high p_T might be smaller than the pion v_2 if the heavy quarks do not lose energy. Owing to the large systematic and statistical uncertainty of the current measurement, the electron v_2 is consistent with the pion v_2.

B. Heavy-flavor electron v_2

The inclusive electron sample has two components: (1) a nonphotonic component, consisting of primarily semi-leptonic decays of mesons containing heavy (charm and bottom) quarks, and (2) a photonic component, consisting of Dalitz

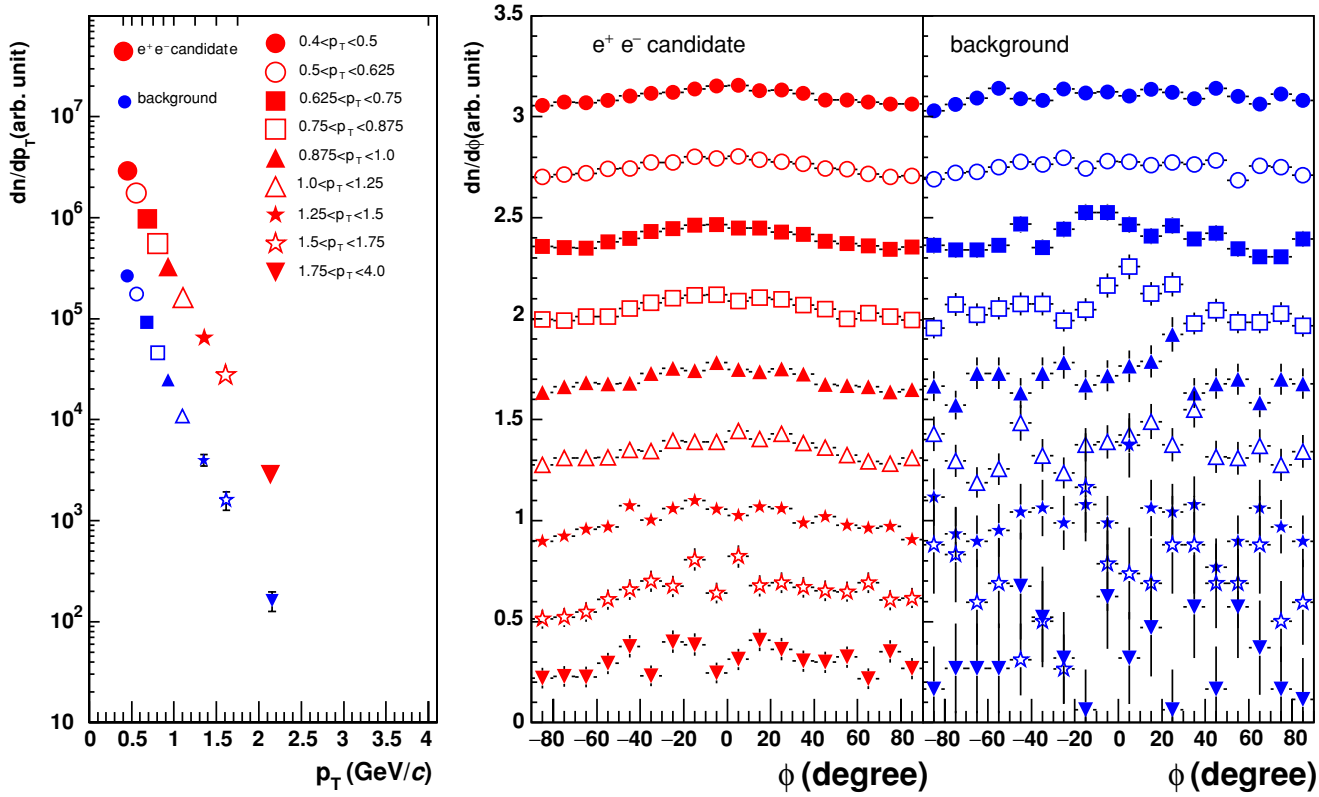

FIG. 5. (Color online) Azimuthal distributions relative to the reaction plane of electrons (middle panel) and the background (right panel) in each momentum bin. The distributions are overlaid by shifting them on the vertical axis such that the spacing between each is equal. The raw yields of each distribution are shown in the left panel.

decays of light neutral mesons (π_0, η, η', ω, and ϕ) and photon conversions in the detector material [9]. The azimuthal distribution of electrons ($dN^e/d\phi$) is the sum of the azimuthal distributions of photonic electrons ($dN^\gamma/d\phi$) and nonphotonic electrons ($dN^{\text{non}-\gamma}/d\phi$):

$$\frac{dN_e}{d\phi} = \frac{dN_e^\gamma}{d\phi} + \frac{dN_e^{\text{non}-\gamma}}{d\phi}. \tag{13}$$

The second harmonic of the Fourier expansion of each azimuthal distribution is defined according to

$$\begin{aligned} &N_e\left[1 + 2v_{2_e}\cos(2\phi)\right] \\ &= N_e^\gamma\left[1 + 2v_{2_e}^\gamma\cos(2\phi)\right] + N_e^{\text{non}-\gamma}\left[1 + 2v_{2_e}^{\text{non}-\gamma}\cos(2\phi)\right] \\ &= \left(N_e^\gamma + N_e^{\text{non}-\gamma}\right)\left[1 + 2\frac{N_e^\gamma v_{2_e}^\gamma + N_e^{\text{non}-\gamma}v_{2_e}^{\text{non}-\gamma}}{N_e^\gamma + N_e^{\text{non}-\gamma}}\cos(2\phi)\right], \end{aligned} \tag{14}$$

where v_{2_e} is the v_2 of inclusive electron, $v_{2_e}^\gamma$ is the v_2 of the photonic electrons, and $v_{2_e}^{\text{non}-\gamma}$ is the v_2 of the nonphotonic electrons. From Eq. (14), the inclusive electron v_2 is given by

$$\begin{aligned} v_{2_e} &= \frac{N_e^\gamma v_{2_e}^\gamma + N_e^{\text{non}-\gamma}v_{2_e}^{\text{non}-\gamma}}{N_e^\gamma + N_e^{\text{non}-\gamma}} \\ &= \frac{N_e^\gamma v_{2_e}^\gamma + \left(N_e - N_e^\gamma\right)v_{2_e}^{\text{non}-\gamma}}{N_e} \\ &= r v_{2_e}^\gamma + (1-r)v_{2_e}^{\text{non}-\gamma}, \end{aligned} \tag{15}$$

where r is defined as $r = 1/(1 + R_{\text{NP}})$, and R_{NP} is the ratio of the number of nonphotonic electrons to photonic electrons

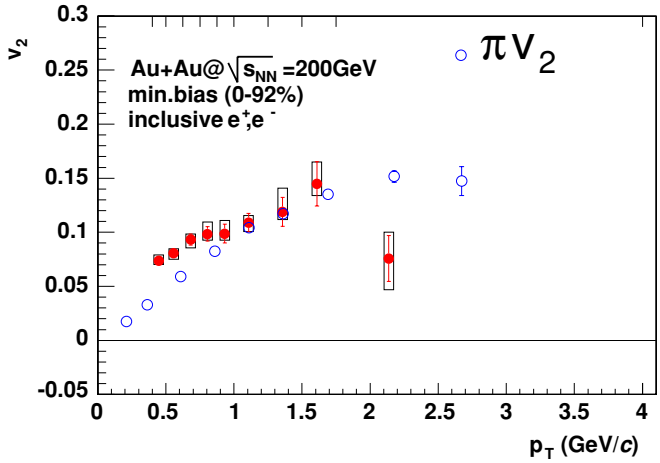

FIG. 6. (Color online) Transverse momentum dependence of the electron v_2 for minimum-bias events (centrality 0–92%). The data points for the electrons represent the inclusive single electrons (e^+ and e^-). The upper horizontal scale shows the bin size in p_T. The statistical errors are shown as vertical lines in the figure. The systematic uncertainty from the determination of the reaction plane and electron identification are shown as boxes. A comparison with the pionπ v_2 is also shown.

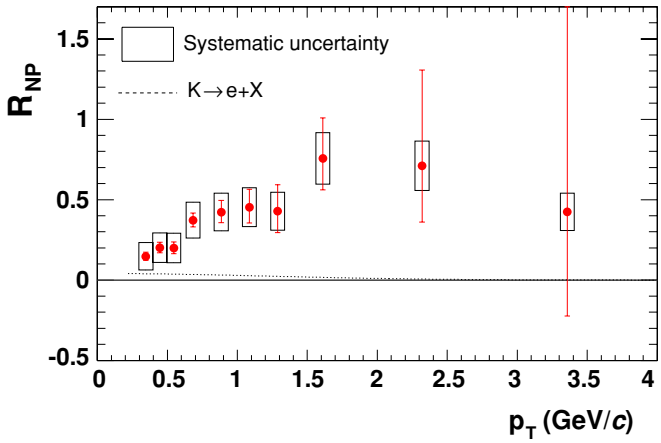

FIG. 7. (Color online) Ratio of nonphotonic to photonic $e^{\pm}$ yields ($R_{\rm NP}$, points) and contribution from kaon decays (dashed line) [9].

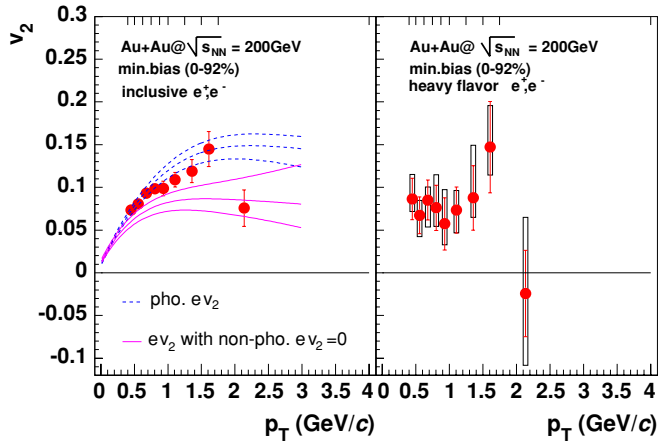

FIG. 8. (Color online) (Left) A comparison of the inclusive electron v_2 with the photonic electron v_2 (dashed line). The solid line is $r v_{2_e^\gamma}$, the photonic electron v_2 scaled by the ratio of the number of inclusive to photonic electrons. The electron v_2 is the same as $r v_{2_e^\gamma}$ if the nonphotonic electron v_2 is zero; that is, the v_2 of the parent particle, such as a D meson, is zero. (Right) Transverse momentum dependence of the heavy quark electron v_2 for minimum-bias events. The vertical line is the statistical error, which is propagated from the statistical errors of the electron v_2 for minimum-bias events. The systematic uncertainty from the electron v_2, the photonic electron v_2, and the ratio $R_{\rm NP}$ is shown as a band.

($N_e^{\rm non-\gamma}/N_e^{\gamma}$). We experimentally determined the ratio from analysis of special runs in which an additional an photon converter was installed. The details of the method are described in [9], and the measured ratio is shown in Fig. 7. The increase in the number of nonphotonic electrons is consistent with that expected from semileptonic charm decays [9]. From Eq. (15) $v_{2_e}^{\rm non-\gamma}$ can be expressed as

$$v_{2_e}^{\rm non-\gamma} = \frac{v_{2_e} - r v_{2_e}^{\gamma}}{1 - r}. \tag{16}$$

The dominant sources of photonic electrons are photon conversions and Dalitz decays from π^0 [8]. In addition, we also took into account electrons from η decays when calculating photonic electron v_2. We assumed that the contributions from η decays is 17% by taking into account $\eta/\pi_0 = 0.45$ [9]. The other sources are ignored when calculating the photonic electron v_2 because of their small contribution. The decay electron v_2 from decay electrons of π^0 and η were calculated by Monte Carlo simulation. The transverse momentum dependence of the $\pi^0 v_2$ was obtained from the measured $\pi^0 v_2$ [12] ($p_T > 1.0$ GeV/c) and the measured charged pion v_2 ($p_T < 1.0$ GeV/c). Both measurements were used since the $\pi^0 v_2$ has been measured only above 1.0 GeV/c, and both v_2 measurements are consistent at intermediate p_T ($1.0 < p_T < 3.0$). The measured π^0 spectra [22] were used to give the input transverse momentum spectrum. We assumed that the transverse momentum dependence of the η v_2 is the same as for the kaon v_2 because their mass difference is small. The transverse momentum spectrum of η was approximated by assuming m_T scaling of π^0 spectra. The photonic electron v_2 calculated from the results is shown as the dashed line in the left panel of Fig. 8. The middle dashed line is the mean value of the photonic electron v_2 and the upper and lower dashed lines show the 1σ systematic uncertainty. The systematic uncertainty of the photonic electron v_2 was estimated from the statistical error and the systematic error of the measured parent v_2. If the nonphotonic electron v_2 is zero, that means the v_2 of the parent particle, such as a D meson, is zero. Additionally, the inclusive electron v_2 is the same as that of the scaled photonic electron ($r v_{2_e^\gamma}$) from Eq. (15). The scaled photonic electron v_2 is shown as the solid line in the left panel in Fig. 8. At intermediate p_T ($1.0 < p_T < 1.5$) the electron v_2 is higher than $r v_{2_e^\gamma}$. This might suggest that the nonphotonic electron has nonzero v_2 at intermediate p_T. The details of this discussion are presented in the next section.

Background from kaon decays ($K \to \pi\ e\ \nu$) remains in the nonphotonic yield. The contribution of kaon decays to the nonphotonic yield, shown in Fig. 7 as a dashed line, is 18% at $p_T = 0.4$ GeV/c and decreases rapidly to less than 6% for $p_T = 1$ GeV/c [9]. The transverse momentum dependence of the kaon v_2 has been measured up to 3.0 GeV/c and that of the K_S^0 v_2 has been measured up to 6.0 GeV/c [5]. The kaon and K_S^0 v_2 are consistent up to 3.0 GeV/c, and the quark coalescence model predicts that these two meson v_2 values are the same. Therefore, kaon and K_S^0 v_2 were combined as input for the kaon v_2. The transverse momentum spectrum of kaons was obtained from measured kaon spectra up to 2.0 GeV/c. In the high-p_T region we used scaled π^0 spectra and assumed that the shapes of the kaon spectra were the same as for the π^0 spectra, which are matched with measured kaon spectra around 2.0 GeV/c.

The nonphotonic electrons mainly come from semileptonic decays of heavy flavor (charm and beauty). Therefore the non-photonic electron v_2 that was obtained by subtracting photonic electron and kaon decays from inclusive electrons should be heavy-flavor electron [9] v_2, which reflects the azimuthal anisotropy of heavy quarks. The result of the heavy-flavor electron v_2 for minimum-bias events is shown in the right panel of Fig. 8. The vertical lines are the statistical errors that are propagated from the statistical errors of the inclusive

TABLE I. The relative systematic uncertainty of heavy-quark electron v_2.

electron v_2 shown in Fig. 6. The 1σ systematic uncertainties of heavy-flavor electron v_2 are shown as bands. The systematic uncertainty includes the systematic uncertainty of the reaction plane, the measured inclusive electron v_2 (without the reaction plane), the photonic electron v_2 (without the reaction plane), and R_{NP}. The systematic uncertainty of R_{NP} is the quadratic sum of the statistical and systematic errors because R_{NP} is measured with a different data set. There are two categories of uncertainty: Type A is a point-to-point error uncorrected between p_T bins, and type B is a common displacement of all points by the same factor independent of p_T. The total systematic uncertainty is calculated by propagating the errors on the individual quantities that enter into Eq. (16). Table I shows the relative systematic uncertainty of heavy-quark electron v_2.

From the result we calculated the confidence level for a nonzero v_2. We assumed that the data of measured heavy-flavor electron v_2 follow a Gaussian distribution; the σ was obtained by calculating the quadratic sum of the statistical and systematic errors of the heavy-flavor electron v_2 assuming these errors to be independent. In the intermediate-p_T region ($1.0\ \text{GeV}/c < p_T < 1.75\ \text{GeV}/c$), the confidence level for a nonzero value for the measured heavy-flavor electron v_2 is 90%.

There are various scenarios to consider that lead to different elliptic flow values for D mesons [14]. One is that the charm quarks do not interact at all in the medium after being produced and eventually fragment in vacuum into D mesons. This scenario leads to zero elliptic flow ($v_2 = 0$). It is also possible that charm quarks do not flow with the medium but do suffer energy loss in the medium and then eventually fragment in vacuum into D mesons. This scenario may yield a nonzero v_2. Alternatively, the charm quarks may flow in the medium and then hadronize via coalescence or recombination with other partons from the medium, which could produce significant nonzero values for v_2. Finally, even if the charm quarks do not flow with the medium, but do hadronize via recombination, they may pick up some v_2 from the light quarks in the medium.

By assuming the quark coalescence model, the decay electron v_2 from D mesons has been predicted [10]. In the model D mesons are formed from charm quark coalescence with thermal light quarks at hadronization. For charm quark momentum spectra, two extreme scenarios are considered. The first scenario assumes no reinteractions after the production of charm-anticharm quark pairs in initial-state hard processes (calculated from PYTHIA). The second scenario assumes complete thermalization with the transverse flow of the bulk matter. Figure 9 shows a comparison of the heavy-flavor electron v_2 with decay electrons from D mesons in the "no reinteraction" scenario as a solid line; the dashed line reflects the "thermalization" scenario. Because of large systematic and statistical uncertainty of the current measurement, neither scenario is excluded by this single-electron v_2 measurement.

IV. SUMMARY

In summary, we have measured the elliptic flow, v_2, of single electrons from heavy-flavor decay. This single-electron v_2 is produced by subtracting the v_2 of electron sources such as photon conversion from the v_2 of inclusive electrons measured with the PHENIX detector in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV with respect to the reaction plane defined at high rapidities ($|\eta| = 3$–4). The measured heavy-flavor electron v_2 is nonzero with a 90% confidence level. Two model calculations from [10] assume extremely different scenarios: either no reinteraction of the initially produced charm quarks or complete thermalization with the bulk matter. Both of these calculations are consistent within errors with the measured heavy-flavor electron v_2.

High-luminosity Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV have been recorded by the PHENIX experiment during Run4

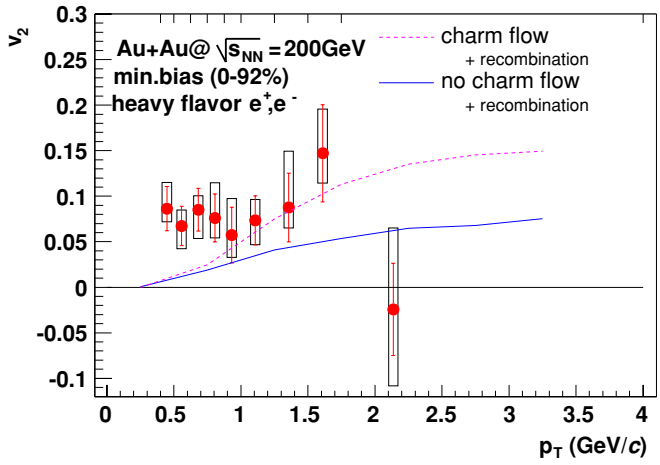

FIG. 9. (Color online) Comparison of the heavy-flavor electron v_2 with two different charm flow scenarios from [10]. The solid line corresponds to no rescattering of the initially produced charm quarks (without flow); the dashed line reflects the effect of complete thermalization (with flow).

(2003–2004). The much higher statistical precision of these data should allow an unambiguous result on the important issue of charm flow.

(Received 2 February 2005; published 8 April 2005)

A measurement of direct photons in $p + p$ collisions at $\sqrt{s} = 200$ GeV is presented. A photon excess above background from $\pi^0 \to \gamma + \gamma$, $\eta \to \gamma + \gamma$ and other decays is observed in the transverse momentum range $5.5 < p_T < 7$ GeV/c. The result is compared to a next-to-leading-order perturbative QCD calculation. Within errors, good agreement is found between the QCD calculation and the measured result.

Measurements of particle production at large transverse momenta (p_T) in hadronic interactions provide the possibility to test perturbative quantum chromodynamics (pQCD). Neutral-pion production in $p + p$ collisions at $\sqrt{s} = 200$ GeV in the range $2 < p_T < 13$ GeV/c measured by the PHENIX experiment at the Relativistic Heavy Ion Collider (RHIC) can be well described by next-to-leading-order (NLO) pQCD [1]. This comparison, however, relies on the choice of the parton-to-pion fragmentation function. Measurement of direct-photon production provides a more direct test of pQCD. Quark-antiquark annihilation ($q\bar{q} \rightarrow \gamma g$) and quark-gluon Compton scattering ($qg \rightarrow q\gamma$) contribute to direct-photon production at leading order [2]. Because of the latter process, which dominates the production, the measurement of direct photons can be used to obtain information on the parton distribution function of the gluon inside the proton.

Previous direct-photon measurements in $p + p$ collisions were made up to energies of $\sqrt{s} = 63$ GeV (see e.g. [3–5]). For $p + \bar{p}$ collisions direct-photon data are available at considerably higher energies, $\sqrt{s} = 546$, 630 GeV [6–8] up to $\sqrt{s} = 1800$ GeV [9,10]. At these energies NLO pQCD calculations describe the direct-photon data within about 20%, although systematic differences in the spectral shapes were observed [11]. At energies below $\sqrt{s} = 63$ GeV the agreement between NLO pQCD and data is generally worse. With phenomenological approaches based on soft-gluon radiation of the incoming parton, which leads to an additional transverse momentum k_T, a better description of the data can be obtained [12]. The RHIC at the Brookhaven National Laboratory provides $p + p$ collisions at energies between the existing data sets, allowing better constraints on the processes affecting incoming partons. A further incentive to study direct-photon production in $p + p$ at $\sqrt{s} =$ 200 GeV comes from the measurement of direct photons in collisions of gold nuclei at the same center-of-mass energy per nucleon-nucleon pair [13,14]. In central Au + Au collisions high-p_T neutral-pion production is suppressed [15] which is due to energy loss of the scattered quarks and gluons in the hot and dense fireball created in these collisions (jet quenching) [16]. As direct photons are not subject to the strong interaction they should not be suppressed in the jet-quenching model. In this context, the $p + p$ direct-photon results serve as a baseline against which possible nuclear effects can be identified.

The data presented in this report were collected during the 2001–2002 run period (Run 2) of RHIC. The neutral-pion cross sections obtained from this data set were published in [1]. The unpolarized neutral-pion spectrum and the unpolarized direct-photon spectrum presented here were obtained by averaging over proton bunches with varying vertical polarization delivered by RHIC.

Direct photons and background photons from decays $\pi^0 \rightarrow \gamma + \gamma$ and $\eta \rightarrow \gamma + \gamma$ were measured with the electromagnetic calorimeter (EMCal) of the PHENIX experiment [17]. The background from charged particles was subtracted with the aid of a layer of multiwire proportional chambers with pad readout (PC3) which was located directly in front of the EMCal. The minimum-bias trigger was provided by two beam-beam counters (BBC) which were also used to determine the collision vertex. In addition to the minimum-bias trigger conditions, a high-p_T photon trigger was used, derived from the analog energy signal measured with the EMCal.

The two BBC's were located symmetrically around the nominal interaction point at ± 1.44 m along the beam line. The BBC's subtended the pseudorapidity range $\pm(3.1–3.9)$ with full azimuthal coverage. The collision vertex was determined by measuring the difference of particle arrival times in the two BBC's. This analysis was restricted to events with a vertex in the range ± 30 cm. The BBC's were calibrated as a luminosity detector with absolute luminosity measurements based on the van der Meer scan technique [18]. With these scans the cross section for firing the BBC minimum-bias trigger was determined to be 21.8 ± 2.1 mb [1]. Thus, roughly 50% of the inelastic $p + p$ events satisfy the minimum-bias trigger condition if an inelastic $p + p$ cross section of 42 mb at $\sqrt{s} = 200$ GeV is assumed. This trigger efficiency is determined by the geometrical acceptance of the BBC's.

The PHENIX EMCal comprises two arms each with 4 sectors [19]. The EMCal consists of two different subdetectors, a lead-scintillator calorimeter (PbSc, 6 sectors) and a lead-glass calorimeter (PbGl, 2 sectors). Each sector covers a pseudorapidity range of $|\eta| < 0.35$ and an azimuthal range of $\Delta\phi \approx 22.5°$. Each PbSc (PbGl) sector is highly segmented and consists of 72×36 (96×48) individual detector modules, called towers, with a lateral size of 5.5×5.5 cm^2 (4×4 cm^2). With a radial distance of the sectors to the beam line of roughly 5 m this corresponds to a segmentation of $\Delta\phi \times \Delta\eta \approx 0.01 \times 0.01$ such that the two decay photons of a π^0 are well separated up to neutral-pion momenta of $p_T \approx 20$ GeV/c. The different detection mechanisms of the two subdetectors (measurement of scintillation light in PbSc and detection of Cherenkov photons in PbGl) result in a different response to hadrons. Thus, the PbSc and PbGl provide photon measurements with different systematic uncertainties. The energy calibration of the detector was obtained from the position of the π^0 invariant-mass peaks. A $\sim$4% ($\sim$ 5%) shift of the π^0 peak position due to energy smearing in conjunction with the influence of the steeply falling π^0 p_T spectrum was taken into account in the PbSc (PbGl) calibration. The calibration was corroborated by correlating the EMCal energy with the momentum of electrons measured with the PHENIX tracking detectors and, in case of the PbSc, by measuring the energy deposited by minimum-ionizing particles. From these studies the systematic uncertainty of the energy measurement was estimated to be less than 1.5%. In

a direct-photon analysis it is essential to exclude bad detector modules ("hot towers") which might give rise to spurious direct-photon signals. A detailed quality assessment was carried out to identify such towers.

The EMCal high-p_T trigger (called 2×2) was based on the analog energy signal measured in 2×2 groups of adjacent EMCal towers (called trigger tiles). The average threshold of the trigger corresponded to an energy signal of 0.75 GeV. The probability as a function of the photon p_T to fire the trigger was determined by Monte Carlo simulations which included the variation of the trigger tile thresholds, the EMCal detector response, and the geometry of the active trigger tiles. This trigger efficiency was confirmed with minimum-bias data. The photon trigger efficiencies for PbSc and PbGl reached a plateau above $p_T = 1.5$–2 GeV/c at the limit of about 0.78 expected from the number of active towers and 2×2 trigger tiles. The high-p_T-trigger photon sample was used above $p_T = 3$ GeV/c in the final spectrum.

Another EMCal trigger which did not require a coincidence with the minimum-bias trigger was used to account for the bias on the particle measurement due to the minimum-bias event selection. To this end the fraction of π^0's measured with this EMCal trigger for events which in addition satisfied the minimum-bias trigger condition was determined to be $f = 0.75 \pm 0.02$. The unbiased photon and neutral pions cross sections were then determined by dividing the total number of measured photons and neutral pions by this number.

The minimum-bias data sample in this analysis consisted of 16.7×10^6 events, corresponding to an integrated luminosity of 0.77 nb^{-1}. About 1 in 47 minimum-bias events also satisfied the 2×2 high-p_T trigger condition. The 18.7×10^6 analyzed 2×2 events thus corresponded to an integrated luminosity of 40.3 nb^{-1}.

The first step in the direct-photon analysis was to define a sample of direct-photon-candidate hits. An EMCal hit was rejected as a direct-photon candidate if it formed an invariant mass in the π^0 or η range with other hits in the same or adjacent sectors. The invariant-mass window was $110 < m_{\gamma\gamma} < 170$ MeV/c^2 for the π^0 and $500 < m_{\gamma\gamma} < 620$ MeV/c^2 for the η, corresponding roughly to a $\pm 2\sigma$ window around the observed π^0 and η peaks. To keep the rate of accidental rejections of genuine direct photons low it was required that the partner hits had a transverse momentum of $p_T > 0.4$ GeV/c. This cut effectively corresponded to a p_T-dependent upper limit on the energy asymmetry $\alpha = |E_{\gamma 1} - E_{\gamma 2}|/(E_{\gamma 1} + E_{\gamma 2})$ in the rejection procedure. In spite of this requirement, a small fraction of genuine direct photons is rejected. This was studied by inserting artificially generated direct-photon hits into real events. In order to keep the hit multiplicity constant, a randomly selected real hit was removed from an event in this procedure. It was found that the loss of genuine direct photons was less than 2% for $p_T > 3$ GeV/c. The final direct-photon spectrum was corrected for this effect. In order to increase the chances of finding the partner photon for a π^0 or η decay photon, direct-photon candidates were required to lie within a restricted fiducial area which was defined by a minimum distance of 16 (20) towers to the edge of the detector for the PbSc (PbGl). For example, for π^0's with $p_T = 4$ GeV/c and the requirement that one decay photon has a $p_T > 0.4$ GeV/c the average distance of the decay photons in tower units is ~ 8 (~ 11) for PbSc (PbGl). With the chosen fiducial area basically all decay photons from neutral pions with $p_T \gtrsim 4$ GeV/c could be tagged, if all towers were active. Monte Carlo studies showed that the rejection of direct-photon candidates based on the π^0 and η tagging lead to a reduction of background photons from hadron decays in the fiducial area of about a factor of 2 for $p_T > 5$ GeV/c. Some direct-photon analyses only measure isolated direct photons for which the total transverse energy or the number of charged tracks in a cone centered around the direct photon is required to lie below a threshold. No such cut was used in this analysis.

In order to reduce the background from hadronic hits in the EMCal, cuts were applied on the lateral shower shape and on the time of flight of the hits. The remaining contamination of charged particles was subtracted on a statistical basis by employing the PC3 as a charged-particle veto detector. The intrinsic efficiency of the PC3 for detecting a charged particle was higher than 99% and the active PC3 area in the EMCal acceptance was roughly 90%. PC3 hits were projected onto the EMCal surface using a straight line given by the PC3 hit and the event vertex. An EMCal hit within a certain veto radius was counted as a charged hit. The chosen veto radius decreased with increasing p_T and for $p_T > 0.8$ GeV/c a constant value of 15 cm was used. The fraction of charged hits was corrected for random associations with the help of a mixed-event technique. The charged-particle background in the direct-photon-candidate sample was $\sim 15\%$ around $p_T = 5$ GeV/c for both PbSc and PbGl. A large fraction of these background hits, however, comes from photon conversion in the field-free region between the vertex and PC3. The photon loss due to conversion was calculated based on the material budget up to PC3. The photon conversion probability was 4.1% for the 2 PbSc sectors in the East Arm of the central spectrometer, 5.3% for the 4 sectors in the West Arm, and 7.4% for the PbGl. These conversion losses were taken into account in the final photon cross section. The correction for the contamination of the raw spectrum of neutral EMCal hits with neutrons and antineutrons was determined with a detailed GEANT simulation [20]. In the case of the PbGl calorimeter the simulation was based on the creation of Cherenkov photons in order to achieve a realistic description of the detector response. The background from neutral particles was found to decrease with p_T and was already less than 1% for $p_T > 2$ GeV/c for both PbSc and PbGl.

The geometric acceptance and the efficiency of the photon detection were calculated with a Monte Carlo

simulation. The efficiency takes the distortion of the direct-photon-candidate spectrum due to energy smearing into account. Moreover, it corrects the small ($\lesssim 5\%$) loss of photons due to the shower shape and time-of-flight cuts. The final direct-photon spectrum was corrected for the difference between the average direct-photon cross section within a finite p_T bin and the value of the cross section at the bin center.

With the described corrections the unbiased differential cross section $\gamma_{\text{direct}}^{\text{cand}} \equiv E\mathrm{d}^3\sigma/\mathrm{d}^3p$ for the direct-photon candidates calculated from the minimum-bias data sample reads

$$E\frac{\mathrm{d}^3\sigma}{\mathrm{d}^3p} = \frac{1}{\hat{\mathcal{L}}} \cdot \frac{1}{2\pi p_T} \cdot \frac{C_{\text{reco}} \cdot C_{\text{conv}} \cdot C_{\text{loss}}}{f} \cdot \frac{N_{\text{direct}\gamma}^{\text{cand}}}{\Delta p_T \cdot \Delta y} \quad (1)$$

where $N_{\text{direct}\gamma}^{\text{cand}}$ is the total number of direct-photon candidates in a p_T bin Δp_T and rapidity bin Δy; C_{reco} is the acceptance and efficiency correction for photons; C_{conv} is the correction for photon conversions; C_{loss} is the correction for the loss of genuine direct photons in the π^0 and η tagging; $f = 0.75 \pm 0.02$ is the fraction of the unbiased direct-photon yield which is measured under the minimum-bias trigger condition; and $\hat{\mathcal{L}}$ is the integrated luminosity for the analyzed data sample. The high-p_T triggered sample required an additional correction for the efficiency of this trigger for photon detection.

The p_T spectrum of the direct-photon candidates contains direct photons as well as remaining background photons from hadron decays. These background photons mostly come from π^0 and η decays for which one decay photon misses the detector. At a representative bin of $p_T = 6.75$ GeV/c about 93% of the background photons originate from π^0 and η decays, the remaining background photons come from decays of other hadrons like ω and η'. The background was calculated with the same Monte Carlo code that was used for the acceptance and efficiency calculation. The Monte Carlo code took a parametrization of the measured π^0 spectrum as input. The π^0 and η tagging was done with the same reconstruction cuts as in the analysis of real events. The spectra of η mesons and other hadrons with photon decay branches were assumed to have the same shape as the π^0 spectrum as a function of $m_T = \sqrt{p_T^2 + m_0^2}$ (m_T scaling [21,22]). The η/π^0 invariant cross section ratio as a function of m_T was taken as 0.48 ± 0.1 which was confirmed by the measured η spectrum.

The dominant systematic uncertainty of the neutral-pion spectrum and the direct-photon-candidate spectrum came from the uncertainty of the energy scale and the uncertainty of the yield correction. At $p_T = 6.75$ GeV/c, the 1.5% uncertainty of the energy scale resulted in a 9% uncertainty in the photon yield. The yield correction included the correction for energy and position smearing of the detector, for photon losses due to particle-identification cuts, for photon conversions, and for the detector acceptance. For the neutral pions an additional 5% uncertainty came from the extraction of the π^0-peak content. In the case of the photon measurement the uncertainty due to the subtraction of charged and neutral backgrounds was taken into account. In the ratio $\gamma_{\text{direct}}^{\text{cand}}/\pi^0$ of the direct-photon-candidate spectrum and the neutral-pion spectrum systematic uncertainties partially cancel. Monte Carlo studies showed that the uncertainty of this ratio at $p_T = 6.75$ GeV/c due to a possible nonlinearity of the energy scale was $\sim 2\%$.

For the determination of the direct-photon spectrum the expected background photons from hadronic decays need to be subtracted from the spectrum of direct-photon candidates. To this end the ratio $R_\gamma = (\gamma_{\text{direct}}^{\text{cand}}/\pi^0)/(\gamma_{\text{bckg}}/\pi^0)$ of the measured direct-photon candidates to the calculated background was determined. The direct-photon spectrum was then calculated as

$$\gamma_{\text{direct}} = (1 - R_\gamma^{-1}) \cdot \gamma_{\text{direct}}^{\text{cand}}. \quad (2)$$

The relative systematic uncertainty of the direct-photon cross section was calculated as the quadratic sum of the relative uncertainties of the two factors in Eq. (2). The factor $1 - R_\gamma^{-1}$ contains the (statistical and systematic) significance of the direct-photon signal. When multiplying with $\gamma_{\text{direct}}^{\text{cand}}$, only the systematic uncertainties that cancelled in the ratio R_γ are added (e.g. the energy scale error). The overall normalization uncertainty from the luminosity determination was 9.6%. The estimated systematic uncertainties for the measured neutral-pion spectrum and the measured direct-photon-candidate spectrum are shown in Table I for a representative bin ($p_T = 6.75$ GeV/c) of the spectrum. The systematic uncertainty of the direct-photon measurement was corroborated by comparing results obtained for the different photon-identification criteria. Moreover, the individual PbGl and PbSc results were found to agree within systematic errors.

TABLE I. Systematic uncertainties of the neutral-pion spectrum, the direct-photon-candidate spectrum, and the measured and simulated γ/π^0 ratios at $p_T = 6.75$ GeV/c.

π^0 error source	PbGl	PbSc
Yield extraction	5%	5%
Yield correction	8%	6%
Energy scale	9%	8%
Total	13%	12%
$\gamma_{\text{direct}}^{\text{cand}}$ error source	PbGl	PbSc
Non-γ background correction	4%	4%
Yield correction	6%	5%
Energy scale	9%	9%
Total	12%	11%
Total error	PbGl + PbSc combined	
$\gamma_{\text{direct}}^{\text{cand}}/\pi^0$	9%	
$\gamma_{\text{bckg}}/\pi^0$	4%	

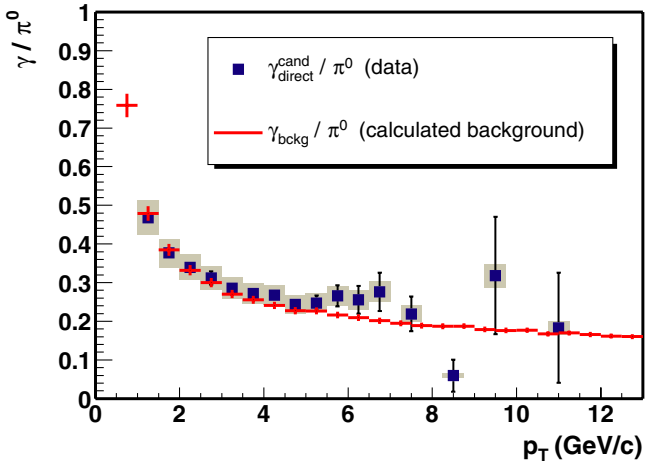

FIG. 1 (color online). Ratio of direct-photon candidates to the π^0 spectrum. The histogram represents the expected background signal from the Monte Carlo calculation. The error bars represent the statistical error and the boxes the systematic error.

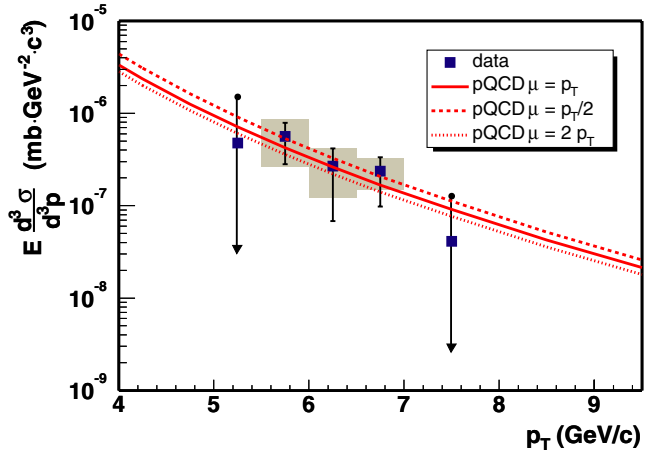

FIG. 2 (color online). Measured cross section and NLO pQCD calculations for direct-photon production in $p + p$ collisions at $\sqrt{s} = 200$ GeV. The normalization error of 9.6% is not shown. The two data points plotted with an arrow indicate the beginning of the low- and high-p_T ranges where the direct-photon signal is consistent with zero. The upper edges of the arrows indicate an upper limit (90% confidence level) for the direct-photon cross section calculated from the statistical and systematic uncertainty.

To make the best use of the available Run-2 statistics the photon and π^0 spectra from PbSc and PbGl were combined for the final result. The ratio of the acceptance- and efficiency-corrected direct-photon candidate p_T spectrum to the measured π^0 spectrum is depicted in Fig. 1. In addition, the Monte Carlo calculation for the ratio of the expected background photons to the π^0 spectrum is shown. At high p_T the statistical significance of the direct-photon-candidate spectrum is weak. However, around $p_T \approx$ 6–7 GeV/c there is clear evidence of a photon signal above the background.

The extracted invariant direct-photon spectrum is shown in Fig. 2 and the numerical values are given in Table II. The experimental result was compared to NLO pQCD calculations [23–28] which used the CTEQ6 parton distribution functions [29] and the Glück-Reya-Vogt parton-to-photon fragmentation function [30]. There are in general two mechanisms for the production of direct photons: the direct contribution from elementary scattering processes of quarks and gluons, described in the introduction, and the contribution from photons which are produced in the fragmentation of quark or gluon jets. The latter is a long-distance process which is not perturbatively calculable. It is described by a parton-to-photon fragmentation function which is determined experimentally. Since no isolation cut was used in the data analysis the pQCD calculation in Fig. 2 includes contributions from the direct production mechanism and the fragmentation mechanism. The separation of short-distance and long-distance processes in the pQCD calculation introduces unphysical renormalization, factorization, and fragmentation scales. Identical values for all three scales were used in the pQCD calculation. In Fig. 2, results are shown for three choices of the scales ($\mu = p_T$, $\mu = p_T/2$, and $\mu = 2p_T$). The theoretical and experimental results agree within the large uncertainties of the data points.

TABLE II. Invariant differential cross section for direct-photon production in $p + p$ collisions at $\sqrt{s} = 200$ GeV. Asymmetric uncertainties ($\sigma_{\rm low}$, $\sigma_{\rm high}$) are given for the cross section. The absolute normalization error of 9.6% is not included.

		Stat. error		Sys. error	
p_T (GeV/c)	$E\mathrm{d}^3\sigma/\mathrm{d}^3p$ (mb GeV$^{-2}c^3$)	$\sigma_{\rm low}$	$\sigma_{\rm high}$	$\sigma_{\rm low}$	$\sigma_{\rm high}$
5.75	5.61×10^{-7}	50%	42%	53%	54%
6.25	2.68×10^{-7}	75%	56%	55%	56%
6.75	2.37×10^{-7}	59%	42%	37%	38%

Prior to the Run-2 $p + p$ beam time PHENIX took data from Au + Au collisions at $\sqrt{s_{\rm NN}} = 200$ GeV. A clear direct-photon signal was observed in midcentral and central Au + Au reactions [13]. The strong suppression of π^0's and η's in Au + Au significantly reduced the number of background photons and eased the extraction of the direct-photon signal. The $p + p$ NLO pQCD was used as a baseline reference for the interpretation of the Au + Au result. In contrast to neutral pions no sign of a suppression of direct photons in Au + Au collisions was found. The direct-photon measurement presented in this paper supports the use of the NLO pQCD calculation as a reference for the results measured in Au + Au.

In summary, a small but significant direct-photon signal has been observed at midrapidity in $p + p$ collisions at $\sqrt{s} = 200$ GeV. The measured direct-photon cross section is in agreement with pQCD calculation, albeit within large errors.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We thank Werner Vogelsang for providing the NLO pQCD direct-photon calculations. We acknowledge support from the Department of Energy and NSF (U.S.A.), MEXT and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), CNRS-IN2P3 and CEA (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE and DST (India), ISF (Israel), KRF and CHEP (Korea), RMIST, RAS, and RMAE (Russia), VR and KAW (Sweden), U.S. CRDF for the FSU, US-Hungarian NSF-OTKA-MTA, and US-Israel BSF.

(Received 29 November 2004; published 3 March 2005)

We report on charged hadron production in deuteron-gold reactions at $\sqrt{s_{NN}} = 200$ GeV. Our measurements in the deuteron direction cover $1.4 < \eta < 2.2$, referred to as forward rapidity, and in the gold direction $-2.0 < \eta < -1.4$, referred to as backward rapidity, and a transverse momentum range $p_T = 0.5$–4.0 GeV/c. We compare the relative yields for different deuteron-gold collision centrality classes. We observe a suppression relative to binary collision scaling at forward rapidity, sensitive to low momentum fraction (x) partons in the gold nucleus, and an enhancement at backward rapidity, sensitive to high momentum fraction partons in the gold nucleus.

DOI: 10.1103/PhysRevLett.94.082302 PACS numbers: 25.75.Dw

Deep inelastic scattering of leptons on the proton revealed the proton's substructure of pointlike parton constituents [1]. This substructure, usually described quantitatively as parton distribution functions, evolves as one probes the proton at shorter wavelength or equivalently higher momentum transfer, Q^2. Using the measured quark and antiquark distribution functions and the DGLAP [2] and BFKL [3] evolution equations, a strong increase in the gluon density is expected at high Q^2 and small x (fraction of the proton momentum carried by the parton). Such an increase is, indeed, observed at HERA [4], suggesting that at sufficiently small x, gluons should overlap in space and time. This overlap should result in gluon fusion, and thus reduce the gluon density at low x and enhance it at larger x. This gluon fusion limits the achievable gluon density, leading to gluon saturation. This saturation is sometimes described as the formation of a color glass condensate [5]. Gluon saturation is expected to be a larger effect in nuclei where the partons from different nucleons overlap as well. Suppression of low x partons in nuclei relative to nucleons has been experimentally observed and is referred to as nuclear shadowing [6]. However, this shadowing is often described in terms of modification of the leading-twist parton densities in nuclei [7].

In 2003 the Relativistic Heavy Ion Collider (RHIC) collided deuteron and gold nuclei at $\sqrt{s_{NN}} = 200$ GeV. At this energy, most hadrons with $p_T > 2.0$ GeV/c arise from parton-parton interactions and can be used as a probe of nuclear partonic structure. Hadrons with $p_T > 2.0$ GeV/c at forward rapidity $1.4 < \eta < 2.2$ are sensitive to low x partons in the gold nucleus $0.001 < x < 0.03$. Hadrons at backward rapidity $-2.0 < \eta < -1.4$ are sensitive to high x partons in the gold nucleus $0.04 < x < 0.5$. It has been predicted that gluon saturation at small x will suppress hadronic yields at forward rapidity [8] with the transverse momentum scale for the onset of the gluon saturation set by $Q_s^2[\mathrm{GeV}^2] = 0.13 N_{\mathrm{coll}} e^{\lambda y}$ [9] for d + Au collisions at RHIC. Here $\lambda \sim 0.3$ is determined from HERA data [10] and N_{coll} is the number of nucleon-nucleon inelastic collisions. Thus, for central collisions and within our forward rapidity coverage Q_s^2 is expected to be of order 2–4 GeV^2 and may have observable consequences. Novel hadron production mechanisms, such as quark recombination [11], can also impact the distribution of particles in the forward rapidity region.

Results on charged hadron yields at forward rapidity from the BRAHMS experiment have shown a suppression of the yield of hadrons in central, compared to peripheral, d + Au collisions [12]. At midrapidity, PHENIX has reported a modest enhancement of the yield of hadrons with $p_T > 1.5$ GeV/c [13]. This enhancement, generally referred to as the "Cronin effect" is often ascribed to initial state scattering of the parton traversing the nucleus prior to the high Q^2 scattering [14]. At backward rapidities (large x), antishadowing and other effects of the surrounding nuclear medium (e.g., the EMC effect) [15] may compete, making predictions challenging.

It is important to note that in the transverse momentum range of this measurement, $0.5 < p_T < 4.0$ GeV/c, hadron production is also sensitive to soft physics phenomena which are determined by coherent hadron-hadron interactions. In $p + A$ reactions at lower energies soft hadron production shifts from forward to backward rapidity, with a larger shift for larger nuclear targets. Thus, at low p_T one may observe an increase (decrease) in hadron yields at backward (forward) rapidity which is not necessarily a reflection of changes at the partonic structure level.

In this Letter, we present results from the PHENIX experiment [16] on the ratio of hadron yields at forward and backward pseudorapidity for different centrality classes of d + Au collisions. PHENIX has two spectrometers designed for measuring muon production over the pseudorapidity range $-2.2 < \eta < -1.2$ (backward spectrometer) and $1.2 < \eta < 2.4$ (forward spectrometer) [16]. The spectrometers start with a thick hadron absorber composed of 19 cm of brass and 60 cm of low-carbon steel between the collision point and active detectors along the beam axis, primarily to reduce hadronic background for muon measurements [17]. After this material, the Muon Tracker (MuTr) detector, consisting of three stations of cathode strip chambers, tracks charged particles in a magnetic field. The momentum resolution is 5% (for typical momenta in this analysis) and the absolute scale is known to better than 1%. Following the muon magnet backplate [30 (20) cm of steel in the forward (backward) spectrometer] there is a Muon Identifier (MuID) detector. The MuID consists of five layers of planar drift tubes interleaved with layers of steel for further hadron absorption (10 cm thick in the first two layers and 20 cm thick for the remaining layers). The layers are numbered 0–4, with 4 being the most downstream. The MuID is used to separate muons from hadrons and provide triggering capabilities.

Although these spectrometers were designed to detect muons, they can also be used to measure charged hadrons via two independent methods. The first method is via the identification of hadrons which penetrate part way through the MuID, referred to as "punch-through hadrons." The second method is via muons from light mesons π, K which decay before interacting in the absorber material. By measuring these decay muons, we can reconstruct the yield of their parent light mesons. In both of these methods the absolute yield of hadrons is difficult to determine due to uncertainties in the punch-through and decay probabilities. However, this small probability is independent of d + Au collision centrality, and thus not knowing the absolute yields does not affect the precision of measured ratios of hadron yields between the different classes of events.

The punch-through hadron identification is achieved by studying particles that stop somewhere within the MuID before the last layer. For muons penetrating up to layers 2

and 3 we expect the average momenta measured in the MuTr of $p = 1.0$ and $1.2\ \mathrm{GeV}/c$, respectively, corresponding to the average ionization energy loss in traversing the spectrometer material. The reconstructed momentum distributions for particles stopping in layers 2 and 3 of the MuID are shown in Fig. 1. In addition to the expected muon peaks, there is a broad distribution extending to higher momentum which is the result of punch-through hadrons. These hadrons also suffer ionization energy loss up to the relevant layer, then suffer an inelastic collision in the MuID steel, and do not penetrate further. We thus select a clean sample of hadrons by demanding that a track stop in MuID layer 2 or 3 and have momentum more than 3σ away from the muon peaks. Muon contamination in our sample is estimated from simulations to be less than 5%.

Another source of background for the punch-through hadrons is secondary particles produced from hadronic showering in the absorber. This background is reduced by requiring that the track point back to the primary collision vertex, as determined from the beam-beam counter (BBC). The background from secondary particles varies as a function of p_T and is typically ~1%–5% of the signal based on simulations. We also apply acceptance cuts $-2.0 < \eta < -1.4$ and $1.4 < \eta < 2.2$ in order to reduce the background at small angles.

Some hadrons will decay into muons before the absorber, and the decay muons are then measured by the muon spectrometers. Muons can result from many sources including decays of π, K, D mesons, and J/ψ. These particles have a finite decay probability P_{decay} before they reach the absorber

$$P_{\mathrm{decay}}(p, L) = 1 - e^{-Lm/\tau p}, \tag{1}$$

where $L \sim 41$ cm is the distance from the collision vertex to the absorber; p, m, and τ are the momentum, mass, and proper lifetime of the parent particle.

Thus, collisions that occur far from the absorber are more likely to produce muons from light meson decays than those that occur close to the absorber. Charm hadrons, however, due to their very short proper decay lengths, $e^{-Lm/\tau p} \ll 1$, will have minimal collision vertex dependence. The right panel of Fig. 1 shows the collision vertex distribution from events in which muons are detected at forward rapidity, corrected for the minimum bias collision vertex distribution. The large vertex dependence indicates a significant fraction of the muons are from pion and kaon decay. Using this distribution, we can separate the muons from pion and kaon decay from other contributions. The acceptance and efficiency vary by less than 5% over the z vertex range, which establishes an upper bound on the systematic error attributable to the subtraction of these nonsignal contributions. It should be noted that the measured muon p_T is approximately 15% lower on average than the parent hadron p_T, which is not corrected for in this analysis.

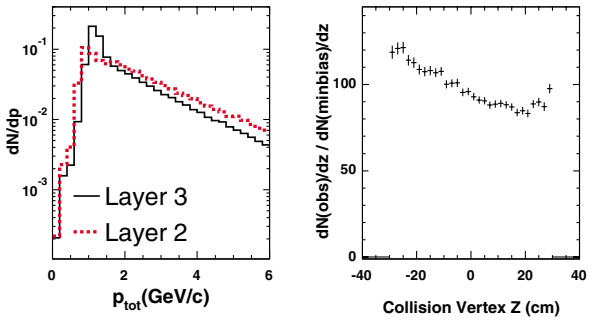

FIG. 1 (color online). Left: The total momentum p_{tot} measured in the MuTr without energy loss correction of all charged tracks penetrating to MuID layers 2 (gray) and 3 (black). Right: Collision vertex distribution for events with muons at forward rapidity, corrected for the minimum bias collision vertex distribution.

The data set for this analysis was collected under two different trigger conditions. We recorded 67×10^6 minimum bias triggers which required at least one hit in both the PHENIX forward $3.0 < \eta < 3.9$ and backward $-3.9 < \eta < -3.0$ BBC and a reconstructed vertex position within $|z| < 30$ cm along the beam axis. The minimum bias trigger accepts $88\% \pm 4\%$ of all inelastic d + Au collisions [13]. The second data set, sampling 5.3×10^9 minimum bias events, was collected with the MuID trigger which requires at least one track penetrating the first four layers of the MuID.

We divide these events into four centrality classes based on the number of particle hits in the backward BBC counter covering $-3.9 < \eta < -3.0$. Using a Glauber model [13] and simulation of the BBC, we determine the average number of binary collisions in each centrality class. The classes are categorized as follows: 60%–88% ($\langle N_{\mathrm{coll}} \rangle = 3.1 \pm 0.3$), 40%–60% ($\langle N_{\mathrm{coll}} \rangle = 7.0 \pm 0.6$), 20%–40% ($\langle N_{\mathrm{coll}} \rangle = 10.6 \pm 0.7$), and 0%–20% ($\langle N_{\mathrm{coll}} \rangle = 15.4 \pm 1.0$).

There is a correlation between having a particular physics process (for example, the production of a high p_T hadron) and the BBC response. The BBC coverage in pseudorapidity is well separated from the muon spectrometers so the correlation is not predominantly due to jet fragmentation, but rather an underlying event correlation. We have studied this effect in detail using proton-proton and d + Au data, as well as in simulations, and have accounted for this correlation bias. The bias correction factors we apply range from 0%–7% depending on the centrality category and the physics process. The systematic errors on these corrections are less than 4%.

The *nuclear modification factor* R_{cp} is defined as the ratio of the particle yield in central collisions to the particle yield in peripheral collisions, each normalized by the average number of nucleon-nucleon binary collisions ($\langle N_{\mathrm{coll}} \rangle$):

$$R_{cp} = \frac{\langle (\frac{dN}{d\eta dp_T})^{\mathrm{central}} \rangle / \langle N_{\mathrm{coll}}^{\mathrm{central}} \rangle}{\langle (\frac{dN}{d\eta dp_T})^{\mathrm{peripheral}} \rangle / \langle N_{\mathrm{coll}}^{\mathrm{peripheral}} \rangle}. \tag{2}$$

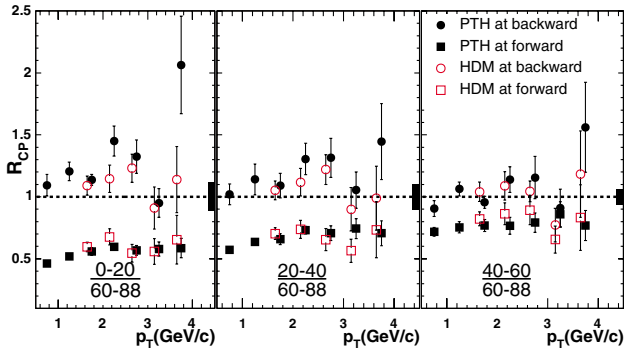

FIG. 2 (color online). R_{cp} as a function of p_T at forward rapidity (squares) and backward rapidity (circles) for different centrality classes.

The hadron R_{cp}, using the most peripheral centrality class (60%–88%) for normalization, is shown in Fig. 2 as a function of p_T at forward and backward rapidities. The results from the punch-through hadron and hadron decay muon techniques are both shown and are in quite good agreement. We also show the results integrated over $1.5 < p_T < 4.0$ GeV/c as a function of pseudorapidity in Fig. 3.

There are two types of systematic uncertainties in our analysis. Common systematic errors which move all data points up and down together include the error on $\frac{N_{\rm coll}^{\rm central}}{N_{\rm coll}^{\rm peripheral}}$ (10.8% for the most central bin), the centrality bias correction factors (4%), and the centrality-dependent tracking efficiency (4%) determined by embedding Monte Carlo particles in real data. Common systematic errors are shown as a black bar. Point-to-point systematic errors result from sensitivities to analysis cuts and are 5%–10%. They are added in quadrature with the statistical errors and shown as error bars.

It is notable that our two measurement methods have different sensitivity to different hadrons. The particle composition ($\pi/K/p$ ratio) of the observed sample is modified relative to the particle composition at the collision vertex due to species-dependent nuclear interaction cross sections affecting the punch-through hadrons and due to species-dependent decay lifetimes affecting the hadron decay muons. Both effects enhance the kaon contribution to our R_{cp} measurements. The uncertainty on our charged hadron R_{cp} values introduced by this effect is estimated to be less than 4% by calculating the difference between the kaon R_{cp} and inclusive charged particle R_{cp} determined by PHENIX at midrapidity [18].

We observe that R_{cp} shows a suppression at forward rapidity that is largest for the most central events. The opposite trend is observed at backward rapidity where R_{cp} shows an enhancement that is also largest for the most central events. We observe a weak p_T dependence with slightly smaller R_{cp} values at lower p_T. We observe a clear pseudorapidity dependence at forward rapidity with R_{cp} dropping further at larger η values. Within our current uncertainties we are unable to discern any pseudorapidity dependence at backward rapidity.

In Fig. 4 we compare results from the BRAHMS experiment [12] with our results at forward rapidity. The PHENIX data and the BRAHMS data are in agreement within systematic uncertainties.

The suppression of hadron yields relative to binary collision scaling at forward rapidity is expected from initial state nuclear effects. However, detailed comparisons with various theoretical approaches is necessary in order to discriminate between different models. In particular, the lack of a strong p_T dependence at both forward and backward rapidities must be understood as the physics processes transition from "soft" to "hard" physics scales.

To summarize, we observe a suppression in hadron yields relative to binary collision scaling at forward rapidities and an enhancement at backward rapidity for central relative to peripheral d + Au reactions at $\sqrt{s_{NN}} =$ 200 GeV. The forward rapidity suppression is in qualitative agreement with the expectation of shadowing and saturation effects in the small x region in the gold nucleus.

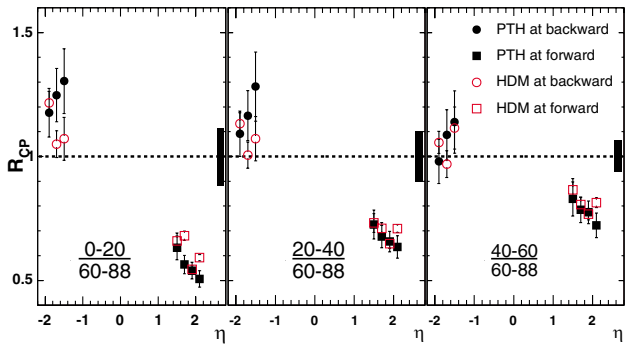

FIG. 3 (color online). R_{cp} as a function of η for $1.5 < p_T < 4.0$ GeV/c for different centrality classes.

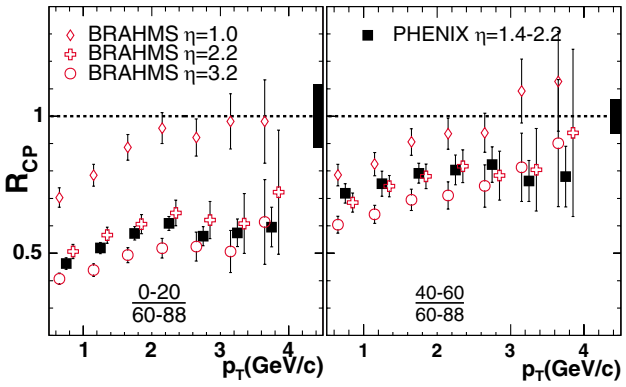

FIG. 4 (color online). PHENIX R_{cp} as a function of p_T at forward rapidities shown as the average of the two methods. Note that the BRAHMS results are for negative hadrons at $\eta =$ 2.2 and 3.2, and their centrality ranges (0%–20%/60%–80% and 30%–50%/60%–80%) are somewhat different from ours.

However, other physics effects must also be considered in understanding the full p_T and η dependence. The source of the backward rapidity enhancement, and the possible contribution of antishadowing of large x partons, has yet to be understood.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We acknowledge support from the Department of Energy and NSF (U.S.A.), MEXT and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), IN2P3/CNRS, CEA, and ARMINES (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE and DST (India), ISF (Israel), KRF and CHEP (Korea), RMIST, RAS, and RMAE (Russia), VR and KAW (Sweden), U.S. CRDF for the FSU, U.S.-Hungarian NSF-OTKA-MTA, and U.S.-Israel BSF.

(Received 19 November 2004; published 17 June 2005)

New measurements are presented for charged hadron azimuthal correlations at midrapidity in Au + Au collisions at $\sqrt{s_{NN}} = 62.4$ and 200 GeV. They are compared to earlier measurements obtained at $\sqrt{s_{NN}} =$ 130 GeV and in Pb + Pb collisions at $\sqrt{s_{NN}} = 17.2$ GeV. Sizeable anisotropies are observed with centrality and transverse momentum (p_T) dependence characteristic of elliptic flow (v_2). For a broad range of centralities, the observed magnitudes and trends of the differential anisotropy, $v_2(p_T)$, change very little over the collision energy range $\sqrt{s_{NN}} = 62$–200 GeV, indicating saturation of the excitation function for v_2 at these energies. Such a saturation may be indicative of the dominance of a very soft equation of state for $\sqrt{s_{NN}} \sim 60$–200 GeV.

DOI: 10.1103/PhysRevLett.94.232302 PACS numbers: 25.75.Ld

Extremely high energy-density nuclear matter is produced in energetic Au + Au collisions at the relativistic heavy ion collider (RHIC) [1,2]. The dynamical evolution of this matter is predicted to reflect the presence and evolution of the quark gluon plasma (QGP)—a new phase of nuclear matter [3–5]. Azimuthal correlation measurements are important in several ways. They serve as a ''barometric sensor'' for pressure gradients developed in the collision and hence yield insight into crucial issues of thermalization and the equation of state (EOS) [6–8]. They provide important constraints for the density of the medium and the effective energy loss of partons which traverse it [9]. They can provide valuable information on the gluon saturation scale in the nucleus [10].

Recent measurements at RHIC ($\sqrt{s_{NN}} = 130$ and 200 GeV) indicate a mixture of (di-)jet and harmonic contributions to azimuthal correlations in Au + Au collisions [11–14]. The asymmetric (di-)jet contributions are found to be relatively small but can be separated; they show an increase with p_T and indicate strong suppression of away-side jet yields [13]. Significant modifications to the away-side jet topology have also been reported [15]. These observations, which are particularly striking for very central collisions, have been interpreted as evidence for parton energy loss and jet quenching in the produced medium [3]. The harmonic contributions show significant strength at midrapidity with characteristic dependencies on p_T and centrality [11,16–18]. They are typically characterized by the second order Fourier coefficient, $v_2 = \langle e^{i2(\phi_1 - \Phi_{\mathrm{RP}})} \rangle$, where ϕ_1 represents the azimuthal emission angle of a charged hadron and ϕ_{RP} is the azimuth of the reaction plane. The brackets denote statistical averaging over particles and events. At low p_T ($p_T \lesssim 2.0$ GeV/c) the magnitude and trends of v_2 are under-predicted by hadronic cascade models supplemented with string dynamics [19], but are well reproduced by models which incorporate hydrodynamic flow [5,7]. This has been interpreted as evidence for the production of a thermalized state of partonic matter [3–5]. At higher p_T the predictions of quark coalescence [20] are consistent with the data [18,21], and quantitative agreement has been achieved with transport model calculations which incorporate large opacities [22].

At Super Proton Synchrotron (SPS) energies ($\sqrt{s_{NN}} \sim$ 17 GeV) azimuthal correlation measurements also indicate a mixture of (di-)jet and harmonic contributions [23,24]. However, the observed anisotropy of the harmonic contribution is approximately 50% of the value observed at full RHIC energy ($\sqrt{s_{NN}} = 200$ GeV). Therefore, an important outstanding issue is the detailed behavior of v_2 over the range which spans SPS-RHIC energies. In recent work, the PHOBOS Collaboration has investigated the patterns for p_T-integrated v_2 over a broad range of pseudorapidities [25]. We present more revealing differential measurements for Au + Au collisions at $\sqrt{s_{NN}} = 62.4$–200 GeV and the first excitation function for differential v_2 which spans beam energies from the Alternating Gradient Synchrotron (AGS) to RHIC ($\sqrt{s_{NN}} \sim$ 3–200 GeV).

The colliding Au beams ($\sqrt{s_{NN}} = 62.4$, 130, and 200 GeV) used in the measurements presented here have been provided by RHIC in three separate experimental running periods (years 2004, 2000, and 2001, respectively). Charged tracks were detected in the two central arms ($|\eta| \leq 0.35$) of PHENIX [26]. Track reconstruction was accomplished at each collision energy via pattern recognition using a drift chamber (DC) followed by two layers of multiwire proportional chambers with pad readout (PC1 and PC3) located at radii of 2, 2.5, and 5 m, respectively [26]. For each analysis, the collision vertex z

along the beam direction was constrained to be within $|z| < 30$ cm. A confirmation hit within a 2σ matching window was required in PC3 to eliminate most albedo, conversions, and decays. Particle momenta were measured with resolutions $\delta p/p = 0.7\% \oplus 0.91\% p$, $\delta p/p = 0.6\% \oplus 3.6\% p$, and $\delta p/p = 0.7\% \oplus 1.0\% p(\mathrm{GeV}/c)$ at $\sqrt{s_{NN}} = 62.4$, 130, and 200 GeV, respectively.

Event centralities were obtained at $\sqrt{s_{NN}} = 62.4$ GeV via a series of cuts on the analog response of the PHENIX beam counters (BBC). For $\sqrt{s_{NN}} = 130$ and 200 GeV, cuts in the space of BBC versus zero-degree calorimeter analog response were employed; they reflect percentile cuts on the total interaction cross section at each beam energy [27]. Estimates for the number of participant nucleons N_{part} were also made for each of these cuts following the Glauber-based model detailed in Ref. [27]. Systematic uncertainties associated with these determinations are estimated to be less than $\sim 10\%$ for central and midcentral collisions.

The differential v_2 measurements reported in this Letter have been obtained via three separate methods of analysis:

First, we used the reaction plane technique which correlates the azimuthal angles of charged tracks detected in the central arms with the azimuth of an estimated event plane Φ_2, determined via hits in the north and south BBC's located at $|\eta| \sim 3$–3.9 [18]. This method was used for the analysis of data taken at both $\sqrt{s_{NN}} = 62.4$ and 200 GeV. Corrections [18,28] were applied to account for possible azimuthal distortions in the distribution of the estimated reaction planes. Values of v_2 were calculated via the expression

$$v_2 = \frac{\langle \cos(2(\phi - \Phi_2)) \rangle}{\langle \cos(2(\Phi_2 - \Phi_{RP})) \rangle}, \quad (1)$$

where the denominator represents a resolution factor which corrects for the difference between the estimated and the true azimuth of the reaction plane Φ_{RP} [18,28]. The estimated resolution of the combined reaction plane from both BBC's [18] has an average of 0.33(0.16) over centrality with a maximum of about 0.42(0.19) for $\sqrt{s_{NN}} =$ 200(62.4) GeV. Thus, the estimated correction factor, which is the inverse of the resolution for the combined reaction plane, ranges from 2.4(5.4) to 5.0(13).

Second, we performed a cumulant analysis on data collected at $\sqrt{s_{NN}} = 200$ and 62.4 GeV to obtain the anisotropy directly [29]

$$\langle e^{2i(\phi_1 - \phi_2)} \rangle = \langle e^{2i\phi_1} \rangle \langle e^{-i2\phi_2} \rangle + \langle\langle e^{2i(\phi_1 - \phi_2)} \rangle\rangle, \quad (2)$$

where the double brackets denote an average over pairs of particles emitted in an event followed by further averaging over events. For a detector having full azimuthal acceptance, the averages $\langle e^{2i\phi_1} \rangle$ and $\langle e^{-2i\phi_2} \rangle$ vanish due to symmetry considerations to give the second order cumulant estimate $v_2\{2\}$ [29] of v_2

$$\langle\langle e^{2i(\phi_1 - \phi_2)} \rangle\rangle = v_2\{2\}^2. \quad (3)$$

Since PHENIX does not have full azimuthal acceptance, $\langle e^{2i\phi_1} \rangle$ and $\langle e^{-2i\phi_2} \rangle$ do not vanish and this leads to an initial underestimate of the extracted anisotropy. To correct for this underestimate, separate correction factors ($\sim 30\%$) were evaluated and applied for each centrality and p_T cut, at each collision energy, following the procedures detailed in Ref. [29].

Third, we extracted the anisotropy at $\sqrt{s_{NN}} = 62.4$, 130, and 200 GeV via assorted two-particle correlation functions [11,18]: $C(\Delta\phi) = N_{\mathrm{cor}}(\Delta\phi)/N_{\mathrm{mix}}(\Delta\phi)$, where $N_{\mathrm{cor}}(\Delta\phi)$ is the observed $\Delta\phi$ distribution for charged particle pairs selected from the same event, and $N_{\mathrm{mix}}(\Delta\phi)$ is the $\Delta\phi$ distribution for particle pairs selected from mixed events. Mixed events were obtained by randomly selecting each member of a particle pair from different events with the same multiplicity and vertex cuts.

To extract the anisotropy of these correlations, two correlation functions were generated for each p_T and centrality selection [11,18]. For the first, charged hadron pairs were formed by selecting both particles from a reference range $p_{T,\mathrm{ref}}$, which excluded the p_T range of interest (i.e., a reference correlation). For the second, assorted hadron pairs were formed by selecting one member from the p_T range of interest and the other from $p_{T,\mathrm{ref}}$. The elliptic flow v_2 was obtained via the ratio $A_{2,a}/\sqrt{A_{2,\mathrm{ref}}} = v_2$, where $A_{2,a}$ and $A_{2,\mathrm{ref}}$ are the anisotropies extracted from the assorted and reference correlation functions (respectively) with the fit function:

$$C(\Delta\phi) = a_1[1 + 2A_2 \cos(2\Delta\phi) + \lambda e^{[-0.5(\Delta\phi/\sigma)^2]}], \quad (4)$$

where the Gaussian and harmonic terms are used to characterize the asymmetry (at small $\Delta\phi$) and the anisotropy of the correlation function, respectively [11,13].

Figure 1 shows representative $\Delta\phi$ correlation functions obtained for charged hadrons detected in the PHENIX central arms ($-0.35 < \eta < 0.35$) at $\sqrt{s_{NN}} = 62.4$ GeV. Correlation functions for midcentral events (centrality = 20%–40%) are shown for hadrons with $0.5 < p_T < 0.7$ GeV/c and $1.0 < p_T < 1.5$ GeV/c in Fig. 1(a) and Fig. 1(c), respectively. The same p_T cuts have been made for the correlation functions shown in Figs. 1(b) and 1(d) but for more peripheral collisions (centrality = 40%–60%). For both sets of correlation functions $0.65 < p_{T,\mathrm{ref}} < 2.5$ GeV/c. Figures 1(a)–1(d) show a clear anisotropic pattern with relatively small asymmetries (0°/180° ratios). Such asymmetries have been attributed to small jet contributions to the correlation functions [11,13], and are expected to decrease with decreasing $\sqrt{s_{NN}}$. The curves in Fig. 1 indicate a fit to the correlation function with Eq. (4); they show an increase of the anisotropy with increasing impact parameter and p_T. These trends are similar to those of prior AGS, SPS, and RHIC measurements [16,23,24,30] and are consistent with the expected patterns for in-plane elliptic flow [5,7].

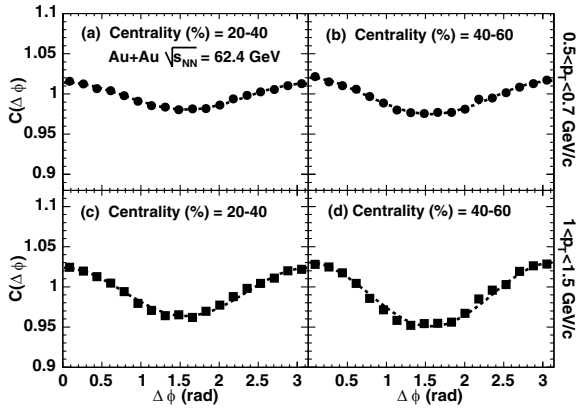

FIG. 1. Assorted-p_T correlation functions ($0.65 < p_{T,\mathrm{ref}} < 2.5$ GeV/c) for charged hadrons of $0.5 < p_T < 0.7$ GeV/c (top panels) and $1.0 < p_T < 1.5$ GeV/c (bottom panels) obtained in Au + Au collisions at $\sqrt{s_{NN}} = 62.4$ GeV. The left and right panels show correlation functions for centrality cuts of 20%–40% and 40%–60%, respectively. The lines represent fits to the correlation functions (see text).

Figure 2 compares the differential anisotropy $v_2(p_T)$, obtained at $\sqrt{s_{NN}} = 62.4$ GeV for all three methods of extraction. The error bars shown indicate statistical errors. Systematic errors are estimated to be ~10%, 5%, and 5% for extractions via the reaction plane, cumulant, and correlation function methods of analysis, respectively. The results, which are shown for two separate centrality cuts (0%–20% and 20%–40%) in each case, indicate an initial increase of v_2 with p_T followed by the previously observed plateau for $p_T \gtrsim 2.5$ GeV/c [11,17]. The close agreement of $v_2(p_T)$ values obtained from the cumulant and correlation function methods of analysis serve to confirm the reliability of these methods of extraction. On the other hand, the agreement between results from these latter methods and that obtained from the reaction plane method is quite striking, given the large rapidity gap (~3 units) between the particles used for reaction plane determination and the midrapidity particles correlated with this plane. It is expected that the latter correlations are less influenced by nonflow contributions, especially for $p_T < 2.0$ GeV/c. Consequently, we attribute this agreement to the absence of strong nonflow contributions to the hadron correlations (for $p_T < 2.0$ GeV/c) at midrapidity. A similarly good agreement between the different methods of analysis was obtained for all centralities presented in this work.

Figure 3 compares the centrality and p_T dependence (respectively) of the anisotropy obtained at several collision energies. The circles, stars, and squares in Fig. 3(a) show $v_2(N_{\mathrm{part}})$ for $\langle p_T \rangle$ selections of 0.4, 0.75, and 1.35 GeV/c obtained via the cumulant and correlation function methods of analysis. The same results obtained via the reaction plane method are consistent with prior results [18]. The open and filled symbols show measurements performed at $\sqrt{s_{NN}} = 62.4$ and 130 (200) GeV as indicated; they show rather striking agreement between the magnitudes of the v_2 values obtained at all three collision energies. Further evidence that this agreement persists down to $\sqrt{s_{NN}} = 62.4$ GeV is given in Fig. 3(b). The open and filled circles compare the differential anisotropy $v_2(p_T)$, obtained at $\sqrt{s_{NN}} = 62.4$ and 200 GeV for the 13%–26% most central collisions ($\langle N_{\mathrm{part}} \rangle = 200$). The comparison indicates that $v_2(p_T)$ saturates above 2 GeV/c independent of beam energy. Such a saturation is compatible with surface emission from a relatively opaque source [22]. More importantly, very little change in v_2 is observed as the collision energy is raised from $\sqrt{s_{NN}} = 62.4$ to 200 GeV. The latter contrasts with the much lower v_2 values measured in Pb + Pb collisions (filled squares) by the CERES Collaboration at $\sqrt{s_{NN}} = 17.2$ GeV for the same centrality cut (13%–26%) [23].

Figure 4 summarizes the $\sqrt{s_{NN}}$ dependence of v_2 for charged hadrons produced in Au + Au collisions for two separate p_T selections (0.65 and 1.75 GeV/c) and

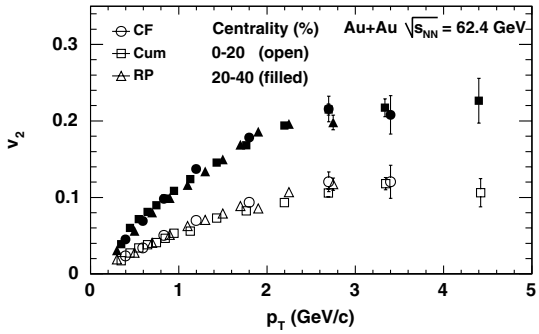

FIG. 2. Differential anisotropy $v_2(p_T)$ for charged hadrons in Au + Au collisions at $\sqrt{s_{NN}} = 62.4$ GeV with centrality cuts of 0%–20% (open symbols) and 20%–40% (filled symbols), obtained via the methods of correlation functions (CF), cumulants (Cum), and reaction plane (RP).

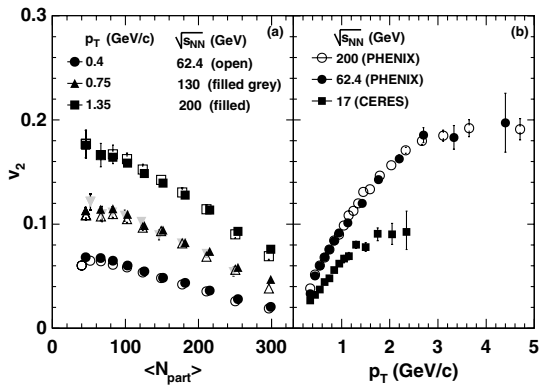

FIG. 3. Differential anisotropy $v_2(N_{\mathrm{part}})$ (left) and $v_2(p_T)$ (right) for several energies as indicated. $v_2(p_T)$ is shown for the centrality selection 13%–26% ($\langle N_{\mathrm{part}} \rangle = 200$) which facilitates a comparison with CERES data (filled squares) from Ref. [23].

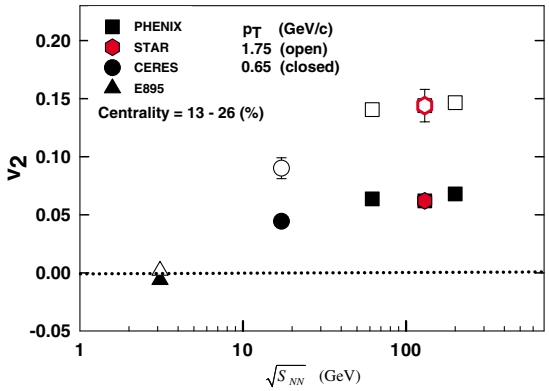

FIG. 4 (color online). Differential v_2 vs $\sqrt{s_{NN}}$ for charged hadrons in nucleus-nucleus collisions. Results are shown for the centrality cut of 13%–26% and p_T selections of 1.75 GeV/c (open symbols) and 0.65 GeV/c (closed symbols). The STAR, CERES, and E895 data are taken from Refs. [17,23,30–32], respectively.

centrality = 13%–26%. These data are taken from the current measurements and earlier measurements at the SPS [23] and the AGS [30–32]. The AGS [E895] measurements [30–32] are for protons but the transition energy is not very different for pions and protons. The STAR results were obtained for a slightly different centrality selection (10%–30%) [17] having essentially the same mean centrality. For both p_T cuts, the magnitude of v_2 shows a significant increase with collision energy (~50% increase from SPS to RHIC) up to the energy $\sqrt{s_{NN}} = 62.4$ GeV. Thereafter, it appears to saturate for larger beam energies. We note that this saturation is not in conflict with the recent observation of an increase of the p_T-integrated v_2 with $\sqrt{s_{NN}}$ [25]. The latter increase is expected if the $\langle p_T \rangle$ increases with $\sqrt{s_{NN}}$.

To summarize, we have measured differential azimuthal anisotropies for charged hadrons in Au + Au collisions spanning the energy range $\sqrt{s_{NN}} = 62.4$–200 GeV. Detailed comparisons of these differential measurements indicate no significant collision energy dependence of the anisotropy over this range. By contrast, comparisons to differential measurements obtained at AGS and SPS energies indicate that v_2 increases with collision energy up to $\sqrt{s_{NN}} = 62.4$ GeV. The energy density is estimated to increase by approximately 30% over the range $\sqrt{s_{NN}} = 62.4$–200 GeV. In a hydrodynamic scenario v_2 is driven by a pressure gradient which is related to the energy density via the equation of state [5,7]. Thus, the apparent saturation of v_2 above $\sqrt{s_{NN}} = 62.4$ GeV may be indicative of the role of a rather soft equation of state. Such a softening could result from the production of a mixed phase [31] for the range $\sqrt{s_{NN}} = 62.4$–200 GeV. Additional combined measurements of v_2, particle spectra, and the space-time extent of emission sources are required to further constrain the EOS.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. Abstract

Directed and elliptic flow of inclusive photons near mid-rapidity in 158 A GeV Pb + Pb collisions has been studied. The data have been obtained with the photon spectrometer LEDA of the WA98 experiment at the CERN SPS. The flow strength has been measured for various centralities as a function of p_T and rapidity over $0.18 < p_T < 1.5$ GeV/c and $2.3 < y < 2.9$. The angular anisotropy has been studied relative to an event plane obtained in the target fragmentation region that shows the elliptic flow to be in-plane. The elliptic flow has also been studied using two-particle correlations and shown to give similar results. A small directed flow component is observed. Both the directed and elliptic flow strengths increase with p_T. The photon flow results are used to estimate the corresponding neutral pion flow.

1. Introduction

Heavy ion collisions at relativistic energies provide a means to study the properties of nuclear matter at high temperature and density. In such collisions it is expected that a high density interaction zone is formed. If this system thermalizes, the thermal pressure will generate collective transverse expansion [1]. Such collective flow, and especially its anisotropy, will reflect the time evolution of the pressure gradients of the system and can provide information on the equation of state (EOS) in the initial phase [2,3] and during the expansion [4], and in particular about the possible formation of the quark–gluon plasma (QGP) [5,6].

QGP formation requires high energy density and local thermalisation of the system. While transverse energy measurements indicate the attainment of high energy densities [7], the degree of thermalization has not been unambiguously determined. Measurements of collective flow may be one of the strongest hints related to the degree of thermalisation. One may consider two extreme cases: the low density limit, where the mean free path is comparable or larger than the system size for which cascade models may be appropriate, and the hydrodynamic limit, where the mean free path of the particles is much less than the system size. The detailed study of collective flow as a function of beam energy, system size, transverse momentum, rapidity, and particle species may allow to separate these two scenarios and to recognize the hadronic or partonic (QGP) nature of the reaction [8].

The anisotropic flow of charged fragments has been measured in nuclear collisions at various beam energies: at 0.1–1.0 A GeV [9–11], at 10 A GeV [12], at 158 A GeV [13–17] and also at $\sqrt{s_{NN}} = 130$ and 200 GeV [18–20]. The first p_T-integrated photon flow measurement was performed by the WA93 experiment [15] for 200 A GeV S + Au collisions, where photons were measured with the Photon Multiplicity Detector (PMD). In the present work we report first results of photon collective flow measurements in 158 A GeV Pb + Pb collisions using photons identified and momentum analyzed in the lead glass calorimeter LEDA of the WA98 experiment. Preliminary results have been presented in [21,22].

2. Experimental setup

The data presented here were obtained in the WA98 experiment [23] for 158 A GeV Pb + Pb collisions at the CERN SPS. The WA98 setup consisted of large acceptance hadron and photon spectrometers, calorimeters for forward and transverse energy measurements, and detectors for photon and charged particle multiplicity measurements.

The centrality of the event was determined by the total transverse energy, E_T, measured with the mid-rapidity calorimeter (MIRAC) [24], which covered the pseudo-rapidity range of $3.5 < \eta < 5.5$. It was placed at 24.7 meters downstream from the target and consisted of 30 stacks, each divided vertically into 6 towers, of size 20×20 cm^2 each. The MIRAC measured both the transverse electromagnetic E_T^{em} and hadronic E_T^{had} energies. Events with large E_T correspond to the most central collisions with small impact parameter. The minimum bias trigger required a beam trigger with a MIRAC transverse energy greater than a low threshold. During datataking, central collision events were accumulated preferentially without prescale by use of a high transverse energy trigger (15% of event sample with largest E_T) [25].

The Plastic Ball spectrometer, used for the reaction plane (RP) determination, had full azimuthal coverage in the pseudorapidity range of $-1.7 < \eta < 0.5$ (i.e., in the target fragmentation region with polar angles $70^\circ < \theta < 160^\circ$). It consisted of 655 detector modules and allowed to identify pions, protons, deutrons, tritons, ^{3}He, and ^{4}He with kinetic energies of 50 to 250 MeV by

the ΔE–E method. Each module comprised a slow 4 mm thick CaF_2 ΔE scintillator followed by a fast plastic scintillator, both read out by a common photomultiplier [26].

Photons, of which $\sim 85\%$ originate from π^0 decay [25], were detected in the electromagnetic calorimeter LEDA, a highly segmented photon detector located 22.1 m downstream the target and covering the photon rapidity region $2.3 < y < 2.9$, i.e., backwards of mid-rapidity ($y = 2.9$). LEDA consisted of 10 080 TF1 lead-glass modules, read out by FEU-84 photomultipliers. The photomultiplier high voltage was generated on-base with custom developed [27] Cockcroft–Walton voltage-multiplier type bases which were individually controlled by a VME processor. The photomultiplier signals were digitized with a custom-built ADC system [28]. The dimensions of each module were $4 \times 4 \times 40$ cm^3 (14.3 radiation lengths depth and 1.1 Moliere radius width). Each group of 24 modules had its own calibration and gain monitoring system based on a set of 3 LEDs mounted inside a sealed reflecting cover dome. Each module viewed the reflected LED light through an aperture on the front surface, while the LED light was simultaneously monitored by a PIN-photodiode [29].

LEDA was calibrated with 10 GeV electrons in the X1 beam at the CERN SPS in the years 1993–1994. Electron beams with energies from 3 to 20 GeV were used to measure the energy and position resolution, and the energy non-linearity. The measured energy resolution was $\sigma/E = (5.5 \pm 0.6)\%/\sqrt{E} + (0.8 \pm 0.2)\%$ and the measured position resolution was $\sigma/E = (8.35 \pm 0.25)\text{mm}/\sqrt{E} + (0.15 \pm 0.07)$ mm. A more detailed description of the WA98 setup is given in [16,23,25].

3. The methods

Two complementary methods have been used in this analysis of anisotropic flow: the study of single-particle angular distributions with respect to an estimated reaction plane (*reaction plane method*) and the study of two-particle correlations (*correlation method*). Both methods assume that the underlying azimuthal distribution of particles with respect to the reaction plane (RP), which is the plane that contains the impact parameter and beam direction vectors, can be described by a Fourier decomposition

$$\frac{1}{N}\frac{dN}{d(\phi - \Psi_{\mathrm{RP}})} = 1 + 2v_1\cos(\phi - \Psi_{\mathrm{RP}}) + 2v_2\cos\bigl(2(\phi - \Psi_{\mathrm{RP}})\bigr), \tag{1}$$

where ϕ is the azimuthal angle of the emitted particle, and Ψ_{RP} is the azimuthal angle of the RP. The anisotropic flow is characterized by the values of the Fourier coefficients v_1, for directed flow, and v_2, for elliptic flow.

3.1. The reaction plane method

The conventional reaction plane method [30,31] uses the distribution of particles in their azimuthal angle relative to the estimated reaction plane. Because the true reaction plane is not known in the experiment, one has to establish an *event plane* (EP) from the measured particles as an estimate for the reaction plane.

Particles measured in the target fragmentation region show significant directed flow—proton, deuterons, and heavier fragments are emitted in the reaction plane in one direction, while pions are emitted in the opposite direction, as has been measured with the Plastic Ball detector [32].

This information has been used to calculate an event plane angle from the particles measured in the Plastic Ball

$$\Phi_{\mathrm{EP}} = \tan^{-1}\left(\frac{\sum_{i=1}^{N} E_T^i \sin\phi_i}{\sum_{i=1}^{N} E_T^i \cos\phi_i}\right), \tag{2}$$

where the sum runs over all fragments and identified positive pions. E_T^i and ϕ_i are the transverse kinetic energy and azimuthal angle in the laboratory frame of the ith particle, respectively. For pions, ϕ was replaced by $\phi + \pi$ to account for the opposite sign pion directed flow [32].

The azimuthal distribution of photons detected by the LEDA calorimeter has been studied relative to this event plane angle. The distributions are studied as a function of $\Delta\Phi = \phi_\gamma - \Phi_{\mathrm{EP}}$ and are fitted with:

$$\frac{1}{N}\frac{dN}{d\Delta\Phi} = 1 + 2v_1^{\mathrm{obs}}\cos(\Delta\Phi) + 2v_2^{\mathrm{obs}}\cos(2\Delta\Phi). \tag{3}$$

The measured EP does not coincide exactly with the true RP because of the finite number of detected particles and resulting fluctuations. Because of this finite reaction plane resolution, the coefficients obtained from the fits have to be corrected by dividing them by the event plane resolution correction factors (RCF_n):

$$v_n = \frac{v_n^{\mathrm{obs}}}{RCF_n}. \tag{4}$$

The resolution correction functions RCF_n are given by [31]

$$\begin{aligned} RCF_n &= \left\langle \cos\big(n(\Phi_{\mathrm{EP}} - \Psi_{\mathrm{RP}})\big)\right\rangle \\ &= \frac{\sqrt{\pi}}{2\sqrt{2}}\chi_m \exp\left(\frac{-\chi_m^2}{4}\right)\left[I_{\frac{k-1}{2}}\left(\frac{\chi_m^2}{4}\right) + I_{\frac{k+1}{2}}\left(\frac{\chi_m^2}{4}\right)\right], \end{aligned} \tag{5}$$

where Ψ_{RP} is the true RP angle, χ_m is the resolution parameter, which is proportional to the square root of the multiplicity, m is the order of the Fourier component used for calculation of the event plane and $k = n/m$.

Since Ψ_{RP} is unknown, the RCF's must be determined from the measured EP themselves. This can be done by a subevent analysis in which each event, in this case consisting of hits in the Plastic Ball detector, is randomly divided into two subevents (A and B) and for each subevent the EP angle Φ_{EP} (Φ_A or Φ_B) is calculated. The quantity $\langle\cos(n(\Phi_A - \Phi_B))\rangle$ is determined directly from the subevent correlation function. It is then equated to the lefthand side of equation 5 to obtain the parameter χ_m^{sub} for the subevent multiplicity, which is then used to calculate $\chi_m = \sqrt{2}\chi_m^{\mathrm{sub}}$ for the full event, and finally to obtain RCF_n. In this analysis we have used $m = 1$ ($k = 1$) for RCF_1 and for RCF_2 ($k = 2$).

3.2. The correlation method

Alternatively, the flow values have been obtained from the azimuthal correlations of photon pairs as described in [2,31,33–35]. The correlation function is calculated as

$$C_{\gamma\gamma}(\Delta\phi) \equiv \frac{d^2N/d\phi_1\, d\phi_2}{dN/d\phi_1 \cdot dN/d\phi_2}, \tag{6}$$

where $\Delta\phi = \phi_1 - \phi_2$. The $C_{\gamma\gamma}$ are calculated as the ratio of the true two-photon distribution to the pair distribution from mixed events. This is necessary to correct for distortions from the

limited acceptance of the photon detector. In the event-mixing procedure we have taken care to mix only events with similar global properties and to use identical cuts, especially regarding the two-cluster separation within the detector. The two-photon correlation functions have then been fitted with

$$C_{\gamma\gamma}(\Delta\phi) = 1 + 2v_1^2\cos(\Delta\phi) + 2v_2^2\cos\big(2(\Delta\phi)\big). \tag{7}$$

From these fits, no significant v_1 component was observed. Since very little directed flow is expected near mid-rapidity, we have set $v_1 \equiv 0$ in this analysis.

If collective flow is dominant, this method should be equivalent to the previous one since (a) the correlation between every particle and the RP induces a correlation amongst the particles, and (b) correlating two subevents amounts to summing two-particle correlations [36]. The correlation method has the advantage that no EP determination, and therefore no resolution correction, is needed. However, non-flow correlations, such as back-to-back correlations due to momentum conservation [22], should be taken into account.

4. Analysis

The data presented here were taken in 1995 and 1996 with the 158 A GeV Pb ion beams of the CERN SPS. Pb targets of 495 and 239 mg/cm^2 thickness were used. About 10^7 events were analyzed. The events were divided into 8 centrality classes defined by intervals in the total E_T measured by MIRAC, as summarized in Table 1. The centralities are expressed as fractions of the minimum bias cross sections as a function of the total E_T, measured by MIRAC. In addition, a multiplicity of greater than 3 fragments measured in the Plastic Ball was demanded to allow for a reasonable determination of the EP. This has a significant effect for the peripheral bins and causes a slight bias towards higher multiplicity within the bin.

In addition to the 8 classes of centrality shown in Table 1, studies were performed with combined centrality classes: $3 + 4$ (24–65%), $5 + 6$ (13–24%) and $7 + 8$ (0–13%). The table also shows the number of participants N_{part} as calculated in a Glauber type calculation discussed in [37].

To further suppress the hadron contamination in the photon sample, only those showers in the calorimeter have been used which satisfy the following cuts:

- The measured energy was greater than 0.75 GeV. This cut suppressed minimum ionizing particles.
- The lateral dispersion of the shower was less than a maximum value. This suppressed showering hadrons.

These cuts kept the hadron contamination in the photon sample to less than $\approx 7\%$ [25,39].

The observed raw Φ_{EP}-distributions showed a variation due to detector biases, such as dead channels and inefficiency, of less than 5%. This non-uniformity has to be removed before extracting the flow strength from the measured correlation functions. This has been done by two methods:

- The real distribution was divided by the equivalent distribution for mixed events, where ϕ_γ and Φ_{EP} are taken from different events.
- In accumulating the distributions, the entries were weighted with the inverse of the Φ_{EP} distribution.

Table 1
Centrality classes used in this analysis. The percentage of the measured minimum bias cross section included in each class is given. Also given is the corresponding average number of participants for each class with an estimate of the systematic error. Cuts on E_T are for 1995 data set, 1996 data set cuts are shown in [38]

	E_T class	E_T (GeV)	N_{part}
1	83–100%	0–28.35	10 ± 2
2	65–83%	28.35–79.05	28 ± 2
3	47–65%	79.05–161.55	63 ± 2
4	24–47%	161.55–281.05	133 ± 3
5	19–24%	281.05–318.05	205 ± 2
6	13–19%	318.05–361.55	247 ± 2
7	6.5–13%	361.55–410.95	291 ± 2
8	0–6.5%	> 410.95	351 ± 1

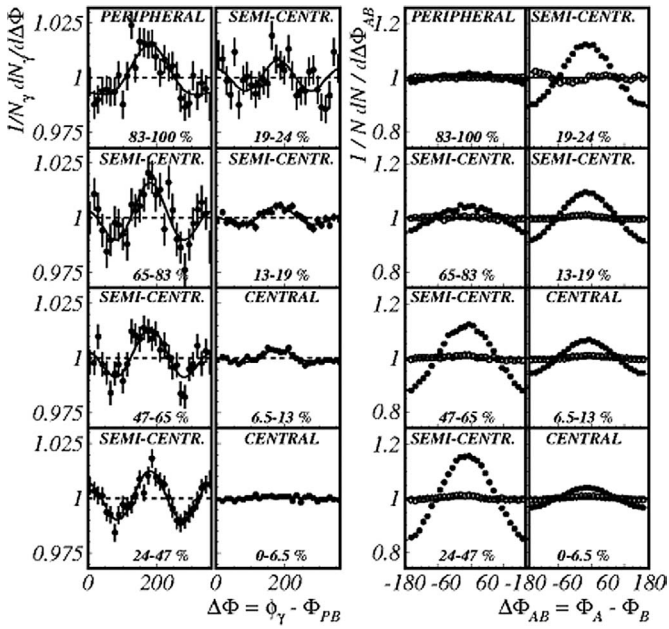

Fig. 1. Left: the measured photon azimuthal correlation functions for different centralities. The solid lines show fits to Eq. (3). Right: subevent correlation functions of particles measured in the Plastic Ball for different centralities. The filled circles show the measured correlation functions. The open circles show the results for mixed subevents.

Both methods gave consistent results within errors, we have used the second method for the final result.

Fig. 1 (left) shows examples of the measured photon azimuthal correlation functions for different centralities. A clear modulation is seen, especially in the semi-central classes, which can be described well with fits to Eq. (3).

The resolution correction factors RCF's for each centrality were determined as described above from the subevent correlation functions as shown in Fig. 1 (right). In this case the Plastic Ball acceptance correction was done by using mixed subevents, i.e., subevents from different events. The deviation of the mixed subevents from unity, i.e., the order of magnitude of this correction, was less than 2% (as shown in Fig. 1 (right)).

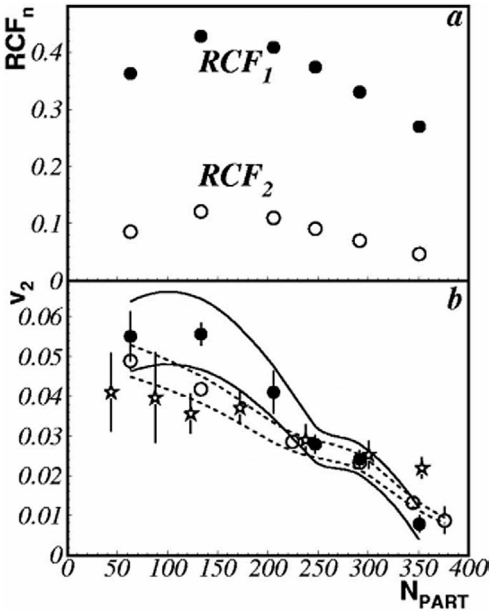

Fig. 2. (a) The resolution correction factors obtained from subevent correlation functions of particles measured in the target fragmentation region as a function of the number of participants. The filled circles show the values for directed flow, the open circles for elliptic flow. (b) The elliptic flow v_2 of photons extracted by the reaction plane method (solid circles, $p_T \geqslant 0.18$ GeV/c) and by the correlation method (open circles, $p_{T1} \geqslant 0.18$ GeV/c, $p_{T2} \geqslant 0.18$ GeV/c), integrated over $p_T > 0.18$ GeV/c and $y = 2.3$–2.9 as a function of the number of participants. The solid and dashed lines indicate the systematic error regions of the two measurements. The inclusive photon v_2 results from Ref. [42] integrated over all p_T and with $y = 3.25$–3.75 are shown by stars with error bars which include both statistical and systematical errors.

Fig. 2(a) shows the values of the resolution correction factors RCF's determined in this way as a function of the number of participants. A stronger subevent correlation implies a better determination of the RP, and the corresponding values of the RCF's are larger [40]. It is seen, that the subevent correlation is strongest for semi-central events, whereas for peripheral and central events the quality of the EP—determination is worse. The RCF's shown in Fig. 2(a) have been obtained for the 1996 beam time. The RCF's have been calculated and applied independently for the 1995 beam time, with values found to be smaller by ~ 20–40%.

Possible non-flow correlations in the RCF determination have been estimated and corrections have been applied. Among such non-flow effects relevant for azimuthal correlations are the correlations due to momentum conservation, long- and short-range two- and many-particle correlations (due to quantum statistics, resonances, jet or mini-jet production, etc.). The contribution of non-flow correlations scales as $1/N$, where N is the multiplicity of particles used to determine the event plane. The "momentum conservation" contribution increases with the fraction of particles detected, and the relative contribution of Bose–Einstein correlations would be independent of N. The effect of non-flow correlations in the reaction plane method is expected to be small as the event plane is determined from particle which have a large pseudorapidity separation $\Delta\eta > 1.8$ from the photons. The non-flow contributions to the event plane determination have been investigated by studying the dependence of the RCF's on the Plastic Ball multiplicity. The conventional subevent analysis was performed excluding various fractions of the Plastic Ball particles to investigate the deviation of the flow pa-

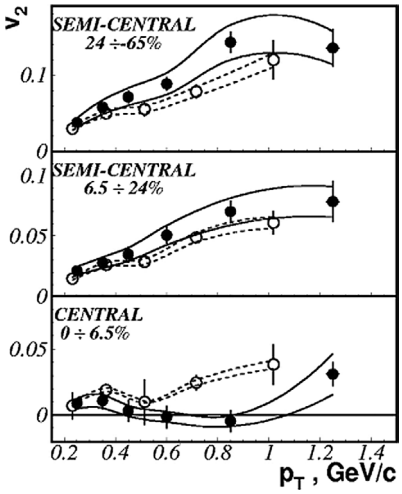

Fig. 3. The elliptic flow v_2 of photons extracted by the reaction plane method (solid circles, $p_T \geqslant 0.18$ GeV/c) and by the correlation method (open circles, $p_{T1} \geqslant 0.18$ GeV/c, $p_{T2} \geqslant 0.18$ GeV/c), integrated over $y = 2.3$–2.9 for three centrality selections.

rameter χ_m from $\chi_m \approx \sqrt{N}$ (see Eq. (5)). A multiplicity-dependent bias was observed and used to extrapolate an $M = \infty$ RCF value. These corrections varied from 2–4% with a systematic error of $< 4\%$. The determination of the RCF's for the two most peripheral centrality bins has been deemed unreliable due to the fact that the non-target background corrections are significant [25] and the average multiplicity in the Plastic Ball is too low (less than 5 hits). Therefore final v_n results for the two most peripheral centralities are not presented.

The v_2 elliptic flow values for photons have also been obtained from the two-photon correlation functions for various centrality classes, although not all of these precisely match those used for the reaction plane method analysis [41]. The v_2 elliptic flow values for photons obtained by the two methods are compared in Figs. 2(b) and 3. The two photon correlation functions have been fitted with Eq. (7) to extract v_2 with $v_1 \equiv 0$. Fig. 2(b) shows the centrality dependence of v_2 integrated over $p_T > 0.18$ GeV/c. The solid circles are the values obtained from the reaction plane method and the open circles are those from the correlation method. The inclusive photon v_2 results measured with the WA98 Photon Multiplicity Detector (PMD) preshower detector are also shown [42] in Fig. 2(b). The PMD provides a p_T integrated result in the rapidity region $y = 3.25$–3.75. For centralities corresponding to $N_{\text{part}} > 50$ there is good agreement between the different results. Fig. 3 shows the elliptic flow as a function of p_T for central and two semi-central classes for the reaction plane and two-particle correlation methods. There is reasonably good agreement between the methods.

One should note that the reaction plane and correlation methods suffer from systematic effects. The determination of the reaction plane has a large uncertainty due to fluctuations and backgrounds for low multiplicities. The correlation method is more susceptible to non-flow components [22] which would influence the extraction of the flow. Furthermore, the directed flow has been neglected in the correlation analysis which may also lead to systematic errors in the v_2 determination. The results from the reaction plane method are used in the discussions that follow.

As a consistency check we have performed the reaction plane analysis independently on the data from the two different beam periods, where the quality of the RP determination was found to be different. The resulting flow values are in good agreement.

5. Systematic error

The systematic errors of the obtained coefficients include:

- Uncertainties in the event plane determination in the Plastic Ball due to non-uniformity of acceptance and efficiency or imperfect particle identification, estimated as $< 2\%$.
- Uncertainties due to non-flow effects in the determination of the RCFs from the Plastic Ball event plane, estimated as $< 4\%$.
- Uncertainties in the photon angular distributions due to charge particle contamination of photons in LEDA. This contamination is less than $\approx 7\%$ [25]. The uncertainties are related to a difference in the observed flow between charged pions and pion decay photons and were estimated as $< 3.5\%$.

Other sources of the systematic errors have been investigated by comparing the results obtained under different conditions. The following checks have been performed:

(1) Different weights (E_T vs. p_T) have been used for the determination of the event plane.
(2) Different acceptance regions of the Plastic Ball detector ($70^\circ < \theta < 160^\circ$ or $60^\circ < \theta < 160^\circ$) have been used.
(3) Different identification cuts for the Plastic Ball fragments were used.
(4) The event plane was determined with and without including pions in the Plastic Ball.
(5) Results of the two different beam periods were analyzed separately.

All of these systematic checks lead to a total systematic error estimate of $\pm 16\%$ ($\pm 50\%$ for the most central bin) for the measured values of both flow coefficients. Unless explicitly stated otherwise, the systematic errors are not included in the figures.

6. Results

Fig. 4(a), (b) shows the final values of the directed flow v_1 and the elliptic flow v_2 coefficients as a function of the number of participants. The data were integrated over $p_T > 0.18\,\mathrm{GeV}/c$ and over rapidity $y = 2.3$–2.9.

Both types of flow decrease in strength with the number of participants. The sign of all values is positive with the sign convention that positive v_1 corresponds to the directed flow direction of the protons in the projectile fragmentation direction and positive v_2 corresponds to the in-plane direction. Thus, the directed flow of photons below mid-rapidity is in the same direction as the directed flow of pions, opposite to the protons, in the target fragmentation region, and the elliptic flow is oriented in the reaction plane.

The transverse momentum dependence of the photon flow integrated over $y = 2.3$–2.9 is shown in Fig. 4(c), (d) for different centrality classes. Both flow coefficients show an increase with p_T which is compatible with a blast-wave fit (see below [19,43]).

To be able to compare the flow of photons to other experimental results we have attempted to establish the relation between the observed photon flow and the underlying flow of the parent

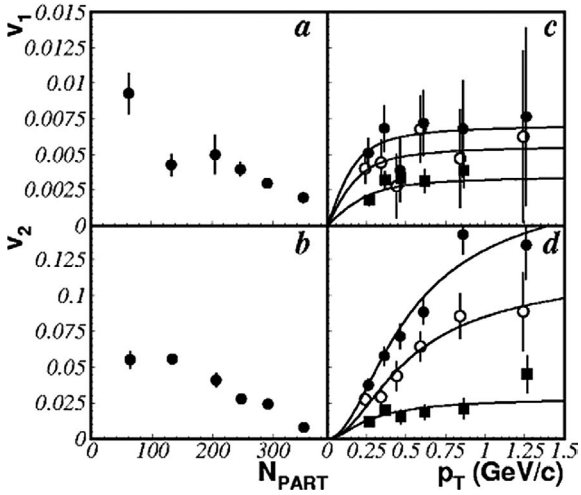

Fig. 4. Directed flow (v_1) (a) and elliptic flow (v_2) (b) of inclusive photons integrated over $p_T > 0.18$ GeV/c and $y = 2.3$–2.9 as a function of the number of participants. Directed flow (v_1) (c) and elliptic flow (v_2) (d) of inclusive photons integrated over $y = 2.3$–2.9 as a function of p_T for various centralities. Solid circles show results for semi-central events (24–65%), open circles show results for semi-central events (13–24%), solid squares show results for central events (0–13%). Solid lines are fitted results to a blast-wave model functional form (Eqs. (9) and (10)).

neutral pions. This has been investigated in Monte Carlo simulations. In the simulations, π^0's and η were generated according to the p_T spectra measured by WA98 [25]. The π^0 and η azimuthal distributions were modulated with directed and elliptic flow components. The values of the π^0 v_1 and v_2 and their p_T-dependence have been constrained by the photon measurement. The p_T-dependence of the azimuthal asymmetry has been parameterized following a simple hydrodynamically motivated blast-wave model, described in [19,44], and generalized in [43] to also describe v_1:

$$v_n(p_T) = \frac{\int_0^{2\pi} d\phi_b \cos(n\phi_b) I_n(\alpha) K_1(\beta)[1 + 2s_n \cos(n\phi_b)]}{\int_0^{2\pi} d\phi_b I_0(\alpha) K_1(\beta)[1 + 2s_n \cos(n\phi_b)]}, \tag{8}$$

where the harmonic n can be either 1 or 2, I_0, I_n, and K_1 are the modified Bessel functions, $\phi_b = \phi - \Psi_{\mathrm{RP}}$, $\alpha(\phi_b) = (p_T/T_f)\sinh[\rho(\phi_b)]$, $\beta(\phi_b) = (m_T/T_f)\cosh[\rho(\phi_b)]$, s_n is the surface emission parameter, and T_f is the freeze-out temperature. The azimuthal flow rapidity is given as $\rho(\phi_b) = \rho_0 + \rho_a \cos(n\phi_b)$ with ρ_0 is the mean transverse expansion rapidity ($v_0 = \tanh[\rho_0]$) and ρ_a is the amplitude of its azimuthal variation, respectively. Further details are given in [43].

Without regard to the physical interpretation of the parameters of this model it can be used to provide a convenient parameterization of the p_T dependence of the flow. For this purpose Eq. (8) can be further simplified by setting $\rho_a = 0$. The integrals can be solved to reduce the expression to two parameters, a_n and b_n. The expressions for the p_T dependence of the directed and elliptic flow are then

$$v_1(p_T) = a_1 \frac{I_1(b_1 p_T)}{I_0(b_1 p_T)}, \tag{9}$$

$$v_2(p_T) = a_2 \left(1 - 2\frac{I_1(b_2 p_T)}{b_2 p_T I_0(b_2 p_T)}\right). \tag{10}$$

Table 2
The blast-wave parameters a_n and b_n of Eqs. (9) and (10) for various centralities obtained by fits to the WA98 inclusive photon data (left) and the corresponding parameters extracted for neutral pions (right) from simulations that reproduce the inclusive photon results

Centrality	Fit to γ				Extracted for π^0

The measured photon $v_n(p_T)$ are described well by these expressions as shown by the solid lines of Fig. 4(c), (d). The extracted a_n and b_n were constrained to have a smooth centrality dependence and are tabulated in Table 2.

In order to extract the π^0 $v_n(p_T)$ from the measured photon $v_n(p_T)$, the simulated π^0 p_T distributions have been parameterized as

$$\frac{1}{N_{\text{Event}}}\frac{d^2N}{dy\,dp_T} = \frac{1}{N_{\text{Event}}}E\frac{d^3N}{dp^3}p_T = C' p_T \left(\frac{p_0'}{p_0' + p_T}\right)^{n'} \tag{11}$$

with parameters C', p_0', n' taken from the measured π^0 results [25]. The η photon decay contributions were also included with the η yield assumed to proportional to the π^0 yield at the same transverse mass (m_T-scaling) [25]. Jetset 7.4 was used to generate the π^0- and η-decay photons which were then filtered in the simulations with the detector acceptance and efficiency.

In the simulations, the π^0's were generated with an azimuthal asymmetry with p_T dependent v_n parameterized by Eqs. (9) and (10). The η v_n were taken to be the same as those of the π^0's, $v_n^\eta(p_T) = v_n^\pi(p_T)$. As an initial ansatz, the measured photon $v_n(p_T) = g(p_T)$ for each centrality was used for the $v_n(p_T) = f(p_T)$ of the simulated pions. The output $v_n(p_T) = g'(p_T)$ of the simulated decay photons was compared to the measured photon dependence and used to adjust the π^0 $v_n(p_T)$ for the next iteration. The procedure was iterated until the simulated (g') and measured (g) photon results were in agreement, which typically required two to three iterations. The a_n and b_n coefficients obtained from the fit to the photon results and the coefficients extracted for the π^0's by the iteration procedure are summarized in Table 2. The ratio of the flow coefficients extracted for the simulated decay photons to the input pion flow coefficients provided the correction factors $k_n(p_T) = v_n^\gamma(p_T)/v_n^\pi(p_T)$ used to extract the π^0 $v_n^\pi(p_T)$ from the measured photon $v_n^\gamma(p_T)$. To extract p_T integrated correction factors k_n over the region of measurement $p_T > 0.18$ GeV/c, or k_n^0 extrapolated to zero transverse momentum, $p_T > 0$ GeV/c, the fitted $v_n(p_T)$ results were weighted by the measured inclusive photon or π^0 spectra extrapolated to $p_T = 0$ GeV/c and integrated over p_T. The systematic errors on the k_n were determined from the uncertainties Δ of the fit parameters: $a_n \pm \Delta a_n$, $b_n \pm \Delta b_n$, $p_0' \pm \Delta p_0'$ and $n' \pm \Delta n'$. The analysis was repeated assuming instead a linear or a square-root dependence of v_n on p_T and the variation of the results was found to be about 10% and 2% for k_1 and k_2, respectively, and has been included in the systematic errors on k_n. The systematic error on k_n from the η contribution in the simulations is estimated to be less than 5%.

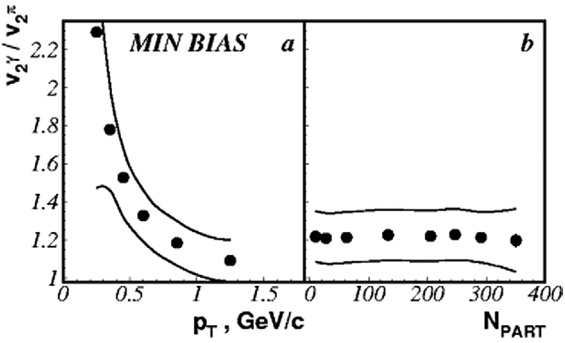

Fig. 5. The ratio of photon elliptic flow to parent pion elliptic flow coefficients. (a) $k_2 = v_2^\gamma / v_2^\pi$ for min. bias, (b) $k_2 = v_2^\gamma / v_2^\pi$ for different centrality bins.

Fig. 5(a), (b) shows k_2, the ratio of the v_2 coefficients of photons and pions, obtained from the simulations. The k_1 ratio is found to be independent of centrality and p_T with a value of $\langle k_1 \rangle = 1.183 \pm 0.03$ with a systematic error ranging from 14% to 22% from peripheral to central collisions. Since v_1^π is small, $k_1 \approx 1$.

The k_2 are seen in Fig. 5(a) to be strongly dependent on p_T, rising at low p_T where the v_2 are small. However, the p_T-integrated k_2 ratios are found to be independent of centrality with $\langle k_2 \rangle = 1.215 \pm 0.002$ and a systematic error which varies from 11% to 14% from peripheral to central collisions. The observation that the k_n ratios are greater than unity can be understood as a simple effect of the π^0 decay and the fact that the v_n increase with p_T. Comparing photons and π^0's at a given p_T, the decay photons will have been produced from π^0's with larger p_T and hence larger v_n, giving $k_n > 1$ (see Fig. 5(a) and (b)).

The π^0 v_2 extracted from the measured WA98 photon v_2 as a function of centrality are compared to the results from NA49 for charged pions [43] in Fig. 6. For this comparison the WA98 results for photons with $p_T > 0.18\,\mathrm{GeV}/c$ were extrapolated to the expectation for the pions without p_T threshold ($p_T > 0\,\mathrm{GeV}/c$) as for NA49 results, with the correction factor $k_1^0 = 1.43 \pm 0.036$ and $k_2^0 = 1.59 \pm 0.003$. The estimated systematic errors on the WA98 points including the errors of the measured photon v_n values and the additional error of the k_n^0 correction are less than $\pm 20\%$ ($\pm 55\%$ for the most central bin), except for the lowest p_T points where the upper systematic errors increase (Fig. 8). The systematic errors on the NA49 data points vary from 13% for the most peripheral to 80% for the most central bin. The two measurements are seen to be in agreement.

The rapidity dependence of the pion flow coefficients is shown in Fig. 7 for two centrality selections. The WA98 photon v_n with $p_T > 0.18\,\mathrm{GeV}/c$ were extrapolated to the expectation for π^0's without p_T threshold using the correction factors k_n^0 described above. The NA49 results for pions with $p_T > 0\,\mathrm{GeV}/c$ with appropriate corrections ([43]) are also shown and the two measurements are seen to be in agreement. Similar agreement between the NA49 and WA98 results is seen in the transverse momentum dependence of the v_2 shown in Fig. 8.

Fig. 9 shows the WA98 π^0 v_2 coefficient deduced from the measured photon v_2 (corrected by k_2^0) together with a compilation of results [43] from other experiments. Results are shown from E877 [8,12], CERES [45], NA49 [43], PHOBOS [46], PHENIX [47], and STAR [48]. The WA98 result follows the general trend of the smooth increase of the elliptic flow with increasing

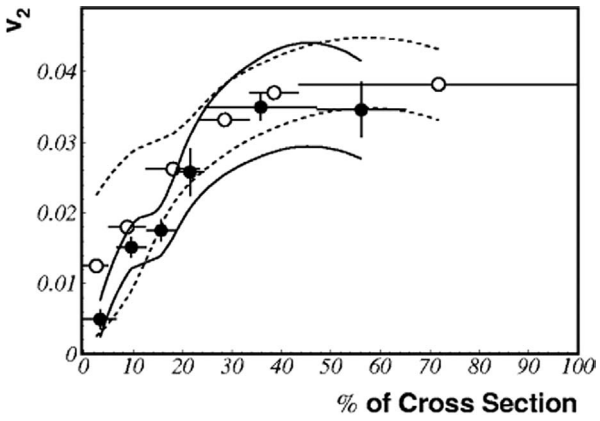

Fig. 6. The centrality dependence of pion elliptic flow v_2 extracted from the measured photon flow from WA98 (solid circles, $-0.6 < y_{\mathrm{CM}} < 0$), compared to pion flow results of NA49 (open circles, $0 < y_{\mathrm{CM}} < 2.1$, [43]).

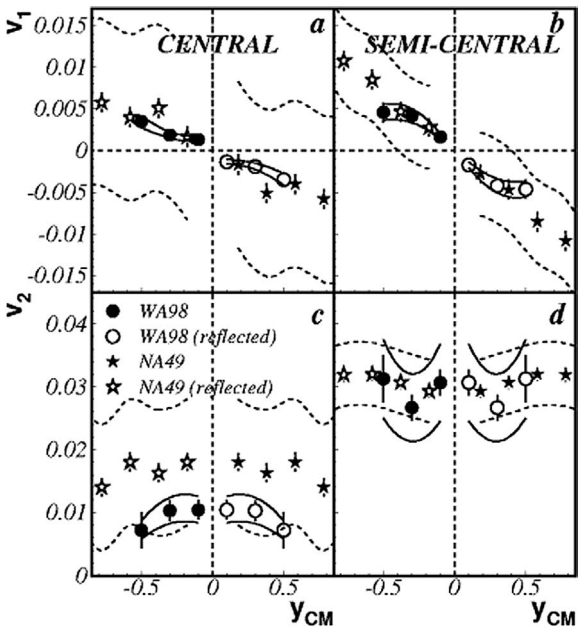

Fig. 7. The rapidity dependence of pion flow extracted from the measured photon flow from WA98 (circles) compared to pion flow results of NA49 (stars, [43]). The results are shown for central on the left panel (WA98: 0–13%, NA49: 0–12.5%) and semi-central on the right panel (WA98: 13–47%, NA49: 12.5–33.5%) selections for the directed flow (a), (b) and elliptic flow (c), (d). Systematic error bands are shown on (c) for NA49 (dashed curves) and for WA98 (solid curves). Open points are reflected at mid-rapidity.

beam energy. It should be kept in mind that the p_T and rapidity coverages as well as centrality selections differ somewhat for the various experiments.

Since the strength of the elliptic flow should be proportional to the initial eccentricity of the collision zone, it is useful to normalize the measured v_2 to the eccentricity of the reaction geom-

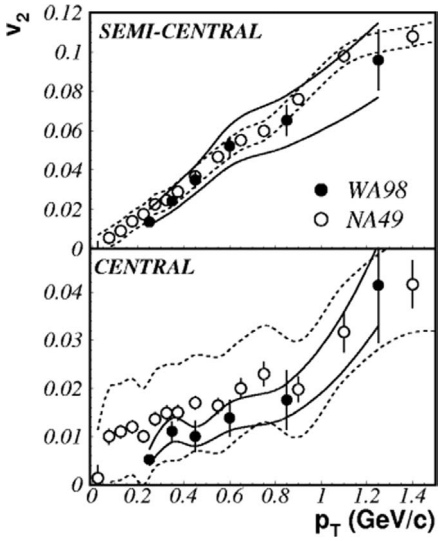

Fig. 8. The transverse momentum dependence of the π^0 elliptic flow extracted from the measured photon flow from WA98 (solid circles) compared to π^+ elliptic flow results of NA49 (open circles, [43]). The results are shown for semi-central selections (top: WA98: 13–47%, $-0.6 < y_{\mathrm{CM}} < 0$, NA49: 12.5–33.5%, $0 < y_{\mathrm{CM}} < 0.8$) and for central selections (bottom: WA98: 0–13%, $-0.6 < y_{\mathrm{CM}} < 0$, NA49: 0–12.5%, $0 < y_{\mathrm{CM}} < 0.8$). Systematic error bands are shown for NA49 (dashed curves) and for WA98 (solid curves).

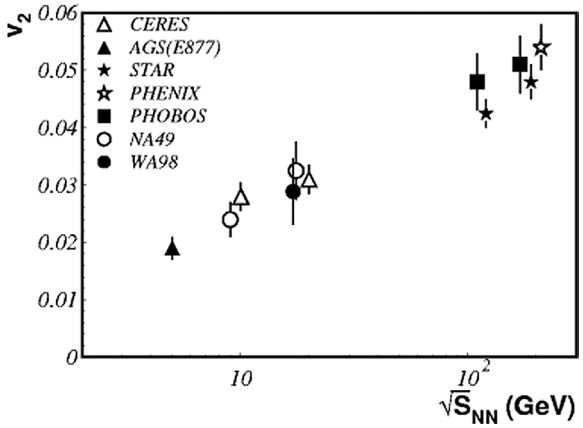

Fig. 9. Comparison of the WA98 p_T-integrated elliptic flow results at $\sqrt{s_{NN}} = 17$ GeV (13–47%, $-0.6 < y_{\mathrm{CM}} < 0$) with results from other experiments for different collision energies. The WA98 result is the π^0 elliptic flow extracted from the measured photon elliptic flow, as described in the text. The total statistical and systematic error is shown on the WA98 point.

etry when investigating the systematics of the elliptical flow [49]. The initial spatial eccentricity was calculated within a Glauber model calculation [37] as

$$\epsilon = \frac{\langle y^2 \rangle - \langle x^2 \rangle}{\langle y^2 \rangle + \langle x^2 \rangle},$$

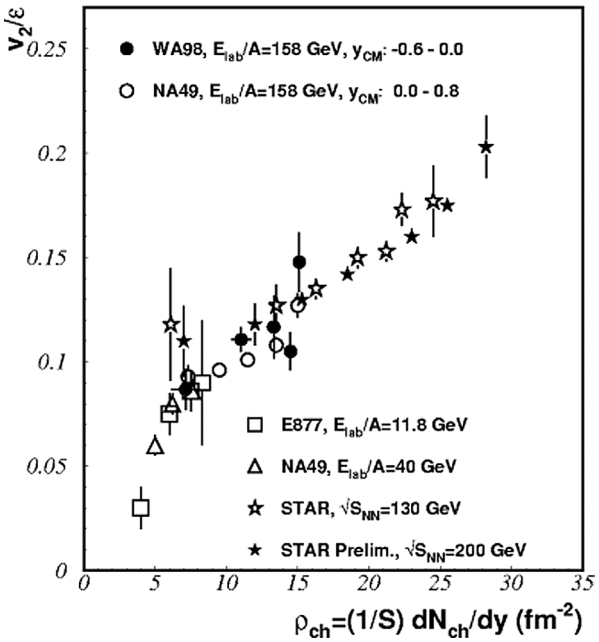

Fig. 10. The scaled elliptic flow v_2/ϵ as a function of particle density. Results are shown for the WA98 p_T-integrated v_2 values at $\sqrt{s_{NN}} = 17$ GeV ($-0.6 < y_{\mathrm{CM}} < 0$). The WA98 results are compared to results from the E877, NA49, and STAR experiments. The WA98 result is the π^0 elliptic flow extracted from the measured photon elliptic flow, as described in the text.

where x and y are the participant nucleon coordinates in the plane perpendicular to the beam and x denotes the in-plane direction.

It is of interest to plot the quantity v_2/ϵ versus the particle density as estimated by the dN/dy of charged particles divided by the area of the overlap region S [8,43]. Neglecting the weak incident energy and centrality dependence of the average p_T, the scaled particle density is proportional to the initial energy density in the Bjorken estimate [52]. Fig. 10 shows the WA98 result for v_2/ϵ for neutral pions together with results for charged pions from NA49 [43] and results for charged particles from STAR [50,51] and E877 [8]. The RHIC data have been corrected for their p_T cutoff, the errors are statistical. For the WA98 points the dN/dy are taken from WA98 measurements [37].

The WA98 results confirm the previous observation [8,43] of a universal dependence of v_2/ϵ on the particle density. It should be noted that results at different incident energies but similar average particle density correspond to dramatically different collision geometries. Generally, a central collision at low energy will have a particle density similar to a more peripheral collision at higher energy. Thus, the universal dependence demonstrates that the scaled v_2 depends only on the initial energy density, or initial pressure, rather than being dependent on the particle density times pathlength, which would be the expectation if only partial thermalization was attained. The observed increase of the scaled elliptic flow with increasing particle density is qualitatively similar to that seen in a recent hydrodynamical model study [53] in which the v_2 value for fixed impact parameter increases smoothly with increasing dN_{ch}/dy corresponding to the increase in pressure. That systematic study of hadron spectra and flow results indicated that existing data are best reproduced by hydrodynamic model calculations with an equation of state which include a

transition to a quark gluon plasma phase at a critical temperature of $T_c = 165$ MeV with a latent heat of 800 MeV [53].

7. Summary

Directed and elliptic flow of photons have been measured in 158 A GeV Pb + Pb collisions using the LEDA electromagnetic calorimeter and the Plastic Ball detector of the WA98 experiment. The conventional reaction plane method for directed and elliptic flow and the pair-correlation method for elliptic flow have been used in the analysis. The elliptic flow values obtained by the two methods are consistent.

The centrality and p_T dependences of the photon directed and elliptic flow coefficients were presented. In-plane elliptic flow is observed. Both flow values increase for more peripheral collisions and with increasing p_T.

For comparison with charged pion measurements, the neutral pion flow coefficients have been extracted from the measured photon flow coefficients using Monte Carlo simulations. The Monte Carlo simulations demonstrate that the average photon flow coefficients are $\approx$ 7–21% greater than the parent π^0 flow coefficients. The extracted neutral pion flow results are compatible with the NA49 charged pion flow and with the general trend of the elliptic flow behaviour as a function of beam energy. The universal dependence of the elliptic flow, scaled by the eccentricity of the initial nuclear overlap, on particle density is confirmed.

We present the results of ϕ meson production in the K^+K^- decay channel from Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV as measured at midrapidity by the PHENIX detector at Brookhaven National Laboratory's Relativistic Heavy Ion Collider. Precision resonance centroid and width values are extracted as a function of collision centrality. No significant variation from the Particle Data Group accepted values is observed, contrary to some model predictions. The ϕ transverse mass spectra are fitted with a linear exponential function for which the derived inverse slope parameter is seen to be constant as a function of centrality. However, when these data are fitted by a hydrodynamic model the result is that the centrality-dependent freeze-out temperature and the expansion velocity values are consistent with the values previously derived from fitting identified charged hadron data. As a function of transverse momentum the collisions scaled peripheral-to-central yield ratio R_{CP} for the ϕ is comparable to that of pions rather than that of protons. This result lends support to theoretical models that distinguish between baryons and mesons instead of particle mass for explaining the anomalous (anti) proton yield.

I. INTRODUCTION

Relativistic heavy-ion experiments have a goal of producing matter at extreme temperatures and energy densities such that conditions are favorable for the transition to a deconfined state of quarks and gluons, the quark gluon plasma (QGP). Theoretical calculations predict that the temperatures and energy densities that can be reached at the Brookhaven National Laboratory's Relativistic Heavy Ion Collider (RHIC) will exceed those needed for the formation of the QGP [1–3].

The production and decay of the ϕ meson have long been recognized as an important probe for the state of matter produced in relativistic heavy-ion (RHI) collisions [4–21]. In pp collisions the creation of the ϕ is suppressed according to the Okubo-Zweig-Iizuka rule [22]. Hence, if there is an enhancement of the ϕ yield in RHI collisions relative to pp collisions, this could be evidence of nonconventional production mechanisms such as strange quark coalescence via the formation and subsequent hadronization of the QGP. The fact that the ϕ yield is undistorted by feed-down from higher mass resonances makes it an attractive probe in this respect.

The decay modes of the ϕ, specifically the dilepton channels (e^+e^- or $\mu^+\mu^-$) and the K^+K^- channel, will probe the final state differently should the decay take place in the presence of the QGP-mixed or the completely hadronized phase. The dileptons will have insignificant interactions with the medium, whereas the kaons can scatter until freeze-out. The lifetime of the ϕ in vacuum is large ($\approx$45 fm/c) compared to say a 10-fm-sized interaction region. However, several theoretical calculations [13,21,23] predict that the ϕ mass and width could be significantly modified in either the hot or the cold nuclear medium. These medium-induced effects could be manifested through measured shifts in the mass centroid of the resonance or changes in the resonance width. Also predicted are changes in the relative branching ratio between kaon and lepton pairs, with respect to the Particle Data Group (PDG) [24].

The production mechanism of strangeness in heavy-ion collisions can be investigated through the measurement of the particle yields. In this paper, we study system size dependence by analyzing centrality-selected data. A comparison between different systems can be made by normalizing to the number of participant pairs. The expectation is that for production dominated by soft processes, the yields scale as the number of participants. We compare the centrality dependence of strange and nonstrange particle yields to reveal a possible flavor dependence.

An additional important question is whether the ϕ mesons participate in radial flow together with the other hadrons, or if they freeze-out earlier, as might be true if the small vacuum cross sections of the ϕ with hadrons persist in the fireball. Previous measurements have yielded contradictory results [25, 26]. One of the important advantages of RHIC experiments is the capability to examine the momentum spectrum as a function of centrality for a variety of hadrons, which should yield important additional information on the radial flow issue. A spectral shape analysis including a simultaneous treatment of the ϕ and the more abundant hadrons (π, K, p) will be presented here.

At high p_T, hadrons are primarily produced from the fragmentation of hard-scattered partons. One of the most exciting results from RHIC was the discovery of hadron suppression in central Au+Au collisions [27,28]; this suppression is absent in d + Au collisions [29]. Surprisingly, it was also discovered that proton and antiproton production at intermediate p_T (1.5–4.5 GeV/c) scales with the number of binary nucleon-nucleon collisions ($N_{\rm coll}$) as would be expected for hard scattering in the absence of any nuclear modification [30]. In fact, the intermediate p_T antiproton to pion ratios were found to exceed by a factor of 3 the values expected from parton fragmentation [30,31]. These experimental results lead to the conclusion that protons and pions have different production mechanisms at intermediate p_T [30]. One possible explanation invokes parton recombination from the QGP [32–35]. A measurement of the nuclear modification factor for the ϕ meson, which has a mass comparable to the proton but carries only two quarks, is crucial for understanding the hadron production at intermediate p_T. In this work we have measured the nuclear modification factor through the ratio $R_{\rm CP}$ of central to peripheral yields scaled by their respective $N_{\rm coll}$ value.

To put our results into perspective, we begin by describing the currently available ϕ data obtained in RHI collisions. The production of ϕ mesons has been studied systematically at ever increasing $\sqrt{s}$ from the AGS to RHIC. The E802 collaboration made the first observation of the ϕ in fixed-target central collisions of 14.6A GeV Si+Au ($\sqrt{s_{NN}} = 5.39$ GeV) via the K^+K^- channel [36]. They obtained a ratio $N_\phi/N_{K^-} = 11.6\%$, roughly consistent with the ratio obtained in pp data over a wide range of $\sqrt{s}$ [37]. The analysis of the E802 rapidity distributions indicated that the ϕ production scaled with the product of the K^+ and K^- separate yields and that either there was significant rescattering of the ϕ after production or the production itself came after rescattering of the colliding participants.

Also at the AGS the E917 experiment has reported another ϕ measurement with 11.7A GeV Au+Au ($\sqrt{s_{NN}} = 4.87$ GeV) in the rapidity range $1.2 < y < 1.6$ in five centrality bins [38]. The observed yield of the ϕ increased toward more central collisions with a distinctly greater than linear dependence on the number of participants. The yield increase of the ϕ in central collisions was stronger than that of the π since the N_ϕ/N_π ratio increased in central collisions. However, the N_ϕ/N_{K^+} and N_ϕ/N_{K^-} ratios were constant as a function of centrality.

At the SPS the NA49 experiment has measured ϕ production in pp, p+Pb, and Pb+Pb collisions with $E_{\rm beam} =$ 158A GeV ($\sqrt{s_{NN}} = 17.5$ GeV) in the rapidity range $3.0 < y < 3.8$ [39]. Relative to the pp yields, these data showed that the ratio of the ϕ yield to the π yield in central Pb+Pb collisions was enhanced by a factor of 3.0 ± 0.7. Another SPS collaboration, NA38/NA50, has measured the ϕ in the $\mu^+\mu^-$ channel [40,41], for which the extracted effective temperature and dN/dy differ from those obtained in the K^+K^- channel in the same systems. The yield difference between the two SPS experiments has been calculated to be factors of 2–4 [42], with the NA38/NA50 result being higher.

The first measurement of the ϕ meson at RHIC was reported by the STAR Collaboration [43], in the collisions of Au+Au

at $\sqrt{s_{NN}} = 130$ GeV at three centralities, 0–11%, 11–26%, and 26–85%, in the rapidity range $-0.5 < y < +0.5$. The extracted temperature T and the ratio $N_\phi/N_{\text{hadrons}}$ did not vary with centrality.

One may summarize the current state of knowledge on ϕ production in heavy-ion collisions by stating that the topic remains highly unexplored territory. The heavy-ion measurements do indicate that the observed ϕ yield is not a simple linear superposition of nucleon-nucleon collisions. Rather, the data imply the influence of some collective effects. Whether those effects are induced by cold and/or hot nuclear matter is not known since there does not yet exist definitive evidence. Moreover, thus far there has not been precise enough heavy-ion data that can address the question of the change in the ϕ mass or its width in the cold nuclear or the hot QGP medium. And except for one experiment measuring the dimuon channel, there is a scarcity of useful quantitative information in heavy-ion collisions concerning the ϕ decay into dileptons.

In this paper we report on a measurement of the ϕ yield at midrapidity in collisions of Au+Au beams from RHIC at $\sqrt{s_{NN}} = 200$ GeV as measured in the K^+K^- channel by the PHENIX detector. The paper is organized as follows. In Sec. II we give a short review of the PHENIX detector configuration. In Sec. III we describe the data analysis procedure. Section IV presents and discusses the results. The first precision measurements of ϕ mass and width values obtained in RHI collisions as a function of centrality are given in Sec. IV A. Absolute yields as a function of p_T for three centrality bins are shown in Sec. IV B. The centrality dependence of yields and ratios are studied in Sec. IV D. In Sec. IV D the spectra shapes are interpreted in the framework of a hydrodynamical model and the freeze-out conditions are extracted. Finally, the nuclear modification factor R_{CP} for the ϕ is obtained and compared to those of pions and protons in Sec. IV E.

II. PHENIX DETECTOR

The PHENIX detector consists of two spectrometer arms at near zero rapidity, two forward rapidity muon spectrometers, and three global event characterization detectors. The central arm spectrometers, shown schematically in Fig. 1, are located east and west of the beam line with $\pi/2$ radian azimuthal coverage each. These spectrometers are designed to detect photons, electrons, and charged hadrons. The ϕ data for this paper were obtained with the central arm detector subsystems, which provide high-resolution particle identification and momentum reconstruction. A complete description of the PHENIX apparatus has been published elsewhere [44–49]. We present a brief review of the relevant detector subsystems in the following sections.

A. Global detectors

The global detectors furnish the start time signals, collision vertex measurements, and interaction centrality. The centrality for events in the Au+Au collisions is determined [50] by combining the data from two subsystems: the zero degree calorimeters (ZDC) [48] and the beam-beam counters (BBC)

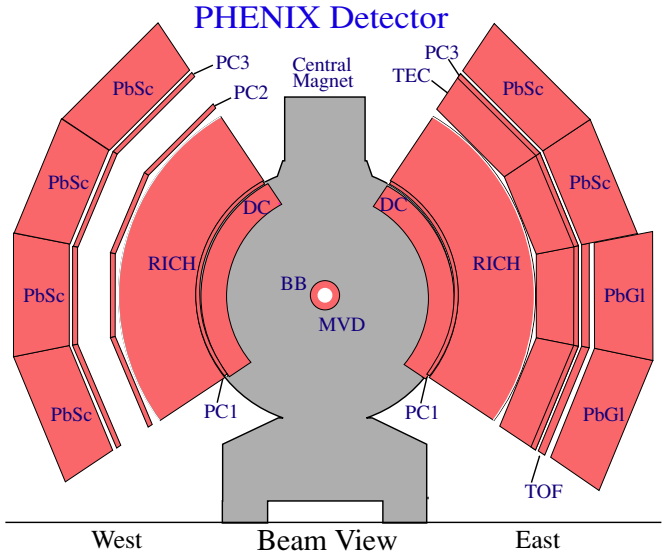

FIG. 1. (Color online) Beam's-eye view of the PHENIX central arm detector subsystems.

[47]. The ZDC are hadronic calorimeters located 18 m downstream and upstream of the interaction point along the beam line. These calorimeters detect the energy carried by spectator neutrons. The BBC are Čerenkov telescopes placed ± 1.44 m from the center of the beam collision region in the pseudorapidity region $3.0 < |\eta| < 3.9$. The correlation between the ZDC energy sum and the charge sum recorded in the BBC determines the centrality of the collision event. The BBC data also determine the longitudinal collision coordinate (z_{vertex}) and the start time for the time-of-flight measurements.

B. Central arm detectors

The central arm spectrometers [49] in PHENIX provide charged particle tracking and particle identification. This analysis was done with the east arm spectrometer. The $\phi \to K^+K^-$ decay kinematics are such that that the PHENIX detector has negligible acceptance for the very low p_T ϕ particles, which would decay into east-west kaon pairs. The data included information from the drift chamber (DC), the pad chambers (PC1 and PC3), the high-resolution time-of-flight (TOF) wall, and the electromagnetic calorimeter (EMCal) lead-scintillator detectors (PbSc), as depicted in Fig. 1.

Pattern recognition and tracking of the charged particles are accomplished using the DC information by a combinatorial Hough transform method [51]. The DC subsystem is located at an average radial distance of 2.2 m from the beam line. It is a projective tracking detector providing high-precision measurements in the azimuthal XY plane, which are combined with the XYZ single spatial point measurement from the PC1 located at 2.45 m. These data, together with the BBC z_{vertex} information, are sufficient to determine the track's initial momentum vector, whose magnitude is obtained with a resolution $\delta p/p \simeq 0.7\% \oplus 1.0\% \times p$ (GeV/c). The first term in this expression is due to the multiple scattering before the DC and the second term is the angular resolution of the DC.

Based on identified mass measurements obtained with the TOF subsystem, the absolute momentum scale is known to $\pm 0.7\%$.

Tracks obtained from the DC/PC1 detectors are projected to the PC3, TOF, and PbSc detectors where associations can be made. The high-resolution TOF subsystem provides one set of mass measurements while the PbSc detectors provide a geometrically independent set of mass measurements. The TOF wall is positioned 5.06 m from the beam line and consists of 960 scintillator slats oriented along the azimuthal direction. It is designed to cover $|\eta| < 0.35$ and $\Delta\phi = \pi/4$ in azimuthal angle.

The PbSc detector, covering half of the east arm and entire west arm, can also be used for hadron timing measurements. The present analysis uses the PbSc modules in the east arm, which are located at 5.1 m in radial distance from the beam line and cover a $\Delta\phi = \pi/4$ azimuthal range. This detector is constructed as separate towers of dimension $5.25 \times 5.25 \times 37\ \mathrm{cm}^3$, in an alternating lead-scintillator sandwich-type structure ("shish-kebob"), approximately 18 radiation lengths in depth. As illustrated in Fig. 1 the TOF and the PbSc sectors are completely nonoverlapping.

III. DATA ANALYSIS

In this section, we describe the event and track selection, particle identification, the details of K^+K^- pair reconstruction, and the corrections for geometrical acceptance, particle decay in flight, multiple scattering, and detector occupancy factors, all of which couple into deriving the ϕ meson spectra.

A. Event selection

The events selected for this analysis were based on the PHENIX minimum-bias trigger provided by the BBC and ZDC. As noted previously, the centrality of each Au+Au collision event was determined by correlating the BBC charge sum and the ZDC total energy [50]. The PHENIX minimum-bias data sample included $92.2^{+2.5}_{-3.0}\%$ of the 6.9-b Au+Au total inelastic cross section [29]. This analysis used 20 million minimum-bias events with a vertex position within $|z_{\mathrm{vertex}}| < 30$ cm.

To study the centrality-dependent physics, we divided these events into different centrality bins. For the ϕ meson lineshape analysis, we used five centrality bins: 0–10%, 10–20%, 20–40%, 40–60%, and 60–92%. The transverse mass (m_T) spectra were reconstructed for three centrality bins: 0–10%, 10–40%, and 40–92%. These bin divisions were chosen to have approximately equal statistical significance for their respective data points. The centrality of collisions is additionally characterized by the average number of participants ($\langle N_{\mathrm{part}} \rangle$) and the average number of binary nucleon–nucleon collisions ($\langle N_{\mathrm{coll}} \rangle$). These two global quantities, shown in Table I as a function of centrality, are derived from a Glauber model calculation [29].

B. Track selection

Only tracks with valid information from the DC and the PC1 were used for the analysis. These tracks were then confirmed by matching the projected and associated hit information at the TOF wall for the TOF analysis, or at the PC3 and the EMCal for the PbSc analysis. The differences between the actual azimuthal and longitudinal hit coordinates compared to the projected hit coordinates were determined. These tracking coordinate residuals were converted to standard deviation residuals by a momentum-dependent function that computed the expected residual coordinate value. On this basis, a 3σ track-matching cut was used to accept track associations. Lastly, for the TOF wall, an energy-loss cut is applied on the analog signal height from the scintillator slat. This cut has been described in a previous publication [50].

TABLE I. Average number of participants and collisions in Au+Au reaction at RHIC for different centralities determined from a Glauber model [29]. The error associated with each number is the systematic error.

Centrality (%)	$\langle N_{\mathrm{part}} \rangle$	$\langle N_{\mathrm{coll}} \rangle$
0–10	325.2 ± 3.3	955.4 ± 93.6
10–20	234.6 ± 4.7	602.6 ± 59.3
20–40	140.4 ± 4.9	296.8 ± 31.1
10–40	171.8 ± 4.8	398.7 ± 40.5
40–60	59.9 ± 3.5	90.6 ± 11.8
60–92	14.5 ± 2.5	14.5 ± 4.0
40–92	32.0 ± 2.9	45.2 ± 7.3
Minimum Bias	109.1 ± 4.1	257.8 ± 25.4

C. Particle identification

As mentioned earlier, the PHENIX central arm spectrometer utilizes the high-resolution TOF wall and PbSc modules for hadron mass identification. The kaons in the TOF wall were identified via reconstructed momentum combined with a TOF measurement. The timing resolution of this subsystem is $\sigma \simeq 115$ ps. A momentum range of 0.3–2.0 GeV/c was selected to compute the mass distributions [52]. Figure 2 shows the mass-squared distribution of all tracks passing through the TOF module for six different momentum bins. The kaons were identified by applying a 2σ mass-squared cut, which is shown by the shaded region in each plot.

The particle identification with the electromagnetic calorimeter modules is sensitive to the fact that the electromagnetic and hadronic interactions produce quite different patterns of energy sharing between calorimeter towers [53]. As a consequence, the hadron timing properties of the PbSc depend on the energy deposited on the central tower of the cluster, particle momentum, particle type, charge, angle of incidence of the track, etc. The PbSc hadronic timing response was corrected for these effects and we obtained an overall timing resolution of $\sigma \simeq 450$ ps, which is sufficient to enable a clear π/K separation within $0.3 < p(\mathrm{GeV/c}) < 1.0$ using a 2σ mass-squared selection criterion. In Fig. 3 the mass-squared distributions are plotted for four different momentum slices for all tracks passing through PC3 and PbSc. The identified kaons are also shown in the figure by the 2σ width shaded histograms superimposed on the M^2 distributions for all tracks in different momentum bins.

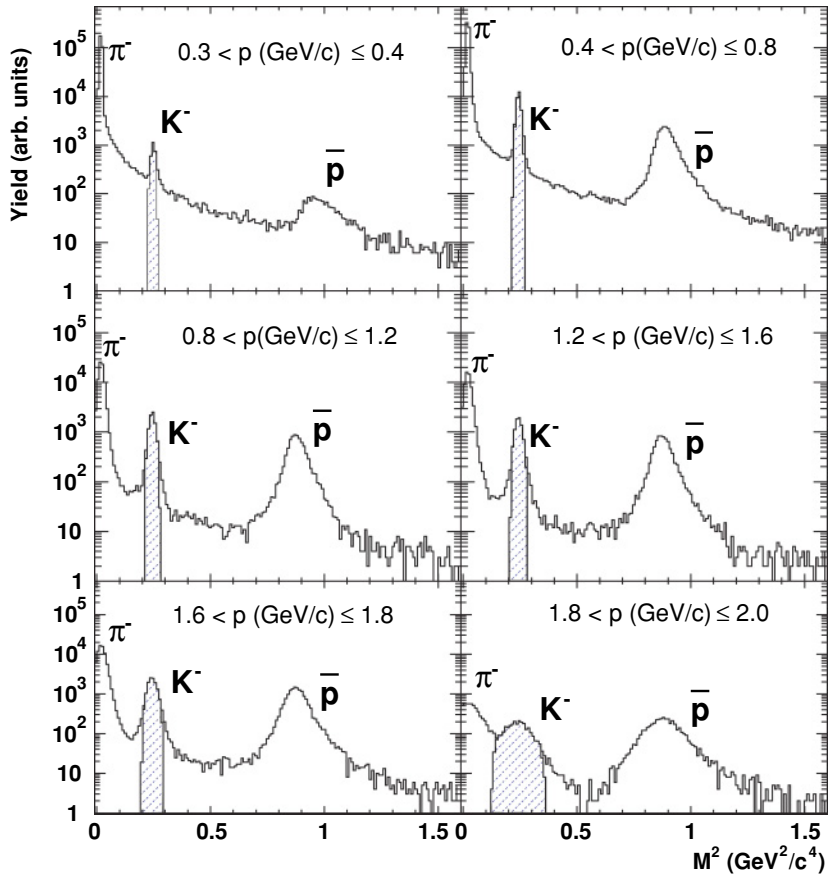

FIG. 2. (Color online) Mass-squared distribution of all accepted tracks passing through the TOF for six selected momentum bins. The identified kaons within 2σ mass-squared boundaries at the different momentum bins are shown by the shaded region on each plot.

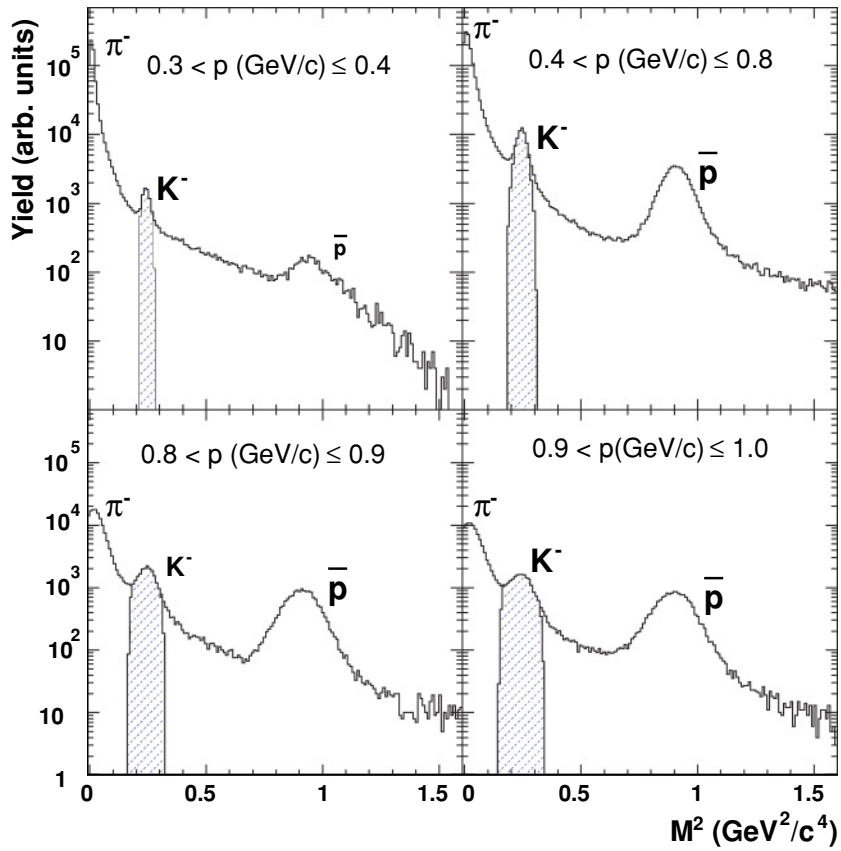

FIG. 3. (Color online) Mass-squared distribution of all selected tracks passing through the PbSc for four momentum bins. The identified kaons within 2σ mass-squared boundaries at the different momentum bins are shown by the shaded region on each plot.

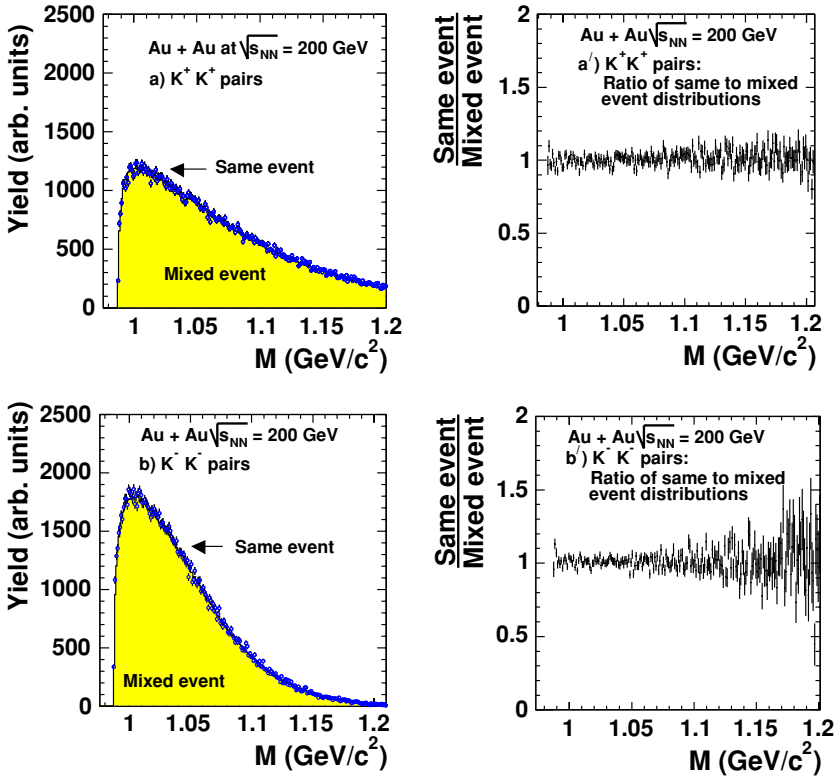

FIG. 4. (Color online) K^+K^+ [(a) and (a′)] and K^-K^- [(b) and (b′)] invariant mass spectra and ratio of real to mixed event spectra, respectively, for the TOF-PbSc combination.

D. K^+K^- invariant mass spectra and ϕ signal extraction

All identified K^+ and K^- tracks in a given event were combined to form the invariant pair mass distributions. Three different pair combinations were used:

(a) both K^+ and K^- identified by the TOF detector (TOF-TOF combination),
(b) K^+ identified with TOF and K^- identified with the PbSc detector (TOF-PbSc combination), and
(c) both K^+ and K^- identified with the PbSc detector (PbSc-PbSc combination).

We did not use the K^+ from PbSc and K^- from TOF in the (b) combination. This is because the PHENIX central arm geometry, in the presence of a 0.8 T m magnetic field, does not have any acceptance for such pairs below an invariant mass of 1.06 GeV/c^2 in the TOF-PbSc combination.

A large combinatorial background is inherent to the K^+K^- pair invariant mass distribution. The combinatorial background was estimated by an event-mixing method in which all K^+ tracks from one event were combined with K^- tracks of ten other events within the same centrality and vertex class. The mixed-event technique reproduces the shape of the unlike-sign combinatorial background. Finally, the size of the combinatorial background is obtained by normalizing the mixed-event invariant mass spectra to $2\sqrt{N_{++}N_{--}}$, where N_{++} and N_{--} represent the measured yields in K^+K^+ and K^-K^- mass distributions, respectively. This normalization is derived analytically starting from the assumption that the number of $K^\pm$ tracks per event-follows a Poisson distribution. A complete derivation of this is given in Appendix A.

The ability of this event-mixing method to reproduce correctly the shape of the combinatorial background distribution was confirmed by constructing, in a similar way, the mixed-event like-sign spectrum and comparing it to the same-event like-sign pair distribution. The assumption is that the like-sign pair distributions are purely combinatoric. For the three detector combinations, TOF-TOF, TOF-PbSc, and PbSc-PbSc, the ratio of the measured and combinatorial like-sign invariant mass distributions were found to be consistent with 1.0 as a function of the pair mass within statistical errors for all centrality bins. As an example, in Fig. 4 we plot the measured and combinatorial "$+\,+$" and "$-\,-$" invariant mass distributions and their ratios for the TOF-PbSc combination as a function of the invariant mass of K^+K^+ and K^-K^- pairs for minimum-bias events. As can be seen from the figures, these ratios are equal to the expected value of 1.0 within the statistical fluctuations.

The systematic uncertainty associated with this normalization procedure was estimated to vary between 0.5% and 2% for the different centralities in the different detector combinations. When we added all data together to derive the ϕ spectrum, the range of the systematic uncertainty is reduced to 0.7–1.0%.

Finally, the ϕ meson signal was obtained by subtracting the combinatorial background from the measured unlike-sign invariant mass spectrum. An example of the K^+K^- invariant mass spectrum for the TOF-PbSc combination is shown in Fig. 5, where we plotted the measured and scaled mixed-event invariant mass distributions for minimum-bias events. The lower panel of the figure shows the subtracted mass spectrum. The corrected yield of the ϕ mesons from the experimental data is then determined by integrating the subtracted invariant

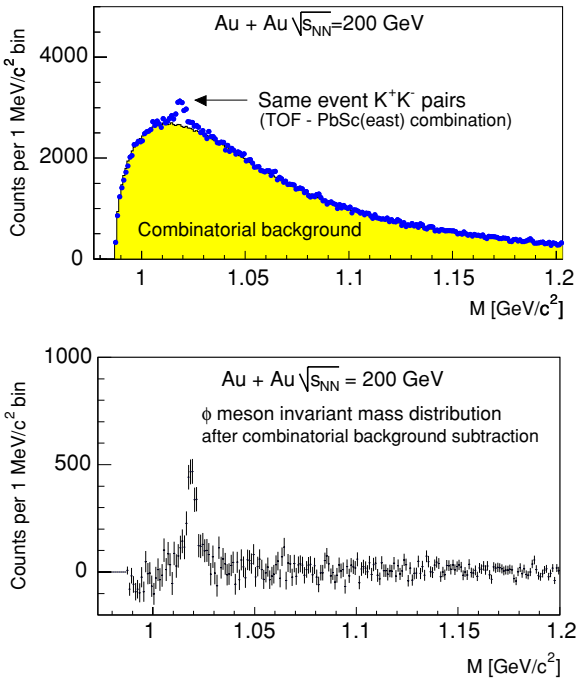

FIG. 5. (Color online) K^+K^- invariant mass spectra for the measured and mixed events (top) in the TOF-PbSc combination, and the subtracted mass spectrum showing the ϕ meson peak clearly above the background (bottom).

mass spectrum within a mass window of $\pm 5\,\mathrm{MeV}/c^2$ about the measured ϕ mass centroid. This narrow mass window was used as it provided a better signal-to-background ratio compared with a wider window. Since we will show that there is no significant centrality dependence of the intrinsic width, then the extracted yields as a function of centrality are not being biased by the use of a constant integration window. The systematic effect of the mass integration window itself on the corrected yield was studied by varying the stated integration limit and was found to contribute 2.6–3.2%, depending on centrality, to the total systematic uncertainty in the integrated yield.

E. Acceptance, decay, and multiple-scattering corrections

The ϕ meson yields were corrected for the geometrical acceptance of the detectors, in-flight kaon decay, multiple-scattering effects, and nuclear interactions with materials in the detector using the PISA software package, which is a GEANT-based [54] Monte Carlo detector simulation of the PHENIX detector. The simulation was carried out by generating 34 million single ϕ mesons in a ± 0.6 rapidity interval with an exponential transverse momentum distribution

$$dN/dp_T = p_T \exp[-m_T/(t_{\mathrm{fo}} + \beta^2 M_\phi)] \qquad (1)$$

with $t_{\mathrm{fo}} = 157$ MeV and $\beta = 0.4$, that is, an effective slope of $T = 320$ MeV in the range $0 < p_T < 10$ GeV/c. The generated ϕ mesons were then propagated through the simulation package. In this simulation, the BBC, DC, PC, TOF, and PbSc detector responses were tuned to match the real data by including their dead areas and by matching their track

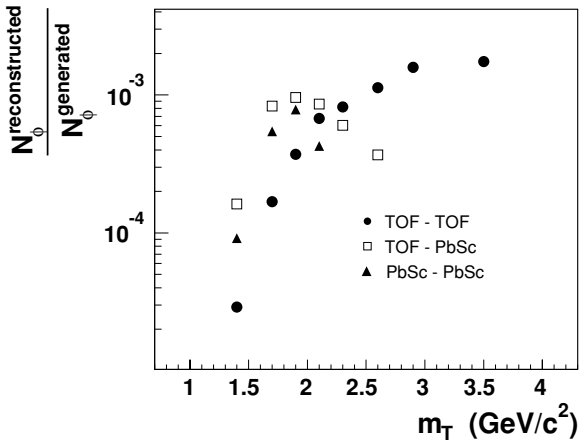

FIG. 6. Detector acceptance efficiency vs transverse mass of the simulated K^+K^- pairs for the TOF-TOF, TOF-PbSc, and PbSc-PbSc combinations. The statistical errors are smaller than the size of the data symbols.

associations and mass-squared resolutions. That is, the track association and mass-squared cut boundaries in the Monte Carlo analysis were parametrized to match the real data. The K^+K^- pair acceptance efficiency as a function of transverse mass was calculated as

$$\epsilon(m_T) = \frac{N_\phi^{\mathrm{reconstructed}}(m_T)}{N_\phi^{\mathrm{generated}}(m_T)}. \qquad (2)$$

The calculated acceptance efficiencies for the TOF-TOF, TOF-PbSc, and PbSc-PbSc combinations are shown in Fig. 6 as a function of m_T. The points in the figure are located at the center of the bins. In the actual m_T spectra, the proper bin centroids were used. The figure shows that the TOF detector (closed circles) has low acceptance for the low-momentum kaon pairs owing to their large opening angles. However, the TOF covers the largest m_T range for the ϕ particles. As a result, the TOF efficiency function increases toward higher transverse mass. In contrast, the TOF-PbSc (open squares) and PbSc-PbSc (closed triangles) combinations offer better low-pair-momentum acceptance than the TOF. However, the high-momentum kaon identification limit in the PbSc leads to the efficiency function decreasing at the highest transverse mass values.

To check the sensitivity of the acceptance correction factors to the input inverse slope of the ϕ mesons, the acceptance corrections are calculated for two input inverse slope parameters, $T = 320$ and 440 MeV. Both are found to be almost consistent within $\sim$1% uncertainty as a function of the momentum of the generated ϕ mesons. This is added as a systematic uncertainty to the acceptance correction factor.

In general, the PHENIX east arm ($|\eta| < 0.35$) particle identification detectors, in the presence of the central arm magnetic field, accepts 0.5% of the $\phi \to K^+K^-$ pairs generated within $|y| < 0.5$ and $1.2 < m_T^\phi(\mathrm{GeV}/c^2) < 4.0$. The factors that influence this geometrical acceptance are the geometry of TOF and PbSc at the PHENIX east arm, in-flight kaon decay, multiple-scattering effects, nuclear interactions of the kaons with detector materials, and the central arm magnetic

field. Out of those, about 17% of the kaon pairs are finally reconstructed after single-track reconstruction, track selection criteria, particle identification cuts, and finally the ϕ meson reconstruction within ± 5 MeV mass window with respect to its centroid.

The systematic error associated with the acceptance correction factor originates from

(i) tuning of detector alignments and mass-squared parameters in the Monte Carlo with reference to the real data ($\sim$3%),
(ii) systematics in the fiducial geometries in the data and the Monte Carlo ($\sim$12%), and
(iii) variation of the input inverse slope of the event generator ($\sim$1%).

F. Detector-occupancy correction

The high-multiplicity environment in the heavy-ion collisions produces multiple hits in a detector cell such as in the slats of the TOF or in the towers of the PbSc. These occupancy effects reduce the track reconstruction efficiency in central collisions compared to that in peripheral collisions, and these occupancy-dependent effects need to accounted for in calculating the invariant yields. The multiplicity-dependent efficiency ($\epsilon_{\text{occupancy}}$) factors were calculated by embedding simulated K^+K^- pairs into real data events. This study was done for different centrality bins from 0 to 92% in steps of 10%. We calculated the multiplicity-dependent efficiencies for TOF-TOF, TOF-PbSc, and PbSc-PbSc pairs separately. The systematic uncertainty associated with the embedding procedure was estimated for the three centrality bins used in the yield determinations, namely, 0–10%, 10–40%, and 40–92%. The systematic errors, calculated by estimating the occupancy-efficiency corrections for different track-confirming criteria, were found to vary from 7% to 10% for the three centrality bins used here, independent of the pair momenta. Figure 7 shows the $\epsilon_{\text{occupancy}}$ factors as a function of collision centrality

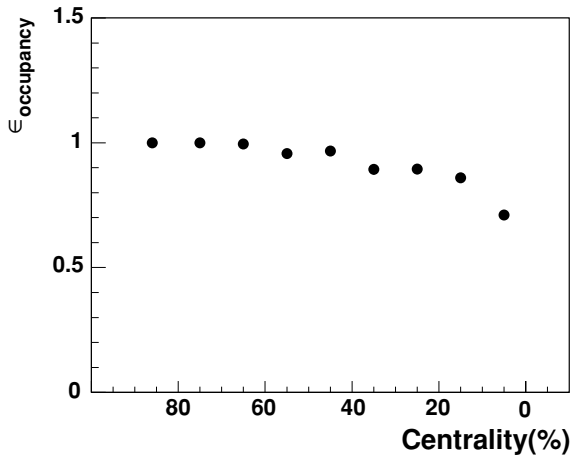

FIG. 7. Multiplicity-(occupancy-)dependent efficiency correction for detecting the ϕ meson in the PHENIX detector as a function of the collision centrality. The most central collisions are to the right; the most peripheral collisions are to the left. The statistical errors are less than the size of the data points.

for the K^+K^- pairs both identified in the TOF detector. The occupancy-dependent efficiency factors were found to be independent of the transverse momenta of the pairs.

IV. RESULTS AND DISCUSSION

In this section, we present and discuss the results of our measurements, which consist of (1) the ϕ line-shape analysis, (2) the transverse mass spectra analysis, (3) the integrated yields and ratios analysis, (4) hydrodynamical fits to $\pi^{\pm}$, $K^{\pm}$, p, $\overline{p}$, and ϕ transverse momentum spectra, and (5) the centrality dependence of the yields and nuclear modification factor R_{CP} as compared to that of pions and (anti)protons.

A. Line-shape analysis

The invariant mass spectra of the ϕ mesons are obtained by subtracting the combinatorial backgrounds from the same event K^+K^- mass spectra. The details of the combinatorial background analysis were described in Sec. III D. For the best statistical precision, we combine data from TOF and PbSc detectors to analyze the ϕ mass centroids and widths at the five different centrality bins. This is done by simply adding the measured and combinatorial invariant mass spectra from the three independent subsystem combinations mentioned in Sec. III D and then subtracting the total combinatorial background from the total measured mass spectra.

Figure 8 shows the minimum-bias $\phi \rightarrow K^+K^-$ invariant mass spectrum for the PHENIX data. The subtracted ϕ mass

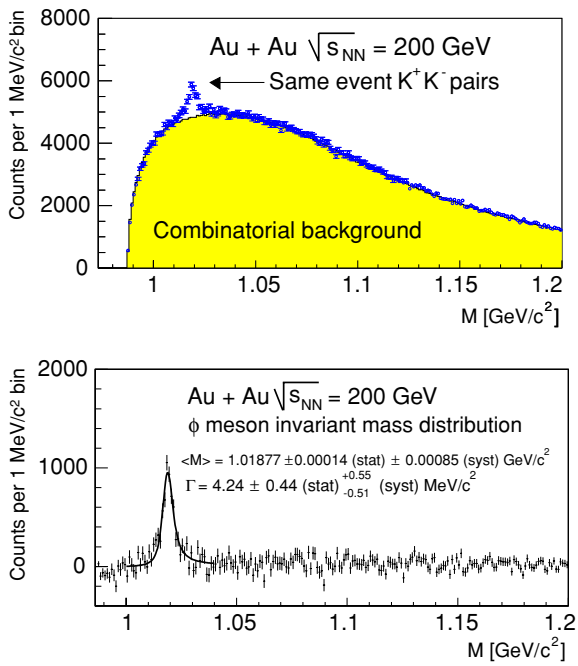

FIG. 8. (Color online) Minimum-bias $\phi \rightarrow K^+K^-$ invariant mass spectrum using the kaons identified in the PHENIX detector. The top panel shows the same event (circles) and combinatorial background K^+K^- mass distributions. The bottom panel shows the subtracted mass spectrum fitted with a relativistic Breit-Wigner function convolved with a Gaussian resolution function.

TABLE II. ϕ meson mass centroid and width for the minimum-bias Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The corresponding PDG values are $M_\phi = 1.019456$ GeV/c^2, $\Gamma_\phi = 4.26$ MeV/c^2.

Parameter	Value (MeV/c^2)
Centroid	1.01877 ± 0.00014 (stat) ± 0.00085 (syst)
Width	4.24 ± 0.45 (stat) $\pm \frac{0.55}{0.51}$ (syst)

spectrum (lower panel), containing approximately 5100 ϕ mesons in the fit region, is fitted with a relativistic Breit-Wigner (RBW) mass distribution function [38] convolved with a Gaussian experimental mass resolution function. Using Monte Carlo studies based on the experimentally measured single-kaon momentum resolution, the experimental ϕ mass resolution is calculated to be 1.0 MeV/c^2. This pair mass resolution value is found to be almost constant across the kinematic region of acceptance.

The errors on the data points in Fig. 8 reflect the statistical errors only. The systematic errors associated with the mass centroid and width measurements originate from the magnetic field uncertainties in the kaon momentum determination and the combinatorial background normalization procedure. The minimum-bias line-shape parameters (centroid and width) derived in our analysis are listed in Table II. The fitted minimum-bias ϕ mass centroid and width are consistent at the one standard deviation (1σ) level with the PDG values [55], taking into account both systematic and statistical errors. The centroids and widths from the mass spectra of the three independent subsystem combinations are also found to be consistent with PDG values within errors.

We investigated the centrality dependence of the ϕ meson line shapes. For each centrality bin, we again fitted the ϕ mass spectrum with the RBW function convolved with a Gaussian experimental ϕ mass resolution. The results are presented in Fig. 9. The left panel of the figure shows the centrality dependence of the fitted centroids. The upper and lower 1σ systematic error limits are indicated. The dotted line shows the PDG mass centroid. The solid line indicates the result obtained with a one-parameter constant fit through the measured data points. These results lead to two immediate conclusions. First, to within less than 1 MeV/c^2 there is no observed centrality dependence of the ϕ meson mass centroid, and second, the fitted centroids at all centralities are consistent with the PDG value within the statistical and systematic uncertainties of our measurements.

The ϕ mass widths, as shown in the right panel of the figure, are studied as a function of the centrality. The error bar on each point shows the statistical error; the bands on the points indicate the systematic errors. The dotted line shows the PDG ϕ mass width. The solid line shows the results of the constant-fit assumption to the data points. Again, within the statistical and systematic error limits shown, there is no convincing evidence of a variation of the ϕ width as a function of centrality.

The topic of medium effects on meson masses has been actively investigated in the recent literature [7–10,20,23,56–58]. The predictions are that for both cold and hot nuclear matter there could be a decrease of the ϕ mass value by a few MeV/c^2 or even tens of MeV/c^2. Even more dramatically the width could increase by several multiples above the PDG value of 4.26 MeV/c^2. A sample of such predictions is given in Table III. However, one of the models [20] considers the $\phi \to K^+K^-$ channel largely insensitive to medium effects since the kaons are "unlikely to escape without reacting further, thus destroying any useful information possessed about the ϕ." In this sense the $\phi \to K^+K^-$ is inherently biased in that only ϕ decays that are unaffected by the medium changes, for example those produced peripherally, can be detected.

It is sometimes thought that because the vacuum $c\tau$ of the ϕ is ≈ 45 fm/c there will be only limited sensitivity to medium effects in any case. However, if the resonance width were to actually increase by several times, as indicated in Table III, then the $c\tau$ would then approach or be even substantially less than 10 fm/c, which is a size compatible with the expected collision volume. The dramatic width changes predicted in either cold or hot nuclear matter might be visible, at least in the dilepton channel if not also the K^+K^- channel, as a function of centrality.

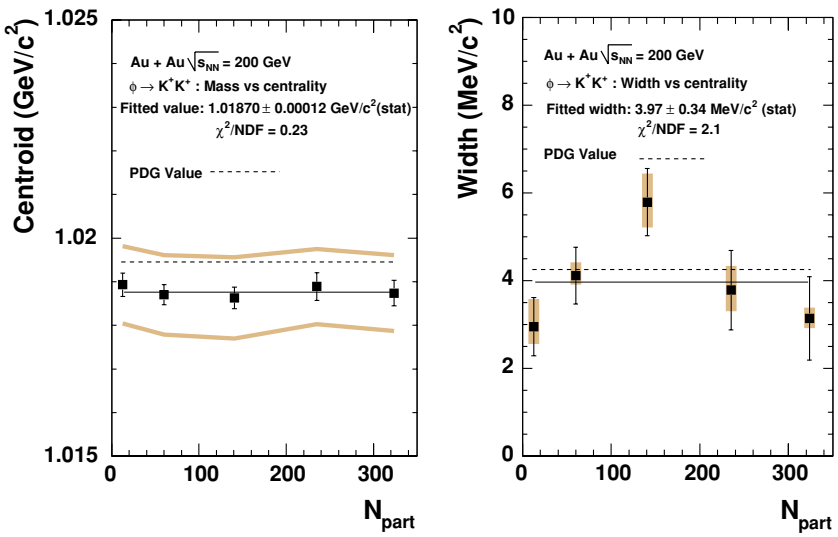

FIG. 9. (Color online) Centrality dependence of the ϕ mass centroid (left panel) and ϕ intrinsic width (right panel), where the $N_{\rm part}$ to Centrality correspondence is given in Table I. For the mass centroid plot, the 1σ systematic error limits on the data points are shown by the two continuous bands. The dotted line shows the PDG centroid value (1.019456 GeV/c^2). The solid line indicates the centroid value obtained from a one-parameter-fit assumption. For the width plot the systematic errors on the RBW widths are indicated as bands on each data point. Similarly, the dotted line shows the PDG width value (4.26 MeV/c^2), and the solid line shows a one-parameter-fit result for the measured data points.

TABLE III. Theoretical predictions for changes in the ϕ resonance.

Authors	Models	Environment	Predictions
Caberara and Vicente Vacas [23]	Chiral SU(3)	Cold hadronic	$M_\phi \rightarrow 1.011$ Gev $\Gamma_\phi \rightarrow 30\,\mathrm{MeV}/c^2$
Pal, Ko, and Lin [13]	AMPT Chiral Lagrangian	Hot hadronic	$M_\phi \rightarrow 0.95\,\mathrm{GeV}/c^2$ at twice normal nuclear density (ρ_0) $\Gamma_\phi \rightarrow 45$ MeV/c^2 at $2\rho_0$ Suppression of $\phi \rightarrow K^+K^-$ relative to $\phi \rightarrow e^+e^-$
Oset and Ramos [21]	Kaon mass renormalization	Cold hadronic	M_ϕ unchanged $\Gamma_\phi \rightarrow 22$ MeV/c^2
Smith and Haglin [20]	One-Boson exchange	Hot hadronic	M_ϕ unchanged $\Gamma_\phi \rightarrow 14$–$24$ MeV/c^2
Blaizot and Mendez Galain [12]	Nambu-Jona-Lasino	Hot hadronic	$M_\phi \rightarrow 2M_K$ at $T \approx T_{\mathrm{critical}}$ Γ_ϕ *reduced* by a factor of 6 $\phi \rightarrow K^+K^-$ disappears
Bi and Rafelski [14]	Bag model Chiral invariance	Hot hadronic	$M_\phi \rightarrow 1.029\,\mathrm{GeV}/c^2$ at $T \approx T_{\mathrm{critical}}$ $\Gamma_\phi \rightarrow 10$ MeV/c^2

The present mass centroid and width data, which are integrated over the available m_T range, rule out any major changes with respect to the PDG values. Specifically, the one-parameter fit result of 3.97 ± 0.34 MeV/c^2 obtained here excludes at the 99% confidence level a width value of 4.75 MeV/c^2 or greater. Possibly at the lowest m_T values, where the ϕ would remain longer in the collision volume, or with the availability of more finely binned centralities, there could be visible evidence of in-medium effects. However, the current data sample is insufficient to explore these possibilities.

It seems clear from the current set of theoretical models that an observed change in the ϕ width would not be itself indicative of a QGP formation. One would first have to constrain the cold nuclear medium effects on the ϕ as could be obtained in d+Au collisions, or by comparing peripheral Au+Au collision data results with central collision data. It is also important to measure the ϕ mass in the dilepton e^+e^- channel. That channel should be more sensitive to the ϕ that are produced deeper or earlier in the collision volume.

B. Spectral-shapes analysis

At low m_T, the spectral shapes carry information about the kinetic freeze–out conditions. Since the centrality dependence reveals the effect of the system size on the fireball evolution it becomes desirable to study the centrality dependence of the spectral shapes. Transverse mass spectra were obtained in three centrality bins corresponding to 0–10%, 10–40%, and 40–92% of the total geometrical cross section. We count the same event K^+K^- pairs within a defined mass window (± 5 MeV/c^2 with respect to the ϕ mass centroid) and estimate the number of combinatorial background pairs within that window. In each centrality bin, the data are divided into different m_T bins. The invariant mass spectrum for the same events and the background distributions are obtained for each of these m_T bins. Finally, the background is subtracted from the same-event invariant mass spectrum within the aforementioned ± 5 MeV/c^2 ϕ mass window to determine the number of reconstructed ϕ mesons within that m_T bin. The reconstruction of the ϕ in the Monte Carlo simulation takes into account the effect of the ϕ mass window size.

The ϕ mesons are reconstructed using kaons identified in the TOF and the PbSc detectors. Three detector combinations (TOF-TOF, TOF-PbSc, and PbSc-PbSc) are used to obtain three independent transverse mass spectra. Figure 10 shows the minimum-bias m_T spectra for these three combinations. The combined result, which is the weighted sum of the three combinations, is also included. For better visibility of the data points, TOF-TOF, TOF-PbSc, and PbSc-PbSc spectra are

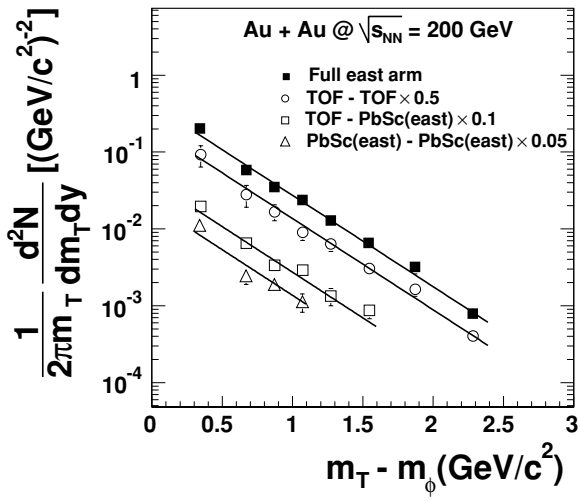

FIG. 10. Minimum-bias m_T spectra of the measured ϕ mesons for three different PHENIX subsystem combinations, with scale factors as indicated. The combined spectrum is fitted with an exponential function in m_T, Eq. (3). The lines drawn through the individual spectra (TOF-TOF, TOF-PbSc, and PbSc-PbSc) represent the same fit parameters as in the minimum-bias case. Statistical error bars are shown.

TABLE IV. Minimum-bias dN/dy and T for different subsystem combinations. The statistical and systematic errors are shown after the first and second $\pm$ signs, respectively.

Subsystem Combination	TOF-TOF	TOF-PbSc	PbSc-PbSc	Full Data Set
dN/dy	$1.16 \pm 0.17 \pm 0.19$	$1.37 \pm 0.15 \pm 0.22$	$1.47 \pm 0.26 \pm 0.27$	$1.34 \pm 0.09 \pm 0.21$
T (MeV)	$380 \pm 18 \pm 22$	$385 \pm 34 \pm 28$	$311 \pm 47 \pm 65$	$366 \pm 11 \pm 18$

scaled by a factor of 0.5, 0.1, and 0.05, respectively. The m_T spectrum obtained from the PHENIX detector is fitted with the exponential function

$$\frac{1}{2\pi m_T}\frac{d^2N}{dm_T dy} = \frac{dN/dy}{2\pi T(T+M_\phi)} e^{-(m_T - M_\phi)/T}, \qquad (3)$$

where dN/dy and the inverse slope T are returned as two fitting parameters. The lines drawn through the TOF-TOF, TOF-PbSc, and PbSc-PbSc spectra represent the same fit but are scaled with the same scaling factors as the data points. Comparison of the individual spectra to the fit obtained from the combined spectrum demonstrates the consistency among the different measurements, which have different systematic uncertainties. The TOF-TOF, TOF-PbSc, and PbSc-PbSc spectra are also independently fitted using Eq. (3). The resulting dN/dy and T are tabulated in Table IV. Both statistical and systematic errors are quoted. The systematic errors on dN/dy originate from the systematic uncertainties associated with extraction of the yields in each m_T bin (see Appendix C) and the uncertainties from the fitting procedure. The latter is sensitive to the extrapolation of the m_T spectra to $m_T = m_\phi$. A detailed account of systematic errors on dN/dy and T in the full dataset from all sources is shown in Appendix C. We also fitted the TOF-TOF and TOF-PbSc data over the smaller m_T range of the PbSc-PbSc data and obtained consistent sets of dN/dy and T values from that check.

Figure 10 and Table IV indicate that the three different analyses with different systematic uncertainties give consistent results. This allowed us to combine the results and make use of the maximum available statistics in each m_T bin. This combined spectrum was used to obtain the physics results discussed in the next sections.

Figure 11 shows m_T spectra of the ϕ mesons in 0–10%, 10–40%, 40–92%, and minimum-bias centrality classes. The data points representing the invariant yield as a function of transverse momentum are given in Appendix B. Each spectrum is fitted with an m_T-exponential function, Eq. (3). The ϕ yield per unit of rapidity (dN/dy) and inverse slope (T) obtained from the fits are shown in Table V and are summarized in Figs. 12 and 13 [59].

C. Yields and ratios

Hadron yields and ratios carry information about the chemical properties of the system. The yields of strange particles have been of particular interest as they help in understanding the strangeness enhancement in heavy-ion collisions and the equilibration of strangeness. It is important to study these phenomena as a function of system size. Centrality-selected data can be particularly useful in this respect. Here we present the yield of the ϕ mesons at midrapidity as a function of centrality and compare this yield to the yields of other hadrons and the results from lower energy heavy-ion collisions. The dN/dy of ϕ (shown in Fig. 12) is found to increase steadily with centrality. In the right panel, the yield is normalized to the number of participant pairs to take into account the size of the system. Within the error bars this normalized rapidity density is approximately independent of centrality with a possible slight increase from peripheral to the midperipheral collisions. The trend is quite different from lower energy results measured at the AGS. In [38], the yield of ϕ was reported to be increasing greater than linearly with the number of participants.

We now consider the ratio of strange to nonstrange particles to understand the extent and mechanism of the strangeness enhancement in heavy-ion collisions. The ratios K^+/π^+ and K^-/π^- are shown in Figs. 14 (a) and (b). Both ratios show an increase of $\approx$60% from peripheral to central collisions. Most of this increase is for $N_{\rm part} < 100$. Only a mild increase or saturation is observed from midcentral to the top centrality bin [50]. Figures 14 (c) and (d) show the centrality dependence of the ϕ/π and ϕ/K ratios. The limited statistics prevent us from extending the ϕ measurements into larger number of centrality bins spanning the more peripheral events. The ϕ/K ratio, in this limited number of centrality bins, is approximately flat as a function of centrality. The possibility of structure in the

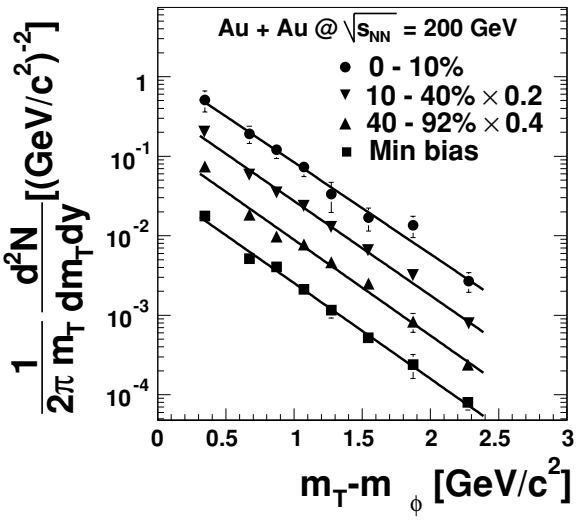

FIG. 11. m_T spectra of ϕ mesons for 0–10%, 10–40%, 40–92%, and minimum-bias (0–92%) centrality classes, with scale factors as indicated. Each spectrum is fitted with an exponential function in m_T, Eq. (3), with the fit parameters listed in Table V. Statistical error bars are shown.

TABLE V. dN/dy and T for different centrality bins.

Centrality (%)	dN/dy	T (MeV)
0–10	3.94 ± 0.60 (stat) ± 0.62 (syst)	376 ± 24 (stat) ± 20 (syst)
10–40	2.22 ± 0.18 (stat) ± 0.35 (syst)	360 ± 13 (stat) ± 23 (syst)
40–92	0.32 ± 0.03 (stat) ± 0.05 (syst)	359 ± 15 (stat) ± 16 (syst)
Minimum Bias	1.34 ± 0.09 (stat) ± 0.21 (syst)	366 ± 11 (stat) ± 18 (syst)

ϕ/π ratio is difficult to infer from our data within the error bars. One might expect to see some centrality dependence in the ϕ/π ratio because there is obviously a centrality dependence to the K/π ratio. However, we do not have enough centrality bins, nor enough signal in each bin, from which to conclusively identify a centrality dependence in ϕ/π. The flat behavior of the ϕ/K ratio indicates that there is no pronounced difference in the production of open (kaon) and hidden (ϕ) strangeness in heavy ion collisions at RHIC energies. Production in the hadronic stage via kaon coalescence $K^+K^- \rightarrow \phi$ seems to be excluded by these data, as it would result in an increase in ϕ/K^- as a function of N_{part}, which is not observed.

The collision energy dependence of the ϕ yield is shown in Fig. 15, where we plot the dN/dy per participant pair as a function of the number of participants for different colliding energies. The figure indicates two aspects of ϕ meson production at various energies. First, as we go from AGS to SPS to RHIC, the ϕ meson yield per participant increases by an order of magnitude overall. Secondly, at the AGS energy, we find a steady increase of ϕ production per participant pair from peripheral to central collisions. It is worth mentioning that the NA50 experiment [25] at CERN SPS reported an increase in fiducial ϕ yield (in the $\mu^+\mu^-$ decay channel) per participant from peripheral to central collisions although the yield per participant showed saturation within the error for the top centrality bins. The yield of ϕ mesons at RHIC, on the contrary, is found to be almost independent of centrality.

To investigate further the mechanism of ϕ enhancement with increase in collision energy, we study the two ratios ϕ/π and ϕ/K^- as a function of collision energy as illustrated in Fig. 16. The ϕ/π ratio is found to increase with the collision energy from AGS to RHIC. The ϕ/K^- ratio, in contrast, remains almost constant within the error bar with increasing collision energy.

D. Hydrodynamical model fits to the spectral-shape data

From the ϕ spectral data shown in the preceding sections, we can conclude that the transverse mass distributions are well described by an exponential distribution and are quite similar for all the centralities. There is little, if any, centrality dependence of the inverse slope parameter in the measured centrality bins, as shown in Fig. 13. The exponential behavior is expected for particle production from a thermal source.

If the system develops collective motion, particles experience a velocity boost resulting in an additional transverse kinetic energy component. This motivates the use of the transverse kinetic energy (i.e., transverse mass minus the particle rest mass) for studying flow effects. Traditionally, the CERN experiments [60,61] have used simple exponential fits to the transverse kinetic energy distributions and often quote just one number, the inverse slope T, to characterize the spectra. These fits are usually done in the range $(m_T - m_0) < 1$ GeV/c^2 to minimize the contribution from hard processes.

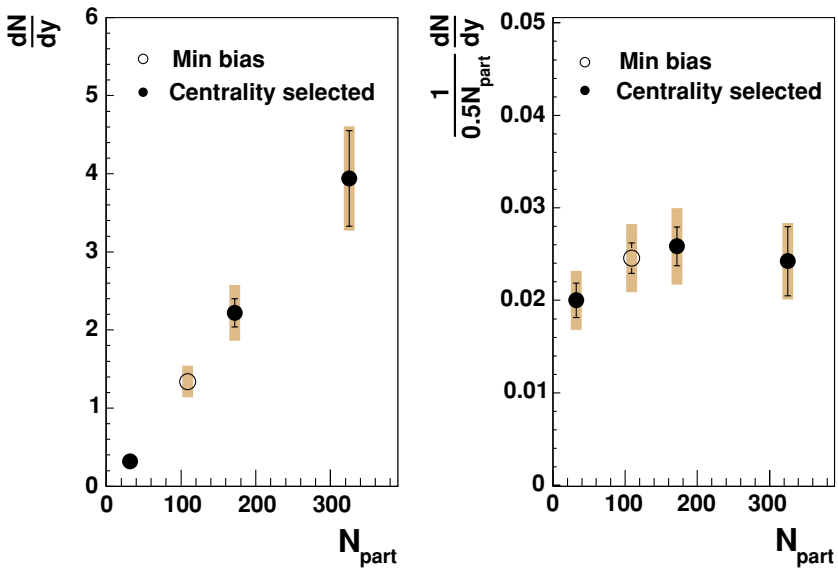

FIG. 12. (Color online) Centrality dependence of ϕ yield at midrapidity. The value of dN/dy increases steadily with the number of participants N_{part} (left) whereas the dN/dy per participant pairs increases slightly from peripheral to midcentral events and saturates after that (right). The error bars indicate the statistical errors. The shaded boxes on each data point are the systematic errors.

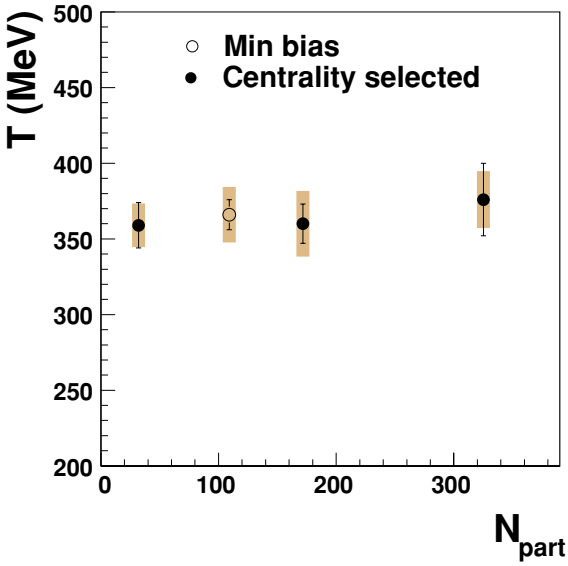

FIG. 13. (Color online) Centrality dependence of the inverse slope T.

The results of such fits, obtained from previously published PHENIX $\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$ data [50] are shown in Fig. 17. The slope parameters show a clear mass dependence, as expected from radial flow. The mass dependence increases from peripheral to central collisions, indicating stronger collectivity in the more central events. The ϕ meson has mass similar to that of the proton. Hence we expect that if the ϕ participates in the collective flow then its inverse slope will be affected by this motion. For protons, the slope parameter changes significantly from peripheral to central collisions. As just noted, the ϕ inverse slopes show no such centrality dependence. An important difference between the results obtained for p, $\overline{p}$, and ϕ is that those for the proton and antiproton have been fitted within a limited low-m_T range [$(m_T - m_0) < 1$ GeV/c^2] as motivated by the previous discussion. In the case of the ϕ the full measured range has been used for the fit because of the limited data at low m_T. As shown in Fig. 11, the three data points below 1 GeV/c^2 are consistent with the fit over the entire m_T range.

The detailed study of the higher statistics (anti)proton spectra [50] indicated that (anti)proton spectra cannot be described by a single exponential in $m_T - m_0$, if the full measured range is considered. Although easy to visualize, the one-parameter inverse-slope analysis proves to be too simplistic as a way to infer the kinetic properties of the system. In particular, the degree to which the ϕ mesons participate in the collective expansion will be shown (see Fig. 22) to be obscured in this simple approach.

A more sophisticated approach to this problem is to compare the particle spectra to a functional form that describes a boosted thermal source, based on relativistic hydrodynamics [62]. This is a two-parameter model, termed the "blast-wave" model, in which the surface radial flow velocity (β_T) and the freeze-out temperature ($T_{\rm fo}$) are extracted from the invariant

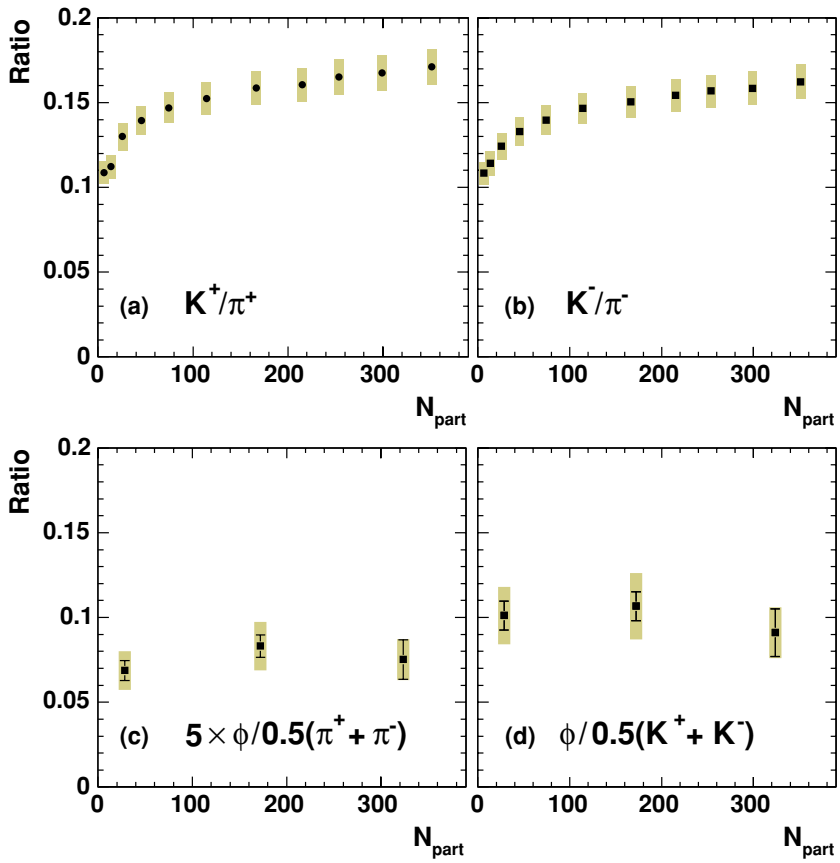

FIG. 14. (Color online) Centrality dependence of particle ratios for (a) K^+/π^+, (b) K^-/π^-, (c) $\phi/[0.5(\pi^+ + \pi^-)]$ (scaled by a factor of 5), and (d) $\phi/[0.5(K^+ + K^-)]$ in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The data points have been placed in the center of each centrality bin. An increase in ϕ production, similar to kaons, would shift the lowest bin slightly to the right by about 20% to an $N_{\rm part}$ of about 40, in (c).

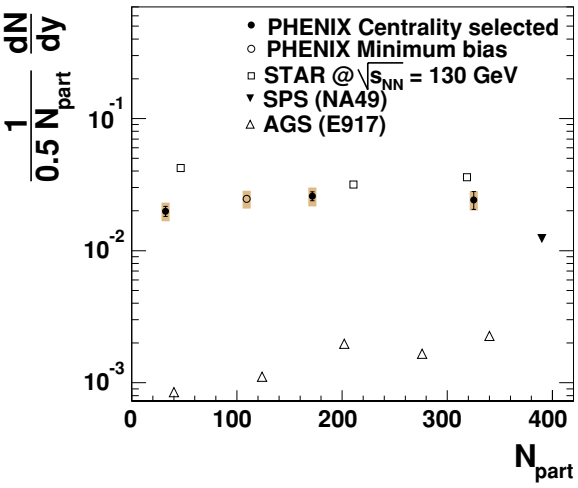

FIG. 15. (Color online) Centrality dependence of ϕ yields at different collision energies. STAR data are from [43], NA49 data are from [39], and E917 are from [38].

cross-section data according to the equation

$$\frac{dN}{m_T\, dm_T} \propto \int_0^R f(r)\, r\, dr m_T I_0\left(\frac{p_T \sinh\rho}{T_{\rm fo}}\right) K_1\left(\frac{m_T \cosh\rho}{T_{\rm fo}}\right), \tag{4}$$

where I_0 and K_1 represent modified Bessel functions with ρ being the transverse boost, which depends on the radial position according to

$$\rho = \tanh^{-1}(\beta_T) r/R. \tag{5}$$

Here the parameter R is the maximum radius of the expanding source at freeze-out. The function $f(r)$ represents the density, which is taken to be uniform in this calculation. A detailed comparison between our implementation of the blast-wave model and the results of full hydrodynamics calculations has been reported previously in [63] and the results were found to be consistent.

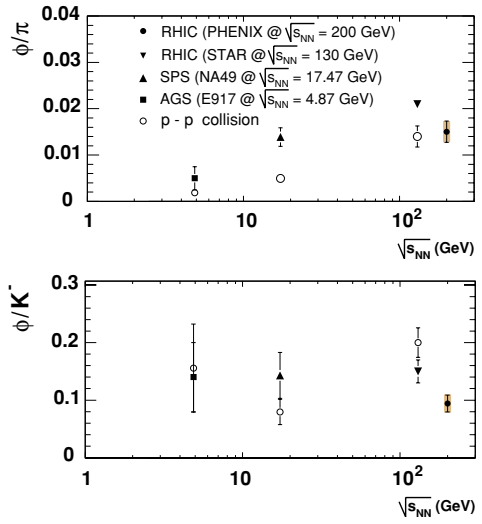

FIG. 16. (Color online) ϕ/π (top) and ϕ/K^- (bottom) ratios as a function of collision energy. The data symbols have the same meanings in both the top and the bottom parts of the figure.

To study the parameter correlations, we make a grid of ($T_{\rm fo}$, β_T) pairs and then for each pair we perform a chi-squared minimization for each particle type. We use a linear velocity profile and constant particle density distribution. The first fit attempt is performed simultaneously for the six particle species $\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$ in the range $(m_T - m_0) < 1.0$ GeV/c^2.

The experimental data for p and $\overline{p}$ have been corrected for Λ and $\overline{\Lambda}$ decays. However, the invariant yields of $\pi^{\pm}$ and $K^{\pm}$ include feed-down from the decay of resonances and weak decays. To take this into account we add the decay of mesonic (ρ, η, ω, K^*, . . .) and baryonic (Δ, Λ, Σ, . . .) resonances as follows:

(1) Generate resonances with the transverse momentum distribution determined by each combination of $T_{\rm fo}$ and β_T.
(2) Simulate the decays using a Monte Carlo approach and obtain $\pi^{\pm}$ and $K^{\pm}$ distributions.
(3) Merge all particles, where the particle abundance is calculated with chemical parameters [64]$T_{\rm ch} = 177$ MeV, $\mu_B = 29$ MeV.

The two-parameter $T_{\rm fo}$ versus β_T fit results obtained in this analysis for the most central bin are shown in Fig. 18. Shown in the lower panel of the figure are the χ^2 contour levels obtained from fitting each particle spectrum separately. We observe that the parameters $T_{\rm fo}$ and β_T are anticorrelated; the different particles have different preferred parameter space and different sensitivity to the parameters. For example, the contours for the heavier particles are more sensitive to the flow velocity than to the kinetic freeze-out temperature. The minimum valleys in the contours for the six particle species do overlap at a single common point at the 2σ level. To find the values of the parameters at this overlap point, a simultaneous fit for the six single-particle spectra ($\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$) was done; the result converges to a best fit value of $T_{\rm fo} = 108.9^{+2.6}_{-2.4}$ MeV and $\beta_T = 0.771^{+0.003}_{-0.004}$. Using these parameters, we obtain the transverse momentum shapes shown in Fig. 19, where we also include the prediction for the ϕ spectrum shape, which was not part of the original fit. The shape of the ϕ spectrum is reproduced well.

For the two other centrality bins in this study, 10–40% and 40–92%, we show the best-fit hydrodynamical results in Figs. 20 and 21, respectively. Again we see that the ϕ transverse momentum shapes are reproduced by the same flow parameters that fit the identified hadron data at the same centrality bins.

For a second hydrodynamical fit attempt, we include the ϕ transverse momentum 0–10% centrality data along with the previously identified hadron data as part of the χ^2 minimization search. The flow parameters derived with the ϕ data included are numerically consistent with the flow parameters derived previously without the ϕ data being included.

The two-dimensional grid-search best-fit values for the blast-wave parametrization as a function of centrality are tabulated in Table VI. The radial average expansion velocity $\langle\beta_T\rangle$ is also given in this table. For the range of centralities studied here, the expansion velocity parameter is seen to decrease moderately for more peripheral collisions whereas

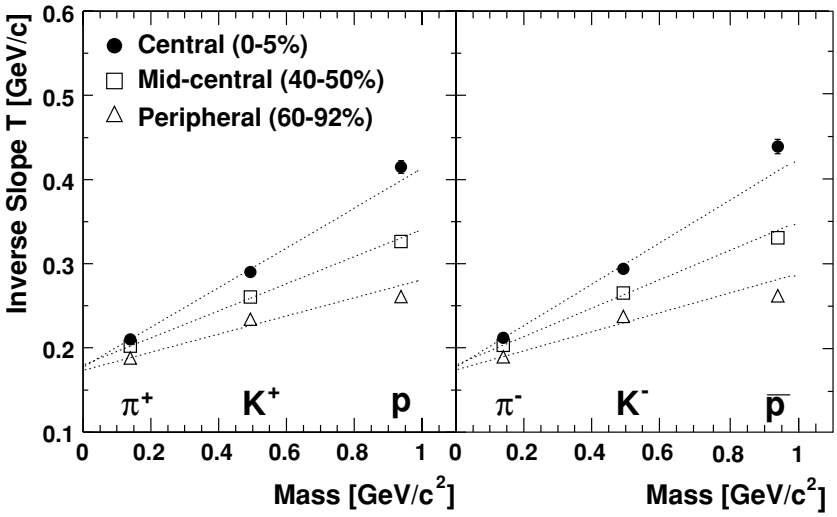

FIG. 17. Mass and centrality dependence of inverse slope parameters T in m_T spectra for positive (left) and negative (right) particles in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The fit ranges are 0.2–1.0 GeV/c^2 for pions and 0.1–1.0 GeV/c^2 for kaons, protons, and antiprotons in $m_T - m_0$. Figure taken from Ref. [50].

the kinetic freeze-out temperature increases more significantly, by approximately 40%. If one takes these parameters literally, then the more peripheral collisions are subject to decreased radial flow while correspondingly the particles are decoupling kinetically from each other at temperatures closer to the chemical freeze-out temperature. This is a physically reasonable scenario given fewer participants in the initial expansion phase.

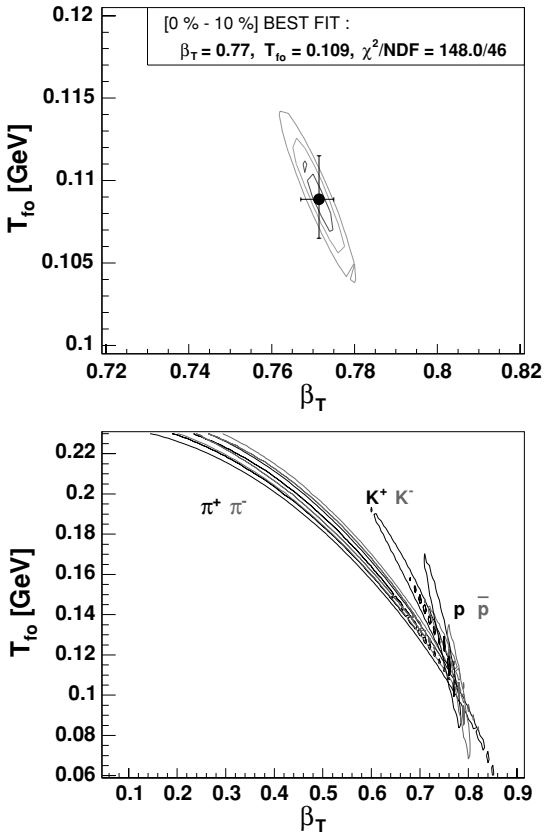

FIG. 18. (Color online) Contour plots for the hydrodynamical fit to the 200-GeV single-particle transverse momentum spectra for the $\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$ in the 0–10% centrality bin. The contour lines are in 1σ steps. The upper plot is from a simultaneous fit with the best value shown as the dot. The lower plot is from independent fits for the six-particle spectra.

It should be pointed out that our present ϕ transverse momentum range does not extend below 0.8 GeV/c. The spectral shapes at low m_T, especially for the heavier particles, are mostly sensitive to the expansion velocity. In the range of our ϕ measurement, it is more appropriate to consider the asymptotic behavior of the spectral shapes, which for $m_T \gg m_0$ is given by [62]

$$T_{\text{eff}} = T_{\text{fo}}\sqrt{(1+\beta_T)/(1-\beta_T)}, \tag{6}$$

where T_{eff} is the slope parameter obtained using an m_T exponential fit, as in Eq. (3). It is interesting to note that the measured asymptotic slopes do not seem to depend on centrality, although both T_{fo} and β_T show a clear centrality dependence. This either is due to a cancellation effect in Eq. (6), since the parameters are anticorrelated, or indicates that the hydrodynamics description is no longer valid at these large transverse momenta. We conclude that although the ϕ data themselves cannot constrain the kinematic freeze-out conditions, they are consistent with the hydrodynamical results obtained from the simultaneous fit to the $\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$ spectra.

TABLE VI. Blast-wave-model parameters [62] as a function of centrality from fitting $\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$ spectra. The fit parameters quoted here are the results from fitting the six identified hadrons spectra simultaneously, without including the ϕ.

Centrality (%)	T_{fo} [MeV]	β_T	$\langle\beta_T\rangle$	χ^2/NDF
0–10	$108.9^{+2.6}_{-2.4}$	$0.771^{+0.003}_{-0.004}$	$0.572^{+0.003}_{-0.003}$	148.0/46
10–40	$119.0^{+1.5}_{-1.5}$	$0.748^{+0.003}_{-0.003}$	$0.550^{+0.002}_{-0.002}$	212.1/46
40–92	150^{+2}_{-2}	$0.630^{+0.005}_{-0.005}$	$0.447^{+0.004}_{-0.004}$	150.9/46

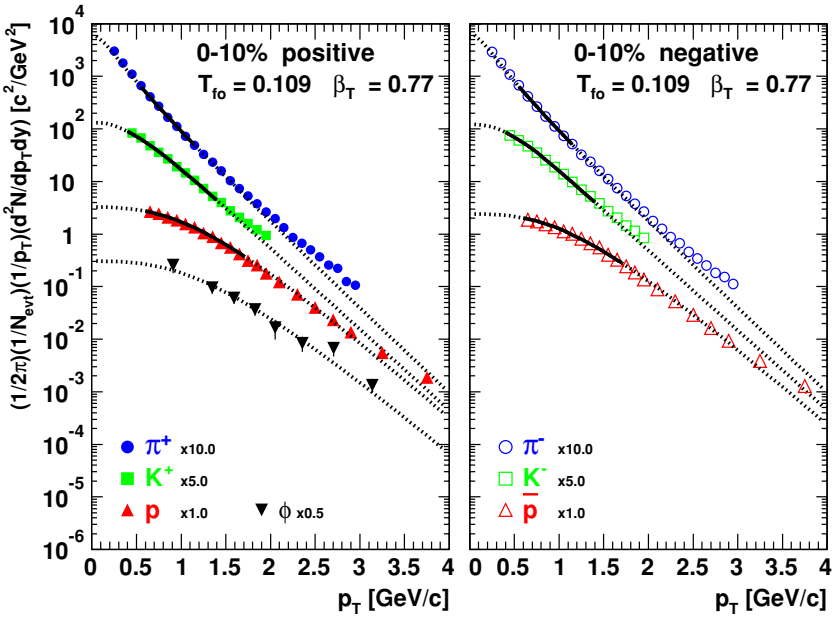

FIG. 19. (Color online) Transverse momentum data and best-fit hydrodynamical results for the 0–10% centrality bin for the 200-GeV $\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$, along with the prediction for the ϕ transverse momentum spectrum. The transverse momentum ranges for the fit are indicated by the solid lines; the dashed lines indicate the extrapolated predictions for each particle species.

E. Nuclear modification factor R_{CP} for ϕ mesons

One of the most important result demonstrated so far in the study of relativistic heavy ions at RHIC is the observed suppression of high-p_T pions in central collisions as compared to either pp collisions or peripheral Au+Au collisions [65]. A second, quite surprising observation is the unusually large (anti)proton-to-pion ratio at high p_T. In particular, PHENIX has observed [30] that in central Au+Au collisions the p/π and $\overline{p}/\pi$ ratios are enhanced by a factor of 3 at intermediate p_T ($1.5 < p_T < 4.5$ GeV/c) as compared to the ratios in pp collisions and the ratios obtained in quark and gluon jets measured in e^+e^- collisions [66]. It was also observed that proton and antiproton production scales with $N_{\rm coll}$ in this p_T region, in sharp contrast to the strong suppression of pion production [30]. In pp collisions high-p_T particles are the result of the fragmentation of partons. Because of the power-law nature of the hard-scattering spectrum, most of the particles at high p_T are expected to be leading hadrons. The fragmentation functions, at least in vacuum, are expected to be universal and independent of the colliding system under consideration. However, at intermediate p_T (1.5–4.5 GeV/c) the PHENIX results from central Au+Au collisions are inconsistent with the known fragmentation functions.

There are several conjectures that may explain the unexpected PHENIX result:

(1) hydrodynamic flow generated from the hadronic stage [67],

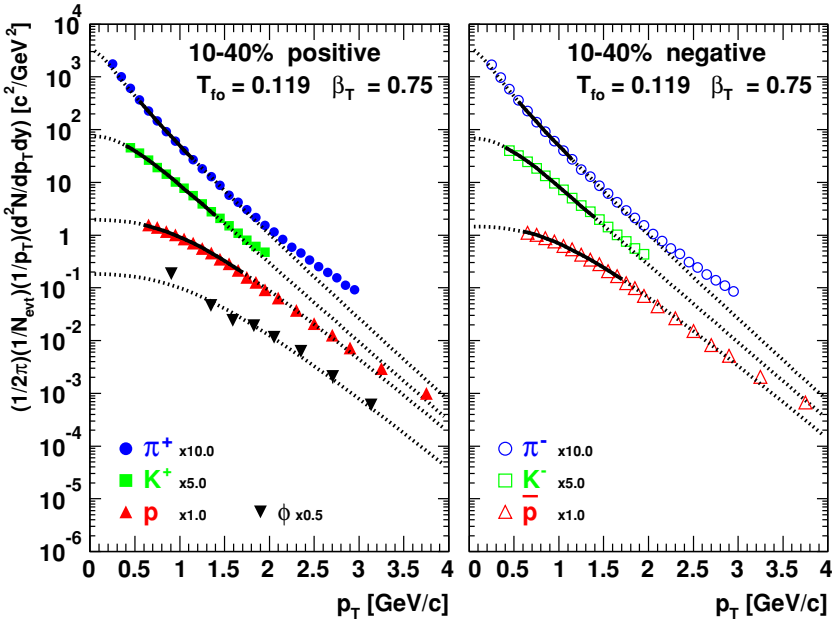

FIG. 20. (Color online) Transverse momentum data and best-fit hydrodynamical results for the 10–40% centrality bin for the 200-GeV $\pi^{\pm}$, $K^{\pm}$, and p, $\overline{p}$, along with the prediction for the ϕ transverse momentum spectrum.

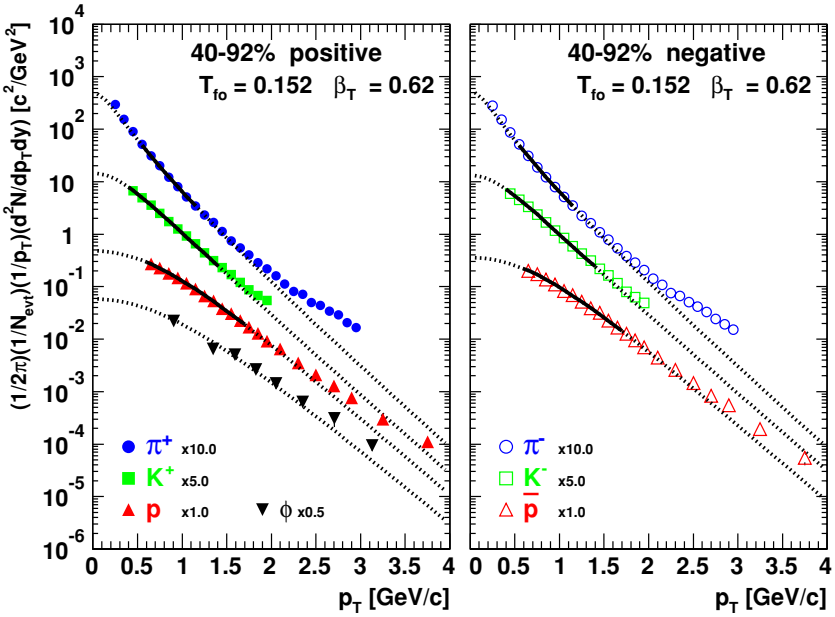

FIG. 21. (Color online) Transverse momentum data and best-fit hydrodynamical results for the 40–92% centrality bin for the 200-GeV $\pi^{\pm}$, $K^{\pm}$, and p, $\overline{p}$, along with the prediction for the ϕ transverse momentum spectrum.

(2) hydrodynamic flow generated at a partonic stage together with particle production from the recombination [32–34],
(3) baryon junctions as a mechanism for an usually large buildup of baryons and antibaryons at midrapidity [68], or
(4) in-medium modified fragmentation functions [69].

The first three possibilities invoke soft processes to populate a region of p_T that is dominated by hard scattering in pp collisions. The soft production at intermediate p_T is enhanced for protons and antiprotons, whereas pions remain dominated by hard scattering. In conjecture 4, the production for both pions and p, $\overline{p}$ is by hard scattering, but the fragmentation functions are modified in the medium, thus resulting in enhanced p/π and $\overline{p}/\pi$ ratios.

The second of these conjectures is particularly important since this hypothesis presupposes a partonic state with collective behavior. A critical factor that may differentiate among these scenarios is whether the large abundance of protons is due to its mass or to the number of constituent quarks [32–35]. Hydrodynamic flow generated at the hadronic stage imparts a single velocity to the moving matter; hence similar mass particles should exhibit the same momentum increase from this effect. In contrast, hypotheses 2 and 3 depend on whether the particles are baryons or mesons.

The ϕ meson which has a mass similar to that of a proton yet, like the pion, has two constituent quarks, should distinguish between conjecture 1 and 2 or 3. We examine the scaling properties of the intermediate-p_T yields of the ϕ and compare those to the yields of $(p + \overline{p})/2$. Figure 22 shows the transverse momentum spectra measured in three different centralities, each scaled down by the number of binary nucleon-nucleon collisions. The (anti)proton spectra show two pronounced features. Below $p_T < 1.5$ GeV/c, the spectral shapes are strongly influenced by the radial flow and thus the more central data have a harder slope. Above $p_T = 1.5$ GeV/c, the effect of radial flow is negligible. The spectra converge to the same line. Moreover, they scale with $N_{\rm coll}$ for all centrality classes, as expected for hardscattering unaffected by the nuclear medium. The ϕ spectra have a quite different behavior. There is no visible curvature at lower p_T. This could be because the ϕ spectra have only two (rather wide) bins below $p_T = 1.5$ GeV/c—the region where the curvature in the proton spectra is most pronounced. A curved functional form can be fit to the spectra with acceptable χ^2, as already discussed in Sec. IV D. At higher p_T the ϕ spectra run parallel to the (anti)proton spectra, but they do not obey $N_{\rm coll}$ scaling. To examine this feature on a linear scale, we plot the ratio between the central and peripheral data, that is, the ratio $R_{\rm CP}$

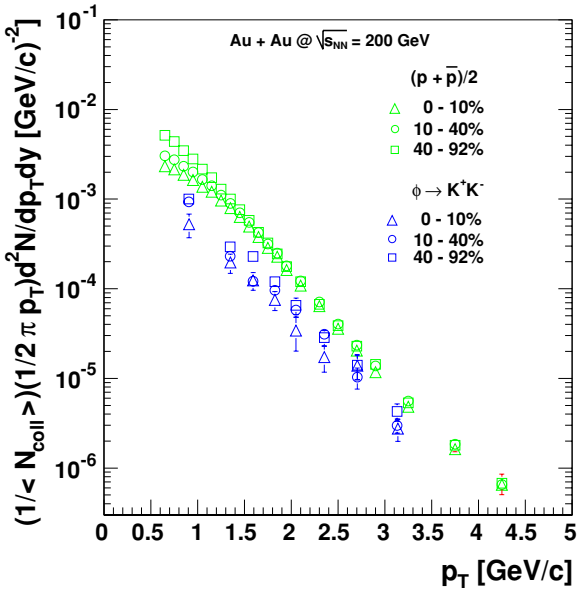

FIG. 22. (Color online) p_T spectra of protons and ϕ mesons at different centralities scaled down by their respective number of $N_{\rm coll}$.

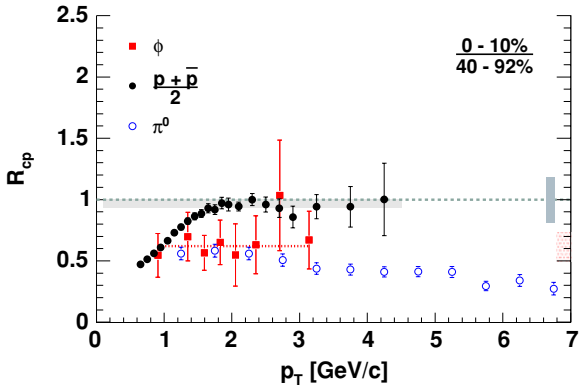

FIG. 23. (Color online) $N_{\rm coll}$ scaled central to peripheral ratio $R_{\rm CP}$ for $(p+\overline{p})/2$, π^0, and ϕ. The proton and pion results are published [30]. The vertical dotted bar on the right represents the error on $N_{\rm coll}^{0-10\%}/N_{\rm coll}^{40-92\%}$. The shaded solid bar around $R_{\rm CP}=1$ represents 12% systematic error, which can move the proton and/or ϕ points with respect to one another. The dotted horizontal line at $R_{\rm CP}=0.62$ is a straight-line fit to the ϕ data.

(Fig. 23). The systematic error arising from the determination of $N_{\rm coll}$ is about 19%. It is common for all three particle species shown in the figure, because the nuclear modification factors were obtained from the same centrality classes. The dotted horizontal line at $R_{\rm CP}=0.62$ is a straight-line fit to the ϕ data. To facilitate the comparison between the proton results and the ϕ including systematic errors, the $N_{\rm coll}$ error is plotted in two places: with a solid bar around $R_{\rm CP}=1$ and with a dotted bar around $R_{\rm CP}=0.62$. Since these errors are correlated, if the curves in the figure were to change owing to a change in the value of $N_{\rm coll}$, they will move together up or down within the extent of the error bars shown. We would like to emphasize the *comparison* between the $R_{\rm CP}$ values for the protons and the ϕ. In this comparison, the systematic errors in determining $N_{\rm coll}$ cancel. The important systematic errors to consider are those that can move the ϕ points with respect to the proton points. When determining a ratio of spectra measured at different centralities, most systematic errors cancel. After removing the $N_{\rm coll}$ error, the sources of error that remain for the ϕ come from the multiplicity-dependent corrections and the effect of the mass window as described previously. For the protons and pions [29,30], the error that remains that is independent of the error determined for the ϕ comes from the multiplicity-dependent corrections. The relative error between the ϕ and the proton measurements is evaluated at 7% and is represented by the extended solid bar just below $R_{\rm CP}=1$. Clearly, the ϕ's behavior is more like that of the pions and not like that of the protons. Thus we conclude that the ϕ meson exhibits a suppression effect at intermediate p_T similar to that of the pions. Although we cannot conclude whether ϕ production at this intermediate p_T is dominated by soft or hard processes, this observation provides support for models that depend on the number of constituent quarks in the particle as opposed to models that depend on just the mass of the particle to explain the anomalous proton yields. Other RHIC data on this subject are reviewed in Ref. [70].

V. CONCLUSIONS

A systematic measurement has been made of ϕ production at midrapidity in Au+Au collisions with $\sqrt{s_{NN}}=200$ GeV at RHIC. The general features of the data include the yield, which rises from 0.318 ± 0.028 (stat) $\pm$ 0.051 (syst) in peripheral collisions to 3.94 ± 0.60 (stat) $\pm$ 0.62 (syst) in central collisions. There is seen to be little centrality dependence to the inverse slope, which is about 360 MeV. The centroid mass and resonance width are extracted with high enough precision to rule out any large (MeV/c^2 scale) deviations from the accepted PDG values. At p_T below 1.5 GeV/c, a blast-wave analysis of the most central pion, kaon, and proton spectra with a freeze-out temperature $T_{\rm fo}$ of 109 MeV and a transverse velocity β_T of 0.77 describes the most central ϕ data as well. A similar conclusion, with monotonically changing results for $T_{\rm fo}$ and β_T, holds for the less central events. At higher transverse momenta, all particles lie above the blast-wave fits, which suggests that the dominant particle production mechanism is no longer soft physics but is giving way to the expected jet fragmentation. A study of the ratio $R_{\rm CP}$ of the ϕ provides a critical new piece of information in understanding the anomalous proton-to-pion ratio seen in central heavy ion collisions at RHIC, since the ϕ is a meson with a mass similar to that of a proton. The $R_{\rm CP}$ value for the ϕ above a transverse momentum of 1.5 GeV/c is about 0.6, similar to that of the pions but inconsistent with the proton value of 1. This indicates that the ϕ meson is being suppressed in this p_T range for the more central collisions. The lower p_T blast-wave fits imply hydrodynamic behavior at the hadronic stage, whereas the inconsistency with simple hydrodynamics at higher p_T is something one would expect in the jet fragmentation region. This transition is an important factor to consider as one begins to understand the mechanism of particle production in central collisions at RHIC.

APPENDIX A: COMBINATORIAL BACKGROUND

Assume there are N tracks per event of which n are positive and $N-n$ are negative, the probability of the partition being $P(n)$ such that $\sum_{n=0}^{N} P(n) = 1$.

All the following expressions refer to the average number of pairs per event

1. General relation between the number of like and unlike pairs

The total number of pairs is

$$N_{\text{pairs}} = \frac{N(N-1)}{2}. \tag{A1}$$

The number of $+-$ pairs is

$$n_{+-} = \sum_{n=0}^{N} n(N-n)P(n) = N\langle n\rangle - \langle n^2\rangle. \tag{A2}$$

The number of $++$ pairs is

$$n_{++} = \sum_{n=0}^{N} \frac{n(n-1)}{2} P(n) = \frac{\langle n^2\rangle - \langle n\rangle}{2}. \tag{A3}$$

The number of $--$ pairs is

$$n_{--} = \sum_{n=0}^{N} \frac{(N-n)(N-n-1)}{2} P(n) \tag{A4}$$

$$= \frac{N(N-1)}{2} - \left(N - \frac{1}{2}\right)\langle n\rangle + \langle n^2\rangle. \tag{A5}$$

We therefore get

$$n_{++} + n_{--} = \frac{N(N-1)}{2} - (N\langle n\rangle - \langle n^2\rangle). \tag{A6}$$

The last expression is trivial: The number of like-sign pairs is equal to the total number pairs minus the number of unlike-sign pairs.

The ratio R of unlike to like pairs is therefore

$$R = \frac{n_{+-}}{n_{++} + n_{--}} = \frac{N\langle n\rangle - \langle n^2\rangle}{N(N-1)/2 - (N\langle n\rangle - \langle n^2\rangle)}. \tag{A7}$$

This is a general result, free of any assumption, and should always be fulfilled, in pure combinatorial background as well as in a mixture of signal plus combinatorial background.

2. Combinatorial background

Consider a pure combinatorial background sample. By its essence there are *no correlations* between tracks in such a sample; that is, within an event the probability p to have a positive (or a negative) track is constant and independent of the number of tracks. Therefore the probability $P(n)$ of having n positive tracks out of the total of N tracks is given by a binomial distribution

$$P(n) = \frac{N!}{n!(N-n)!} p^n (1-p)^{N-n}, \tag{A8}$$

$$\langle n\rangle = pN, \tag{A9}$$

$$\langle n^2\rangle = \sigma^2 + \langle n\rangle^2 = Np(1-p) + p^2N^2. \tag{A10}$$

Replacing these values in expression (6) gives

$$R = \frac{(p-p^2)}{(1/2 - p + p^2)}. \tag{A11}$$

If there is charge symmetry (i.e., $p = 0.5$) one gets $R = 1$ and consequently the combinatorial background is given by

$$n_{+-}^{\text{CB}} = n_{++} + n_{--}. \tag{A12}$$

This is an exact relation. It holds with quite good accuracy even if there is some charge asymmetry. For example, for an asymmetry of 10% (i.e., $p = 0.525$), $R = 0.995$.

3. The formula $N_{+-}^{\text{CB}} = 2\sqrt{N_{++}N_{--}}$

The combinatorial background is rigorously given by this formula provided that the number N of tracks per event has a Poisson distribution:

$$\mathcal{P}(N) = \frac{\langle N\rangle^N e^{-N}}{N!}. \tag{A13}$$

Again we assume that the N tracks are divided into n positive and $N-n$ negative tracks, the partition is given by the binomial distribution (A7), and all expressions to follow refer to average number of pairs per event.

The number of $++$ pairs is

$$N_{++} = \sum_{N=2}^{\infty} \mathcal{P}(N) \sum_{n=0}^{N} P(n) \frac{n(n-1)}{2}. \tag{A14}$$

Using relations (A7) and (A11) and some algebra leads to

$$N_{++} = \tfrac{1}{2} p^2 \langle N\rangle^2. \tag{A15}$$

Similarly, the number of $--$ pairs is given by

$$N_{--} = \sum_{N=2}^{\infty} \mathcal{P}(N) \sum_{n=0}^{N} P(n) \frac{(N-n)(N-n-1)}{2} \tag{A16}$$

$$= \frac{1}{2}(1-p)^2 \langle N\rangle^2. \tag{A17}$$

TABLE VII. m_T spectra of ϕ mesons in different centrality bins. The systematic errors on invariant yields are from combinatorial background normalization, ϕ counting mass window, acceptance correction efficiencies from Monte Carlo and occupancy-dependent corrections.

Centrality (%)	m_T (GeV/c^2)	m_T Bin Size (GeV/c^2)	$\frac{1}{2\pi m_T}\frac{d^2N}{dm_T dy}$ [(GeV^2/c^4)$^{-2}$]	Stat. Error [(GeV^2/c^4)$^{-2}$]	Syst. Error [(GeV^2/c^4)$^{-2}$]

The number of combinatorial background $+-$ pairs is

$$N_{+-}^{\mathrm{CB}} = \sum_{N=2}^{\infty} \mathcal{P}(N) \sum_{n=0}^{N} P(n) n(N-n) \quad \text{(A18)}$$

$$= p(1-p)\langle N^2 \rangle. \quad \text{(A19)}$$

Inspecting (A15), (A16), and (A17) shows that

$$N_{+-}^{\mathrm{CB}} = 2\sqrt{N_{++}N_{--}}. \quad \text{(A20)}$$

APPENDIX B: DATA TABLES OF CENTRALITY-SELECTED ϕ SPECTRA

The invariant yields, $(\frac{1}{2\pi m_T})(\frac{d^2N}{dm_T dy})$, of the ϕ mesons in different centrality bins are shown in Table VII.

APPENDIX C: SYSTEMATIC ERRORS ON dN/dy, T, AND m_T- SPECTRA

The sources of the systematic errors on yield (dN/dy), T, and m_T- spectra measurements come from the following sources:

(a) Systematic error on the combinatorial background normalization δ_{norm}: This originates from the systematics of the event mixing. Since both same-event and mixed-event like-sign distributions represent pure combinatorials, we estimated unlike-sign combinatorial background by normalizing the mixed-event unlike-sign distributions to $2\sqrt{N_{++}^{\text{Same event}} N_{--}^{\text{Same event}}}$ and $2\sqrt{N_{++}^{\text{Mixed event}} N_{--}^{\text{Mixed event}}}$, and the difference in the extracted ϕ signal from the real data between these two normalizations are attributed to the systematic uncertainty.

TABLE VIII. Systematic error in dN/dy.

Centrality (%)	δ_{norm} (%)	δ_{mass} (%)	δ_{extrap} (%)	δ_{MC} (%)	δ_{occu} (%)	$\delta_{\mathrm{sys}}^{\mathrm{tot}}$ (%)
Minimum Bias	0.7	2.6	4.0	12.4	7.8	15
0–10	0.8	4.2	5.2	12.4	10	17
10–40	1.1	2.3	5.9	12.4	8.5	16
40–92	0.7	3.1	6.0	12.4	7	16

TABLE IX. Systematic error in T.

Centrality (%)	δ_{mass} (%)	δ_{fit} (%)	$\delta_{\mathrm{sys}}^{\mathrm{tot}}$ (%)
Minimum Bias	0.6	4.9	5
0–10	1.1	5.2	5
10–40	1.1	6.2	6
40–92	1.1	4.2	4

We use the same normalization factor for all m_T bins. So, these systematics are applicable to the measured dN/dy only and the absolute normalization of the m_T spectra, but they do not affect their shape and the inverse slope, T.

(b) Systematics of the ϕ mass window, δ_{mass}: We count the number of reconstructed ϕ mesons by integrating the ϕ meson invariant mass spectra within a ± 5 MeV mass window with respect to the measured centroids in both data and Monte Carlo. The systematic associated with this mass window is estimated by measuring the extent of the changes in dN/dy and T after constructing ϕ meson m_T spectra within five different mass windows (± 3, ± 5, ± 8, ± 10, and ± 15 MeV) with respect to the measured ϕ centroids.

(c) Uncertainties in extrapolation of ϕ meson m_T spectra to $m_T = m_\phi$, δ_{extrap}: This is studied by

(i) fitting the m_T distributions with two different fitting functions (exponential and Boltzmann functions) and

(ii) fitting the transverse mass spectra within different m_T ranges. These are applied to both dN/dy and T.

(d) Acceptance correction systematics, δ_{MC}: The systematics associated with acceptance correction factors derived from Monte Carlo analysis are investigated by considering two sources:

(i) tuning of detector alignments in Monte Carlo with reference to the real data ($\sim 3\%$) and

(ii) systematics in the fiducial geometries in data and Monte Carlo ($\sim 12\%$).

The systematic error from this source is independent of the momenta of reconstructed ϕ mesons. So, this is attributed to dN/dy and the absolute normalization of the m_T spectra.

(e) Systematic error in the occupancy-dependent efficiency corrections, δ_{occu}: The systematic error associated with this efficiency is estimated by calculating the occupancy-dependent correction with different track confirmation criteria and is independent of the pair momenta. This systematic effect was shown to be momentum independent and hence affects these normalization of spectra and dN/dy, but not the extracted slope parameters.

These systematic errors are quoted in Tables VIII and IX for dN/dy and T, respectively.

[59] The STAR experiment at RHIC has recently reported its analysis of the $\phi \to K^+K^-$ data for Au+Au at $\sqrt{s_{NN}} = 200$ GeV [71]. The analyses for PHENIX and STAR have one common centrality bin, 0–10%, for which the extracted dN/dy are not in agreement. The STAR value is $6.65 \pm 0.35\,(\mathrm{stat}) \pm 0.73\,(\mathrm{sys})$, compared with the PHENIX value $3.94 \pm 0.60\,(\mathrm{stat}) \pm 0.62\,(\mathrm{sys})$. The discrepancy persists even if one eliminates the four lowest m_T data points from the STAR data set to fit over the same m_T range for both the STAR and the PHENIX data. There is not a discrepancy between the quoted inverse slope parameters.

Abstract

Extensive experimental data from high-energy nucleus-nucleus collisions were recorded using the PHENIX detector at the Relativistic Heavy Ion Collider (RHIC). The comprehensive set of measurements from the first three years of RHIC operation includes charged particle multiplicities, transverse energy, yield ratios and spectra of identified hadrons in a wide range of transverse momenta (p_T), elliptic flow, two-particle correlations, nonstatistical fluctuations, and suppression of particle production at high p_T. The results are examined with an emphasis on implications for the formation of a new state of dense matter. We find that the state of matter created at RHIC cannot be described in terms of ordinary color neutral hadrons.

1. Introduction

1.1. Historical introduction

A recurring theme in the history of physics is the desire to study matter under extreme conditions. The latter half of the twentieth century saw this quest extended from "ordinary" atomic systems to those composed of nuclear matter. Even prior to the identification of quantum chromodynamics (QCD) as the underlying theory of the strong interaction, there was considerable interest in the fate of nuclear matter when subjected to density and temperature extremes [1–3]. Particularly intriguing was the suggestion that new phases of nuclear matter could be associated with a corresponding change in the structure of the vacuum [4]. These considerations gained additional impetus with the realizations that (a) QCD was the correct theory of the strong interaction, (b) the phenomena of quark confinement was a consequence of the nonperturbative structure of the vacuum and (c) this vacuum structure is modified at high temperatures and/or densities, suggesting that quarks and gluons under such conditions would be deconfined. Taken together, these facts suggest that QCD is a fundamental theory of nature containing a phase transition *that is accessible to experimental investigation*.

It is quite remarkable that this understanding was achieved very early in the development of QCD. Collins and Perry noted in 1975 [5] that the reduction of the coupling constant at small distances indicated that the dense nuclear matter at the center of neutron stars would consist of deconfined quarks and gluons.[1] Their treatment focused on the high-density, low-temperature regime of QCD, but they did note that similar arguments might apply to the high temperatures present in the early universe. An extensive review by Shuryak in 1980 [7] is the first to have examined the high-temperature phase in detail,

[1] In fact, prior to the development of QCD the quark hypothesis raised serious issues concerning the stability of neutron stars [6].

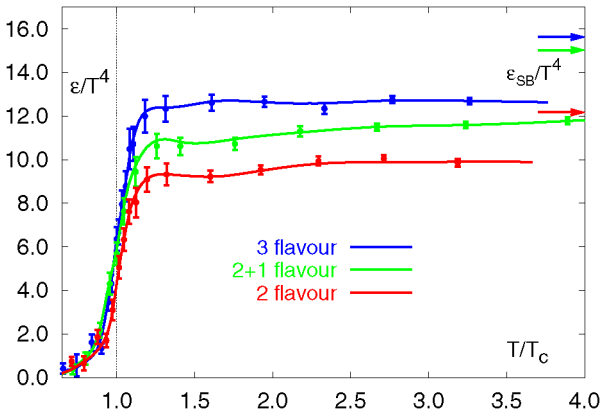

Fig. 1. Lattice QCD results [11] for the energy density/T^4 as a function of the temperature scaled by the critical temperature T_C. Note the arrows on the right side indicating the values for the Stefan–Boltzmann limit.

and is also notable for proposing the phrase "quark–gluon plasma" (QGP) to describe the deconfined state:

> When the *energy* density ε exceeds some typical hadronic value (~ 1 GeV/fm^3), matter no longer consists of separate hadrons (protons, neutrons, etc.), but as their fundamental constituents, quarks and gluons. Because of the apparent analogy with similar phenomena in atomic physics we may call this phase of matter the QCD (or quark–gluon) plasma.

Developing a quantitative understanding of the deconfining phase transition in hadronic matter and of QGP properties has proven to be a challenging task. While simple dimensional arguments suffice to identify both the critical energy density $\varepsilon_C \sim 1$ GeV/fm^3 and the associated critical temperature $T_C \sim 170$ MeV, these values also imply that the transition occurs in a regime where the coupling constant is of order unity, thereby making perturbative descriptions highly suspect.

Progress in understanding QCD in the extremely nonperturbative domain near the critical temperature has relied on an essential contribution by Creutz [8], who showed that numerical implementations of Wilson's lattice formulation [9] could be used to study phase transition phenomena. This work, together with the continued exponential increases in computing power, stimulated the development of lattice QCD, which in turn has led to detailed investigations of the thermodynamic properties of quarks and gluons [10].

Lattice QCD predicts a phase transformation to a quark–gluon plasma at a temperature of approximately $T \approx 170$ MeV $\approx 10^{12}$ K, as shown in Fig. 1 [11]. This transition temperature corresponds to an energy density $\varepsilon \approx 1$ GeV/fm^3, nearly an order of magnitude larger than that of normal nuclear matter. As noted above, this value is plausible based on dimensional grounds, since such densities correspond to the total overlap of several (light) hadrons within a typical hadron volume of 1–3 fm^3. No plausible mechanism exists under

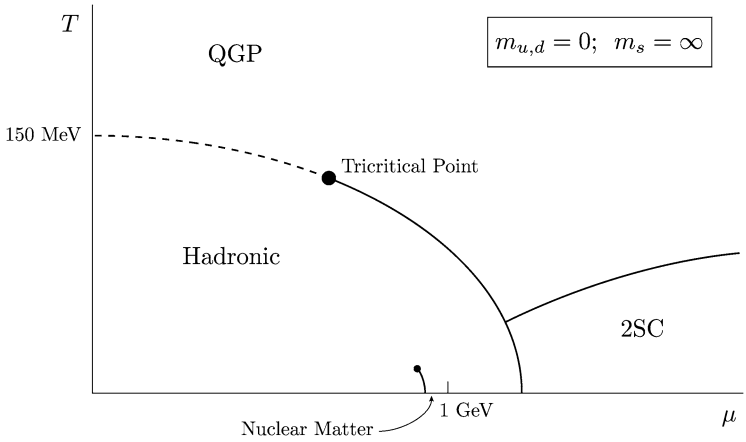

Fig. 2. Theoretical phase diagram of nuclear matter for two massless quarks as a function of temperature T and baryon chemical potential μ [12].

which hadrons could retain their *in vacuo* properties under these conditions. Lattice calculations also indicate that this significant change in the behavior of the system occurs over a small range in temperature (~ 20 MeV), and suggest that the change of phase includes the restoration of approximate chiral symmetry resulting from greatly reduced or vanishing quark constituent masses.

In the limit of massless noninteracting particles, each bosonic degree of freedom contributes $\frac{\pi^2}{30}T^4$ to the energy density; each fermionic degree of freedom contributes $\frac{7}{8}$ this value. The corresponding "Stefan–Boltzmann" limits of the energy density $\varepsilon_{\mathrm{SB}}$ for the case of 2(3) active flavor quark–gluon plasma is then

$$\varepsilon_{\mathrm{SB}} = \begin{cases} \left\{2_f \cdot 2_s \cdot 2_q \cdot 3_c \frac{7}{8} + 2_s \cdot 8_c\right\} \frac{\pi^2}{30} T^4 = 37 \frac{\pi^2}{30} T^4, & (1) \\ \left\{3_f \cdot 2_s \cdot 2_q \cdot 3_c \frac{7}{8} + 2_s \cdot 8_c\right\} \frac{\pi^2}{30} T^4 = 47.5 \frac{\pi^2}{30} T^4 & (2) \end{cases}$$

after summing over the appropriate flavor, spin, quark/antiquark and color factors for quarks and spin times color factors for gluons. The large numerical coefficients (37 and 47.5) stand in stark contrast to the value of ~ 3 expected for a hadron gas with temperature $T < T_C$, in which case the degrees of freedom are dominated by the three pion species π^-, π^0, π^+.

The exact order of this phase transition is not known. In a pure gauge theory containing only gluons the transition appears to be first order. However, inclusion of two light quarks (up and down) or three light quarks (adding the strange quark) can change the transition from first order to second order to a smooth crossover. These results are obtained at zero net baryon density; dramatic changes in the nature of the transition and in the medium itself are expected when the net baryon density becomes significant. A schematic version of the phase diagram for an idealized form of nuclear matter with vanishing light quark (up and down) masses and infinite strange quark mass is presented in Fig. 2 [12]. For sufficiently large values of the baryon chemical potential μ this system exhibits a first order phase transition between hadronic matter and QGP, along with a tricritical point below which

the transition becomes second order. However, nonzero values of the light quark masses dramatically alter this simple picture: the second order phase transition denoted by the dashed line in Fig. 2 becomes a smooth crossover, and the tricritical point correspondingly becomes a critical point designating the end of the first order transition found at higher values of μ. For example, recent calculations [13,14] indicate that the transition is a crossover for values of $\mu \lesssim 400$ MeV. Given that both theoretical arguments and experimental data suggest that nucleus–nucleus collisions at RHIC (at least near mid-rapidity) are characterized by low net baryon density, we will restrict our attention to this regime, while noting that the predicted smooth nature of the transition in this region increases the experimental challenges of unambiguously establishing that such a transition has occurred. We also note that while Fig. 2 shows that the region of low temperature and high baryon density is expected to show a transition to a color superconducting phase of matter, this regime is not accessible to RHIC collisions and will not be discussed further.

While the lattice results plotted in Fig. 1 show that the energy density reaches a significant fraction (~ 0.8) of the Stefan–Boltzmann values in the deconfined phase, the deviation from $\varepsilon_{\mathrm{SB}}$, and the reason for the persistence of that deviation to the highest studied values of T/T_C, are of great interest. For instance, Greiner has noted [15] that "in order to allow for simple calculations the QGP is usually described as a free gas consisting of quarks and gluons. This is theoretically not well founded at $T \approx T_C$". In fact, analysis of the gluon propagator in a thermal system [16,17] has demonstrated that effective masses of order $g(T)T$ are generated, suggesting that the relevant degrees of freedom are in fact massive near T_C. $m_g \approx T_C$ could be generated by gluons. Especially interesting is recent work which indicates that both heavy [18–20] and light [21] flavor states may remain bound above T_C, calling into question the naive interpretation of $\varepsilon(T)$ as an indicator of the explicit appearance of quark and gluon degrees of freedom. This is supported by explicit calculations of the spectrum of bound states above T_C [22] which predict a rich structure of states that belies a description as a weakly interacting parton gas.

To emphasize this point, consider the standard measure of the degree of coupling in a classical plasma, obtained by comparing the relative magnitudes of the average kinetic and potential energies:

$$\Gamma \equiv \frac{\langle V(r)\rangle}{\langle E_{\mathrm{kin}}\rangle}. \tag{3}$$

In the case of the QCD plasma the mean inter-particle spacing should scale as some numerical coefficient times $1/T$. Naively, this gives a mean potential energy $\langle V(r)\rangle \sim \alpha_s(T)\langle 1/r\rangle \sim \alpha_s(T)T$, leading to

$$\Gamma \sim \frac{\alpha_s(T)T}{3T} \sim \alpha_s(T). \tag{4}$$

Any reasonable estimate for the numerical coefficients leads to $\Gamma > 1$, which is the condition for a "strongly-coupled" plasma. In reality, the screening present at such densities (or equivalently, the generation of effective gluon masses) modifies the mean potential energy to $\langle V(r)\rangle \sim g(T)T$, which only increases the estimated value of Γ [23].[2] Considerations

[2] We wish to acknowledge B. Müller for this observation.

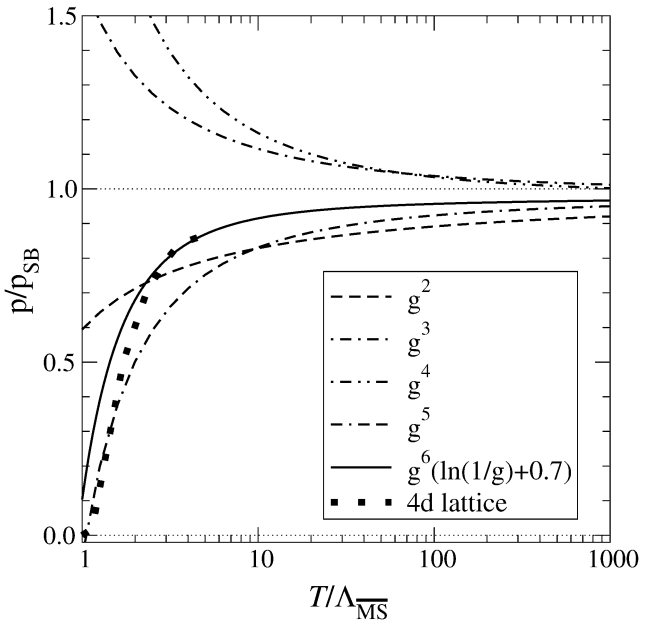

Fig. 3. Perturbative QCD results for the pressure as a function of temperature at various orders normalized to the Stefan–Boltzmann value p_{SB} [29].

such as these have led some authors [24,25] to denote quark–gluon plasma in this regime as "sQGP" for "strongly interacting QGP".

It is worth noting that this state of affairs has been anticipated by many authors. Whether the argument was based on the divergence of perturbative expansions [26], on phenomenological descriptions of confinement [27], on the development of effective gluon masses from plasmon modes [28] or on general principles [15], it is clear that the QGP near T_C should not be regarded as an ideal gas of quarks and gluons.

How high a temperature is needed not just to form a quark–gluon plasma, but to approach this "weakly" interacting plasma? A calculation of the pressure of hot matter within perturbative QCD [29] is shown in Fig. 3. The pressure result oscillates significantly as one considers contributions of different orders. These oscillations are an indication that the expansion is not yielding reliable results. However at temperatures approaching 1000 times of T_C ($\approx \Lambda_{\overline{\mathrm{MS}}}$), they appear to be converging toward the Stefan–Boltzmann limit (asymptotically free partons). It is interesting that in considering the highest-order term, the results are still nonconvergent though one seems to approach the lattice calculated pressure. Unlike the case of single parton–parton scattering at zero temperature, the infrared problems of finite-temperature field theory prevent further analytic progress even for very small values of the coupling constant [29–31].

The goal of relativistic heavy ion physics is the experimental study of the nature of QCD matter under conditions of extreme temperature. A great emphasis has been placed on "the discovery of the quark–gluon plasma", where the terminology "quark–gluon plasma" is used as a generic descriptor for a system in which the degrees of freedom are no

longer the color neutral hadron states observed as isolated particles and resonances. This definition is limited since high-energy proton–proton reactions cannot be described purely in terms of color-neutral hadrons, but rather require analysis of the underlying partonic interactions. The hoped-for essential difference in heavy ion collisions is the dominance of the partonic-level description for essentially all momentum scales and over nuclear size distances. Beyond this simple criterion, in order to characterize the produced system as a state of matter it is necessary to establish that these nonhadronic degrees of freedom form a statistical ensemble, so that concepts such as temperature, chemical potential and flow velocity apply and the system can be characterized by an experimentally determined equation of state. Additionally, experiments eventually should be able to determine the physical characteristics of the transition, for example the critical temperature, the order of the phase transition, and the speed of sound along with the nature of the underlying quasi-particles. While at (currently unobtainable) very high temperatures $T \gg T_C$ the quark–gluon plasma may act as a weakly interacting gas of quarks and gluons, in the transition region near T_C the fundamental degrees of freedom may be considerably more complex. It is therefore appropriate to argue that the quark–gluon plasma must be defined in terms of its unique properties *at a given temperature*. To date the definition is provided by lattice QCD calculations. Ultimately we would expect to validate this by characterizing the quark–gluon plasma in terms of its experimentally observed properties. However, the real discoveries will be of the fascinating properties of high temperature nuclear matter, and not the naming of that matter.

1.2. Experimental program

The theoretical discussion of the nature of hadronic matter at extreme densities has been greatly stimulated by the realization that such conditions could be studied via relativistic heavy ion collisions [32]. Early investigations at the Berkeley Bevalac (c. 1975–1985), the BNL AGS (c. 1987–1995) and the CERN SPS (c. 1987–present) have reached their culmination with the commissioning of BNL's Relativistic Heavy Ion Collider (RHIC), a dedicated facility for the study of nuclear collisions at ultra-relativistic energies [33].

The primary goal of RHIC is the experimental study of the QCD phase transition. The 2002 Long-Range Plan for Nuclear Science [34] clearly enunciates this objective:

> ...the completion of RHIC at Brookhaven has ushered in a new era. Studies are now possible of the most basic interactions predicted by QCD in bulk nuclear matter at temperatures and densities great enough to excite the expected phase transition to a quark–gluon plasma. As the RHIC program matures, experiments will provide a unique window into the hot QCD vacuum, with opportunities for fundamental advances in the understanding of quark confinement, chiral symmetry breaking, and, very possibly, new and unexpected phenomena in the realm of nuclear matter at the highest densities.

The RHIC accelerator and its four experiments were commissioned and brought online in the summer of 2000. The initial operation of both RHIC and the experiments has been remarkably successful. In these first three years the accelerator has collided, and the experiments have acquired data on, Au + Au collisions at five energies, an essential $p + p$

baseline data set, and a critical $d + \mathrm{Au}$ comparison. The analyses of these various systems have resulted in a correspondingly rich abundance of results, with over 90 publications in the refereed literature.

It is therefore appropriate to reflect on the physics accomplishments to date, with a particular emphasis on their implications for the discovery of a new state of matter. At the same time, it is essential to identify those features of the data (if any) that are at odds with canonical descriptions of the produced matter, to specify those crucial measurements which remain to be made, and to outline a program for continued exploration and characterization of strongly interacting matter at RHIC. The PHENIX Collaboration [35] has performed such an assessment; this document represents a summary of its findings.

The PHENIX Conceptual Design Report [36], submitted to BNL/RHIC management on January 29th, 1993, outlined a comprehensive physics program focused on the search for and characterization of new states of nuclear matter. The measurement of electromagnetic probes and high-transverse-momentum phenomena formed a major thrust of the proposed program. It was also realized that the measurement of global variables and soft identified hadron spectra in the same apparatus was essential to the goal of understanding the evolution of the produced matter over all relevant timescales. These diverse criteria required combining an unprecedented number of subsystems together with a high-bandwidth trigger and data-acquisition system into an integrated detector design. Particular attention was given to minimizing the conflicting design criteria of the central arm spectrometers, with their requirement for minimal mass in the aperture, and those of the muon spectrometers which require maximal absorption of the incident hadron flux. The data acquisition and trigger system was designed to accommodate the great variety of interaction rates and event sizes provided by RHIC. Every effort was made to provide for future upgrades, both in the geometry of the experiment and in the architecture and design parameters of the read-out system.

The published PHENIX results of $\mathrm{Au} + \mathrm{Au}$ collision at a center-of-mass energy per nucleon pair, $\sqrt{s_{NN}}$, of 130 GeV [37–48] and at $\sqrt{s_{NN}} = 200$ GeV [49–59], $p + p$ collisions at $\sqrt{s} = 200$ GeV [60–63], and $d + \mathrm{Au}$ at $\sqrt{s_{NN}} = 200$ GeV [64,65] clearly demonstrate that PHENIX's goal to make high-quality measurements in both hadronic and leptonic channels for collisions ranging from $p + p$ to $\mathrm{Au} + \mathrm{Au}$ has been realized. A summary of these results illustrates this point.

- First measurement of the dependence of the charged particle pseudo-rapidity density [37] and the transverse energy [38] on the number of participants in $\mathrm{Au} + \mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 130$ GeV; systematic study of the centrality and $\sqrt{s_{NN}}$ dependence of $dE_T/d\eta$ and $dN_{\mathrm{ch}}/d\eta$ [59].
- Discovery of suppressed production for π^0's and charged particles at high p_T in $\mathrm{Au} + \mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 130$ GeV [39] and a systematic study of the scaling properties of the suppression [47]; extension of these results to much higher transverse momenta in $\mathrm{Au} + \mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV [49,53].
- Co-discovery (together with BRAHMS [66], PHOBOS [67] and STAR [68]) of absence of high-p_T suppression in $d + \mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV [64].
- Discovery of the anomalously large proton and antiproton yields at intermediate transverse momentum in $\mathrm{Au} + \mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 130$ GeV through the system-

atic study of $\pi^{\pm}$, $K^{\pm}$, p and $\bar{p}$ spectra [40]; study of the scaling properties of the proton and antiproton yields in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [52];

- Measurement of Λ's and $\bar{\Lambda}$'s in Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV [43]; measurement of ϕ's at $\sqrt{s_{NN}} = 200$ GeV [69]; measurement of deuteron and antideuteron spectra at $\sqrt{s_{NN}} = 200$ GeV [58].
- Measurement of Hanbury–Brown–Twiss (HBT) correlations in $\pi^+\pi^+$ and $\pi^-\pi^-$ pairs in Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV [41] and 200 GeV [56], establishing that the "HBT puzzle" of $R_{\text{out}} \approx R_{\text{side}}$ extends to high pair momentum.
- First measurement of single electron spectra in Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV, suggesting that charm production scales with the number of binary collisions [42]; measurement of centrality dependence of charm production in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [57].
- Sensitive measures of charge fluctuations [44] and fluctuations in mean p_T and transverse energy per particle [45,55] in Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV and 200 GeV.
- Measurements of elliptic flow for charged particles from Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV [46] and 62 GeV to 200 GeV [70] and identified charged hadrons from Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [50].
- Extensive study of hydrodynamic flow, particle yields, ratios and spectra from Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV [48] and 200 GeV [54].
- First observation of J/ψ production in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [51].
- Measurement of the nuclear modification factor for hadrons at forward and backward rapidities in d + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [65].
- First measurement of the jet structure of baryon excess in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [71].
- First measurement of elliptic flow of single electrons from charm decay in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [72].
- First measurement of direct photons in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [73].
- Measurement of crucial baseline data on π^0 spectra [60], direct photon production [63], and J/ψ production [61] in $p + p$ collisions at $\sqrt{s} = 200$ GeV.
- First measurement of the double longitudinal spin asymmetry A_{LL} in π^0 production for polarized $p + p$ collisions at $\sqrt{s} = 200$ GeV [62].

These publications encompass physics from the barn to the picobarn level; their very breadth precludes a detailed presentation here. These data, together with a rich program of future RHIC measurements, will allow us to address many of the features that would characterize a quark–gluon plasma:

- temperature;
- parton number density;
- energy density;
- opacity;
- collective behavior;
- thermalization leading to the quark–gluon phase;
- deconfinement;
- number and nature of degrees of freedom;

- recombination of quarks and gluons to form final-state hadrons;
- chiral symmetry restoration;
- time evolution of system parameters;
- equation of state;
- color and thermal transport properties;
- critical behavior.

As emphasized above, the present PHENIX data set from RHIC runs in year 2000 to 2003 already provides an extensive set of measurements on global variables: (transverse energy and multiplicity, elliptic flow); correlations and fluctuations: (fluctuations in charge and $\langle p_T \rangle$, HBT measurements), hadron spectra: (low-p_T single-hadron spectra and radial flow, particle ratios, resonances, anomalous p/π ratio at intermediate p_T); high-p_T physics: (high-p_T singles spectra, suppression phenomena in $A + A$, nonsuppression in $d + A$, high-p_T two-particle correlations, nuclear suppression/enhancement in forward/backward directions), heavy flavor production: (charm, J/ψ), and electromagnetic probes: (direct photons). However, an important conclusion of this report is that systematic studies of these observables (vs. collision species and energy) are needed to extract unambiguous information on most of these features.

1.3. Organization of this document

As a result, this paper concentrates on those aspects of the present data that address the broad features of energy density, thermalization, deconfinement and critical behavior. The focus in most cases will be on the data of the PHENIX experiment, but the data of the other RHIC experiments will be cited to support and to extend the discussion.[3] The experimental tools that allow the systematic study of all phenomena as a function of the inferred impact parameter are presented in the context of hard-scattering phenomena. These methods and the associated data are then used to discuss the experimental evidence for the formation of a state of high-density matter. The measured abundances, spectra and flow patterns are used to analyze the degree of thermalization and collectivity in the produced matter. These results are then examined for evidence establishing the role of deconfined quarks and gluons in the produced system, along with the implications for its description as a quark–gluon plasma. A concluding section summarizes the findings and identifies key future measurements required to further refine our observations.

2. Energy density and E_T, N_{ch}

A prerequisite for creating a quark–gluon plasma is producing a system with sufficiently large energy density. From both elementary estimates [22] and from extensive numerical studies in lattice QCD [10,11], the required density is known to be on the order of

[3] An underappreciated aspect of the RHIC program is the excellent agreement between the various experiments in almost all measured channels.

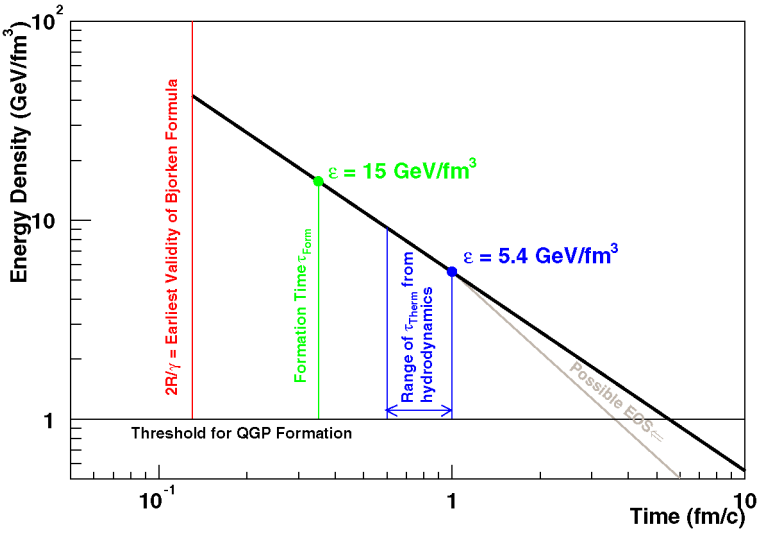

Fig. 4. Schematic drawing of the time and energy density scales derived through the Bjorken picture.

1 GeV/fm^3. Establishing that this energy density is created in RHIC collisions is a basic ingredient in establishing the creation of a QGP at RHIC.

In this section we explore what can be deduced about the energy densities achieved in RHIC $A + A$ collisions from measurements of the global transverse energy and multiplicity. In later sections these estimates will be compared to densities inferred from hydrodynamics-based models (Section 3) and from jet quenching evidence (Section 6).

Specifically, we will address three different energy density estimates, and introduce two distinct time scales: (i) The peak *general energy density* that is achieved when the incoming nuclei overlap; (ii) The peak *formed energy density* involving created particles at proper time τ_{Form}; and (iii) The peak *thermalized energy density* present at proper time τ_{Therm} when local thermal equilibrium is first achieved (assuming that this occurs). The values and time scales for formed and thermalized energy densities are indicated schematically in Fig. 4; detailed explanations follow in Sections 2.3 and 2.4.

In this section we will also review data on overall particle multiplicities, and through them distinguish between different models of the initial particle production.

2.1. General energy density

The simplest definition of "energy density" is the total mass-energy within some region of space divided by the volume of that region, as seen at some instant of time in some Lorentz frame. However, this definition is not satisfactory since we can "trivially" raise any simple energy density by viewing the system in a different frame. For example, a static system with constant energy density ρ_0 in its rest frame—say, a gold nucleus—will appear to have energy density $\gamma^2\rho_0$ when viewed in a frame boosted by Lorentz γ. Accordingly, we can only calculate a *meaningful* energy density $\langle\varepsilon\rangle$ as mass-energy/volume for some region *in the case* when the total momentum in the region is zero.

Now let us imagine a symmetric RHIC $A + A$ collision at a moment when the two original nuclei are overlapping in space, as seen in the laboratory/center-of-mass frame. The total momentum in any overlap region is zero by symmetry, so we can calculate a meaningful—if short-lived—energy density for such a region. If each nucleus has energy density ρ_0 in its rest frame then the total energy density in the overlap region is just $\langle\varepsilon\rangle = 2\rho_0\gamma^2$. If we take a nominal $\rho_0 = 0.14$ GeV/fm^3 for a nucleus at rest and $\gamma = 106$ for a full-energy RHIC collision, then the result for the peak general energy density is $\langle\varepsilon\rangle = 3150$ GeV/fm^3. This is a spectacularly, almost absurdly high number on the scale of ~ 1 GeV/fm^3 associated with the familiar transition described by lattice QCD.

This energy density is of course artificial, in that it would be temporarily present even in the case of no interactions between the two nuclei. It is instructive to consider the (again artificial) case where the nucleons in the two nuclei have only elastic interactions. Then the time during which a high energy density is present over *any* volume cannot last longer than $t = 2R/\gamma$, where R is the rest-frame radius of the nucleus. With $R = 7$ fm for Au this time is only 0.13 fm/c at RHIC, and after this time all energy densities will fall precipitously back to ρ_0 if no secondary particles are created. The scale of this interval is so short that a scattering cannot even be said to have occurred within that volume unless its momentum transfer scale Q exceeds at least 1.5 GeV/c, or more. Accordingly, we will turn our attention instead to energy densities involving only produced particles as the potential source for a QCD transition.

2.2. *Formed energy density*

In any frame (not just the center-of-mass frame) where the two incoming nuclei have very high energies the region when/where the nuclei overlap will be very thin in the longitudinal direction and very short in duration. In this limit, then, it is fair to describe all secondary produced particles as having been radiated out from a very thin "disk", and that they are all created at essentially the same time. These realizations lead directly to the picture described by Bjorken [74], whose original diagram is reproduced in Fig. 5 and whose derivation we retrace briefly here.

Once the beam "pancakes" recede after their initial overlap, the region between them is occupied by secondaries at intermediate rapidities. We can calculate the local energy density of these created particles if we make one further assumption: that the secondaries can be considered "formed" at some proper time τ_{Form} after they are radiated out from the thin source disk.

Our region of interest, in any frame, will be a slab perpendicular to the beam direction, with longitudinal thickness dz, with one face on the "source" plane in this frame, and transverse extent with area A covering the nuclear overlap region.[4] At time $t = \tau_{\text{Form}}$ this volume will contain all the (now-formed) particles with longitudinal velocities $0 \leqslant \beta_\parallel \leqslant dz/\tau_{\text{Form}}$ (since we assume that the particles cannot scatter before they are formed!). We can then write this number of particles as $dN = (dz/\tau_{\text{Form}})\frac{dN}{d\beta_\parallel}$, or equivalently $dN =$

[4] The region described here corresponds to half the shaded region shown in Fig. 5. Since $\beta_\parallel \simeq 0$ for particles near the source location, this is an appropriate region over which we can calculate a meaningful energy density.

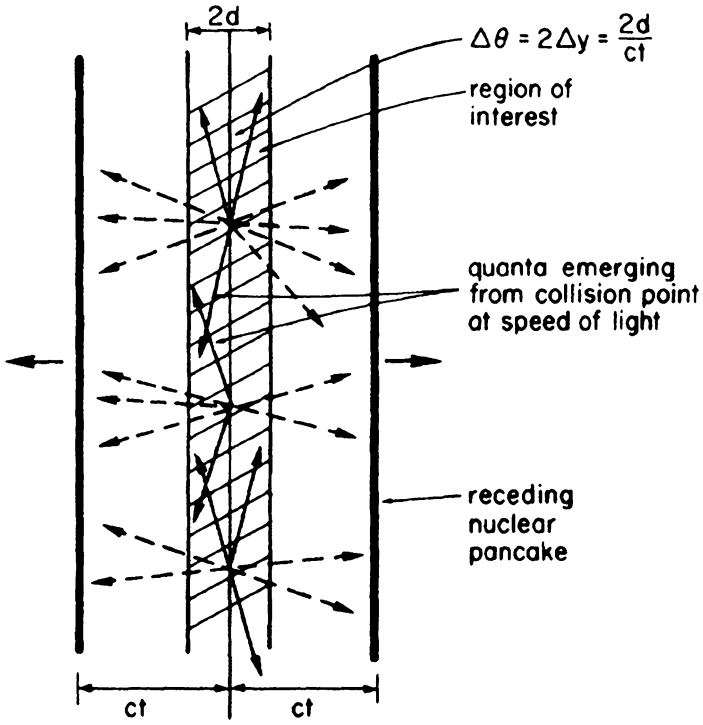

Fig. 5. Figure from Bjorken [74] illustrating the geometry of initially produced particles at a time t after the overlap of the incoming nuclei in some frame. The picture is valid in any frame in which the incoming nuclei have very high energies and so are highly Lorentz contracted.

$(dz/\tau_{\rm Form})\frac{dN}{dy}$, where y is longitudinal rapidity, since $dy = d\beta_\parallel$ at $y = \beta_\parallel = 0$. If these particles have an average total energy $\langle m_T\rangle$ in this frame ($E = m_T$ for particles with no longitudinal velocity), then the total energy divided by the total volume of the slab at $t = \tau_{\rm Form}$ is just

$$\left\langle \varepsilon(\tau_{\rm Form})\right\rangle = \frac{dN\langle m_T\rangle}{dz\,A} = \frac{dN(\tau_{\rm Form})}{dy}\frac{\langle m_T\rangle}{\tau_{\rm Form}A} = \frac{1}{\tau_{\rm Form}A}\frac{dE_T(\tau_{\rm Form})}{dy}, \tag{5}$$

where we have equated $\frac{dE_T}{dy} = \langle m_T\rangle\frac{dN}{dy}$ and emphasized that Eq. (5) is true for the transverse energy density present at time $t = \tau_{\rm Form}$.

Eq. (5) here is essentially identical[5] to Eq. (4) of Bjorken's result [74], and so is usually referred to as the *Bjorken energy density* $\varepsilon_{\rm Bj}$. It should be valid as a measure of peak energy density in created particles, on very general grounds and in all frames, as long as two conditions are satisfied: (1) A finite formation time $\tau_{\rm Form}$ can meaningfully be defined for the created secondaries; and (2) The thickness/"crossing time" of the source disk is small compared to $\tau_{\rm Form}$, that is, $\tau_{\rm Form} \gg 2R/\gamma$. In particular, the validity of Eq. (5) is completely independent of the shape of the $dE_T(\tau_{\rm Form})/dy$ distribution to the extent that

[5] A (well-known) factor of 2 error appears in the original.

$\beta_\parallel$ is infinitesimally small in a comoving frame; a plateau in dE_T/dy is *not* required. For present practical purposes, we will consider condition (2) above to be satisfied as long as $\tau_{\rm Form} > 2R/\gamma$ is true, corresponding to $\tau_{\rm Form} > 0.13$ fm/c for full-energy Au + Au collisions at RHIC.

Bjorken's original motivation was to estimate, in advance of data, the energy densities that would be reached in high-energy $A + A$ collisions using knowledge of $p(\bar{p}) + p$ collisions to estimate $\langle m_T \rangle$ and dN/dy, and choosing $\tau_{\rm Form} \sim 1$ fm/c without any particular justification other than as an order-of-magnitude estimate. With $A + A$ collision data in hand, attempts have been made to use Eq. (5) to estimate the energy densities that are actually achieved in the collisions. Historically, $\varepsilon_{\rm Bj}$ has been calculated using the final-state dE_T/dy and simply inserting a nominal value of 1 fm/c for $\tau_{\rm Form}$. In addition, fixed target experiments have been using $dE_T/d\eta$ as an estimate for dE_T/dy, which is a good approximation for these experiments; at RHIC a correction is made for the Jacobian $dy/d\eta$ which is important for a collider geometry. These "nominal Bjorken energy density" estimates, which we term $\varepsilon_{\rm Bj}^{\rm Nominal}$, range for central event samples from about 1.5 GeV/fm^3 in Au + Au collisions at AGS energies [75] ($\sqrt{s_{NN}} = 5$ GeV), to about 2.9 GeV/fm^3 in Pb + Pb collisions at SPS energies [38,76] ($\sqrt{s_{NN}} = 17$ GeV; and see also [59]) to about 5.4 GeV/fm^3 in Au + Au collisions at full RHIC energy [59] ($\sqrt{s_{NN}} = 200$ GeV).

It has often been noted that all of these values are similar to, or higher than, the 1 GeV/fm^3 scale required for the QCD transition. However, we cannot take these $\varepsilon_{\rm Bj}^{\rm Nominal}$ estimates seriously as produced energy densities without some justification for the value of 1 fm/c taken for $\tau_{\rm Form}$. An indication of potential problems with this choice arises immediately when considering AGS Au+Au and SPS Pb+Pb collisions, where the center-of-mass "crossing times" $2R/\gamma$ are 5.3 fm/c and 1.6 fm/c respectively, which implies that this choice for $\tau_{\rm Form} = 1$ fm/c actually violates the validity condition $\tau_{\rm Form} > 2R/\gamma$ we set for the use of Eq. (5). So we will deprecate the use of $\varepsilon_{\rm Bj}^{\rm Nominal}$ as an quantitative estimate of actual produced energy density, and instead treat it only as a compact way of comparing $dE_T/d\eta$ measurements across different systems, centralities and beam energies.

2.3. *Realistic $\tau_{\rm Form}$ and $\varepsilon_{\rm Bj}$ estimates*

Can we justify a better estimate for $\tau_{\rm Form}$? We might say, on general quantum mechanical grounds, that in a frame where its motion is entirely transverse a particle of energy m_T can be considered to have "formed" after a time $t = \hbar/m_T$ since its creation in that frame. To estimate the average transverse mass, we can use the final-state $dE_T/d\eta$ to estimate $dE_T(\tau_{\rm Form})/dy$ and, correspondingly, use the final-state $dN/d\eta$ as an estimate for $dN(\tau_{\rm Form})/dy$ to obtain

$$\langle m_T \rangle = \frac{dE_T(\tau_{\rm Form})/dy}{dN(\tau_{\rm Form})/dy} \simeq \frac{dE_T/d\eta}{dN/d\eta} \quad \text{(Final state)}. \tag{6}$$

PHENIX has measured the ratio of final-state transverse-energy density to charged-particle density, each per unit pseudorapidity, and the results are shown in Fig. 6. For a wide range of centralities the ratio is remarkably constant at about 0.85 GeV for full-energy central

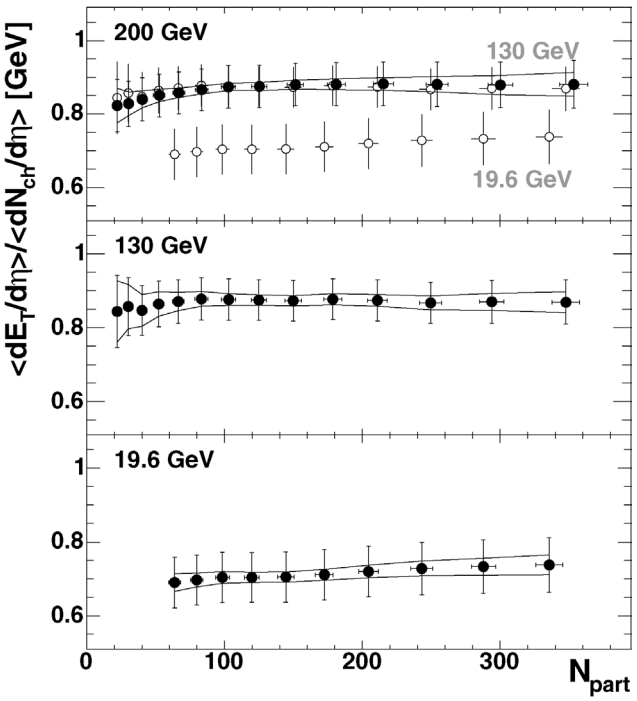

Fig. 6. The ratio of transverse energy density in pseudorapidity to charged particle density in pseudorapidity, at mid-rapidity; shown as a function of centrality, represented by the number of nucleons participating in the collision, N_{part}, for three different RHIC beam energies [59].

Au + Au collisions and shows very little change with beam energy, decreasing to only 0.7 GeV when $\sqrt{s_{NN}}$ is decreased by an order of magnitude down to 19.6 GeV.

If we approximate $dN^{Ch}/d\eta = (2/3)\,dN/d\eta$ in the final state then Eq. (6) would imply $\langle m_T \rangle \simeq 0.57$ GeV and corresponding $\tau_{\text{Form}} \simeq 0.35$ fm/c, a value shorter than the "nominal" 1 fm/c but still long enough to satisfy our validity condition $\tau_{\text{Form}} > 2R/\gamma$ at RHIC. Inserting this value into Eq. (5), along with the highest $dE_T/d\eta = 600$ GeV for 0–5% central events as measured by PHENIX [59], yields a value of $\langle \varepsilon \rangle = 15$ GeV/fm^3 for the energy density in initially produced, mid-rapidity particles in a central RHIC Au + Au collision, that is, roughly 100 times the mass-energy density of cold nuclear matter.

It is important to note that this large value of the energy density as obtained from Eq. (5) represents a conservative *lower* limit on the actual $\langle \varepsilon(\tau_{\text{Form}}) \rangle$ achieved in RHIC collisions. This follows from two observations: (1) The final-state measured $dE_T/d\eta$ is a solid lower limit on the $dE_T(\tau_{\text{Form}})/dy$ present at formation time; and (2) The final-state ratio $(dE_T/d\eta)/(dN/d\eta)$ is a good lower limit on $\langle m_T \rangle$ at formation time, and so yields a good *upper* limit on τ_{Form}. We justify these statements as follows.

Several mechanisms are known that will decrease dE_T/dy as the collision system evolves after the initial particle formation, while no mechanism is known that can cause it to increase (for $y = 0$, at least). Therefore, its final-state value should be a solid lower limit on its value at any earlier time. A partial list of the mechanisms through which dE_T/dy

will decrease after $t = \tau_{\rm Form}$ includes: (i) The initially formed secondaries in any local transverse "slab" will, in a comoving frame, have all their energy in transverse motion and none in longitudinal motion; if they start to collide and thermalize, at least some of their E_T will be converted to longitudinal modes in the local frame; (ii) Should rough local thermal equilibrium be obtained while the system's expansion is still primarily longitudinal, then each local fluid element will lose internal energy through pdV work and so its E_T will decrease; (iii) If there are pressure gradients during a longitudinal hydrodynamic expansion then some fluid elements may be accelerated to higher or lower rapidities; these effects are complicated to predict, but we can state generally that they will always tend to *decrease* dE_T/dy where it has its maximum, namely at $y = 0$. Given that we have strong evidence that thermalization and hydrodynamical evolution do occur in RHIC collisions (Section 3), it is likely that all these effects are present to some degree, and so we should suspect that final-state $dE_T/d\eta$ is substantially lower than $dE_T(\tau_{\rm Form})/dy$ at mid-rapidity.

Turning to our estimate of $\tau_{\rm Form}$, the assumption that $\tau_{\rm Form} = \hbar/\langle m_T \rangle$ cannot be taken as exact, even if the produced particles' m_T's are all identical, since "formed" is not an exact concept. However, if we accept the basic validity of this uncertainty principle argument, then we can see that the approximation in Eq. (6) provides a lower limit on $\langle m_T \rangle$. First, the numerator $dE_T/d\eta$ is a lower limit on $dE_T(\tau_{\rm Form})/dy$, as above. Second, the argument is often made on grounds of entropy conservation that the local number density of particles can never decrease [77], which would make the final-state denominator in Eq. (6) an upper limit on its early-time value.

With these limits in mind, then, it is not unreasonable for us to claim that the peak energy density of created particles reached in central Au + Au collision at RHIC is at least 15 GeV/fm^3, and in all likelihood is significantly higher.

2.4. Thermalized energy density

We have arrived at a reasonably solid, lower-limit estimate for the energy density in produced particles in a RHIC Au + Au collision, and it is more than enough to drive a QCD transition. But the situation at $t = \tau_{\rm Form}$ pictured in Fig. 5 looks nothing like local thermal equilibrium. It is an important question, then, to ask: if and when the system evolves to a state of local thermal equilibrium, is the energy density still sufficient to drive the transition to a QGP?

To answer this we begin by looking at the state of the system at $t = \tau_{\rm Form}$ and immediately afterward. At the time they are formed the particles have sorted themselves out automatically, with all the particles on a "sheet" at a longitudinal position z having the same longitudinal velocity $\beta_\parallel = z/t$; and so in the rest frame of a sheet all the sheet's particles have only transverse motion. If the particles continue free-streaming and never reinteract then the energy density will continue to fall as $\varepsilon \sim 1/t$ and the Bjorken formula in Eq. (5) will be valid, with t in place of $\tau_{\rm Form}$, as long as the expansion is primarily longitudinal.[6]

[6] For long times $t > R$ transverse expansion will become significant and the energy density will decrease as $\varepsilon \sim 1/t^3$.

For thermalization to occur the particles will have to start interacting and/or radiating. Once this happens the particles which were originally together on one "sheet" will start to spread in longitudinal velocity, though on short time scales we would expect their group average longitudinal velocity to remain the same. If the thermalization process is fast enough, then, we would expect that at time $t = \tau_{\rm Therm}$ these groups will have formed locally equilibrated fluid elements, with a velocity profile following $\beta_{\parallel}^{\rm Fluid} = z/t$. The energy density at this time will be reduced from the energy density at formation time $\varepsilon(\tau_{\rm Form})$ by a factor $\tau_{\rm Form}/\tau_{\rm Therm}$; i.e., the $\varepsilon_{\rm Bj}$ of Eq. (5) but with $\tau_{\rm Therm}$ in place of $\tau_{\rm Form}$. This evolution is illustrated in Fig. 4.

Once local equilibration is achieved we would then expect the system to evolve hydrodynamically, and the behavior of $\varepsilon(t)$ will depend on the details of the local equations of state (EOS). Without knowing those details, though, we can say that in the limit of low pressure, $p/\varepsilon \sim 0$, the energy density will continue to evolve (during longitudinal expansion) as $\varepsilon \sim 1/t$, while in the limit of high pressure, $p/\varepsilon \sim 1/3$, the energy density will decrease somewhat more quickly, $\varepsilon \sim 1/t^{4/3}$, within a fluid element. This range of possible behaviors for $t > \tau_{\rm Therm}$ is indicated schematically in Fig. 4.

A direct theoretical determination of $\tau_{\rm Therm}$ would require a detailed description of both the parton–parton interactions and the resulting evolution of the system density. However, other lines of reasoning may provide information on $\tau_{\rm Therm}$. For example, it has been argued [78] that the strong elliptic flow in RHIC collisions can be taken as evidence for fast thermalization (see Section 3.3). In a hydrodynamic picture the source of elliptic flow is the spatial anisotropy of the energy density in the transverse plane at the time hydrodynamics becomes valid. If local equilibration and the onset of hydrodynamics is delayed because interactions between the initially produced particles are weak at first, then the spatial anisotropy which could give rise to elliptic flow will be reduced (see Fig. 14). This, in effect, limits how high $\tau_{\rm Therm}$ can be if hydrodynamics is the mechanism for generating elliptic flow.

We can see from Table 1 in Section 3.5 that hydrodynamical models typically require quite short thermalization times, in the range of 0.6–1.0 fm/c, in order to reproduce the magnitude of elliptic flow which is observed at RHIC. If we take this range as typical of what hydrodynamics would imply for $\tau_{\rm Therm}$, then we can calculate the corresponding "typical" implied energy densities at thermalization time as in range of 5.4 to 9.0 GeV/fm^3. These densities are well above that required to drive the QCD transition, so the combination of our transverse energy measurements and the fast thermalization times from hydrodynamics can be taken, to some degree, as evidence that conditions to create the equilibrated upper phase of QCD matter are achieved at RHIC.

2.5. What are the initial quanta?

With our extensive use of the picture in Fig. 5 it is only natural to ask, "What are these initially produced particles?" that Bjorken referred to, nonspecifically, as "quanta". What models do we have for initial production, and what can we say about them using our data on E_T and multiplicity?

The simplest assumption is that the initially produced particles in a RHIC collision are scattered partons at mid- to low-p_T, traditionally known as "mini-jets". For a long period in

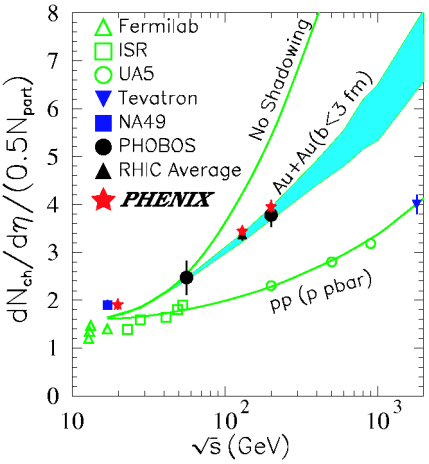

Fig. 7. Figure from Li and Wang [79] showing trends in final-state charged multiplicity per participant pair vs. (nucleon–nucleon) beam energy. (PHENIX data points [59] have been added.) The curves are the result of their two-component "hard/soft" model, which reproduces well the multiplicities from elementary $p(\bar{p}) + p$ collisions at RHIC energies. The same model extended to nuclear collisions with no regulating mechanism on hard processes (the "no shadowing" line) over-predicts the multiplicities in central RHIC collisions, while the data can be matched if substantial nuclear shadowing of gluons is invoked (shaded band).

advance of RHIC data, it was widely expected that mini-jets would be the dominant channel for E_T and particle production, and this led to two further, general expectations. First, that multiplicity and E_T per interacting nucleon would go up sharply at collider energies, as compared to fixed-target energies, since jet and mini-jet cross sections are increasing quickly with $\sqrt{s_{NN}}$ (see Fig. 7). And, secondly, that E_T and multiplicity per participating nucleon would increase steeply in more central events, since the rate of hard pQCD scatterings goes up faster with centrality than does the number of interacting nucleons.

It was therefore quite surprising when the first RHIC data [37,38,80] showed lower multiplicities than had been predicted from mini-jet models, and only a modest increase in E_T and multiplicity per participant as functions of centrality. Compared to the sharp rise, shown in Fig. 7, predicted by straightforward factorized pQCD, it was clear that some mechanism must be acting at RHIC energies to restrict, or regulate, particle production [79,81].

pQCD-based models have parameters regulating the momentum scales; these include a lower-momentum cutoff, and the factorization and fragmentation scales. Fig. 8 shows that the pQCD-based HIJING model, circa 2002, was able to reproduce 130 GeV and 200 GeV $dN_{\mathrm{ch}}/d\eta$ reasonably well. However, in that model jet production via hard scattering is an important mechanism for particle production, and the combination of the $\sqrt{s}$ dependence of hard-scattering cross sections with the growth of the nuclear overlap with centrality causes the model to predict an increase in the ratio between the two data sets with centrality. The observed ratio is, instead, quite constant. Thus the authors found it necessary to introduce a centrality-dependent shadowing to regulate the jet growth [79].

An alternative to models which use collinearly factorized pQCD is found in the "color glass condensate" picture, in which the gluon population of low-x, low-p_T states in the

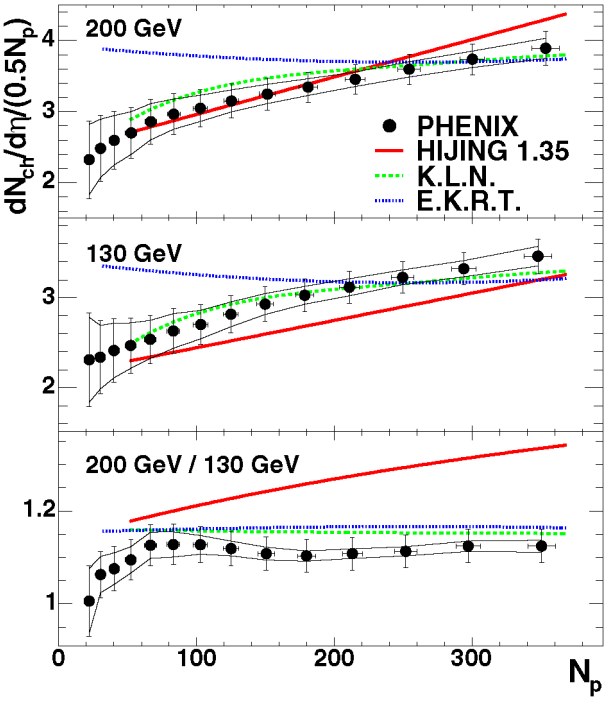

Fig. 8. Multiplicity per participant nucleon pair, as a function of centrality, for $\sqrt{s_{NN}} = 130$ GeV and 200 GeV Au + Au collisions as measured in PHENIX [59]; compared to theoretical predictions available in 2002. "HIJING" is a pQCD-based model [82], while "KLN" features gluon saturation in the initial state [83,84]; "EKRT" assumes saturation in the final state [85,86].

initial nuclear wave function is limited by transverse overlap and fusion of these low-p_T gluons. The phase-space density saturates because of the competition between extra gluon radiation from higher-x gluons and nonlinear fusion of the gluons at high density. Au + Au collisions are then collisions of two sheets of colored glass, with the produced quarks and gluons materializing at a time given by the inverse of the saturation momentum, $\tau = 1/Q_s$. Saturation of gluons with momenta below Q_s provides a regulating mechanism that limits the rise in gluon—and later, hadron—multiplicity with centrality and beam energy. Models featuring this initial-state gluon saturation agree well with essentially all RHIC data on the multiplicity density, which is dominated by low-momentum particles [83,84]. This is seen, for instance, in Fig. 8.

In this picture, the total gluon multiplicity is proportional to $1/\alpha_s \cdot Q_s^2$, which limits the number of low-momentum charged particles produced. Q_s evolves slowly with collision centrality and beam energy. For central Au + Au collisions, it has been estimated that the typical m_T scale of the gluons "liberated" from the colored glass is about 1 GeV per particle [77], which is above the lower limit of 0.53 GeV per particle that we set above using the PHENIX data. Though there are fewer predictions of E_T than total charged-particle production from gluon-saturation models, the existing models are broadly consistent with

data at RHIC. Consequently, gluon saturation is considered to be a promising candidate for describing the initial state of RHIC collisions.

2.6. Conclusions

Using reasoning similar to that of Bjorken [74], combined with some simple formation-time arguments, we can draw the following conclusions from the PHENIX data on transverse energy production and overall particle multiplicity.

- The peak energy density in created secondary particles is at least 15 GeV/fm^3, and this is most likely an underestimate. This is well in excess of the ~ 1 GeV/fm^3 required, according to lattice QCD predictions, to drive a QCD transition to QGP.
- We note that hydrodynamical calculations which reproduce the magnitude of elliptic flow observed at RHIC require local thermalization to occur very quickly, typically by 1 fm/c or earlier (see Section 3.5). If the system does reach local equilibrium on this time scale then the energy density of the first thermalized state would be in excess of 5 GeV/fm^3, well above the amount required to create the QGP.
- Pre-RHIC expectations that E_T and charged particle production would be dominated by factorized pQCD processes were contradicted by data, which showed only very modest increases with centrality and beam energy. A new class of models featuring initial-state gluon saturation compares well with RHIC multiplicity and E_T data, and are also consistent with our Bjorken-style arguments for estimating energy densities at early times.

3. Thermalization

A key question is whether the matter formed at RHIC is thermalized, and if so when in the collision was equilibration achieved. If thermalization is established early then evidence for strong transverse expansion can be potentially related to the equation of state of the dense matter produced at RHIC. To explore these issues we review several experimental observables from integral quantities (numbers of particles produced and in what ratios), to differential distributions (measured p_T and azimuthal distributions), to two-particle (HBT) correlations.

3.1. Chemical equilibrium

For many years it has been known that the abundances of different hadron species in $e^+ + e^-$ and $p + \bar{p}$ reactions can be reproduced by statistical models [87,88]. This success is often attributed to hadronization statistically filling the available phase space. At RHIC there is also the possibility that the strong scattering deduced from the measurements of elliptic flow (Section 3.3) may prove sufficient to establish chemical equilibrium.

The production of strange particles provides a means to check whether chemical equilibrium is achieved. For $e^+ + e^-$ and $p + \bar{p}$ reactions strange particle production is suppressed due to the small size of the system. This canonical suppression is largely removed for central heavy-ion collisions. If the measured strangeness yields are still lower than full

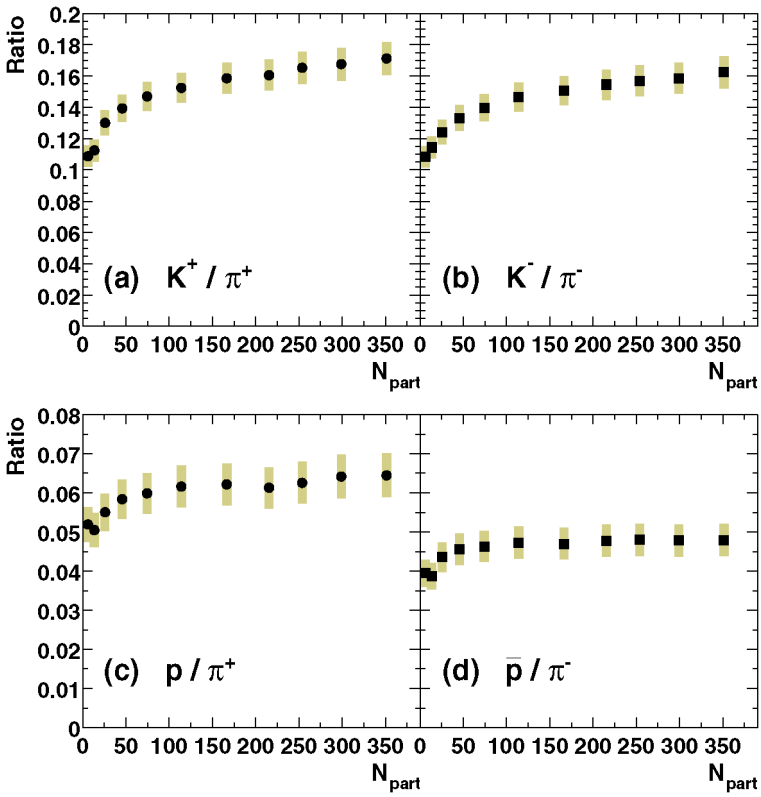

Fig. 9. Centrality dependence of particle ratios for (a) K^+/π^+, (b) K^-/π^-, (c) p/π^+, and (d) $\bar{p}/\pi^-$ in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV [54].

equilibrium predictions, then the partial equilibrium can be quantified by a multiplicative factor of γ_s for each strange quark in a hadron, where $\gamma_s = 1$ for complete equilibration and $\gamma_s < 1$ for partial equilibration.

Fig. 9 shows the centrality dependence of K/π and p/π ratios in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [54]. Both K^+/π^+ and K^-/π^- increase rapidly for peripheral collisions, and then saturate or rise slowly from mid-central to the most central collisions. The ratios p/π^+ and $\bar{p}/\pi^-$ also increase from peripheral collisions but appear flatter than the K/π ratios. Canonical statistical models [89] predict an increase in these ratios with centrality, as the larger system-size effectively places less of a constraint on conserved quantities. In addition the chemical parameters, $T_{\rm chem}$ and μ_B, can also vary with centrality [90,91].

Focusing on the ratios from central collisions at $\sqrt{s_{NN}} = 200$ GeV, the data are compared to the thermal model data analysis of Kaneta and Xu [90] in Fig. 10. The extracted thermal parameters from this fit are $T_{\rm chem} = 157 \pm 3$ MeV, $\mu_B = 23 \pm 3$ MeV, and $\gamma_s = 1.03 \pm 0.04$. A large γ_s is also found by STAR [92] who extract $\gamma_s = 0.96 \pm 0.06$, while Cleymans et al., [91] extract γ_s that increases from $\gamma_s \simeq 0.85$ in peripheral collisions

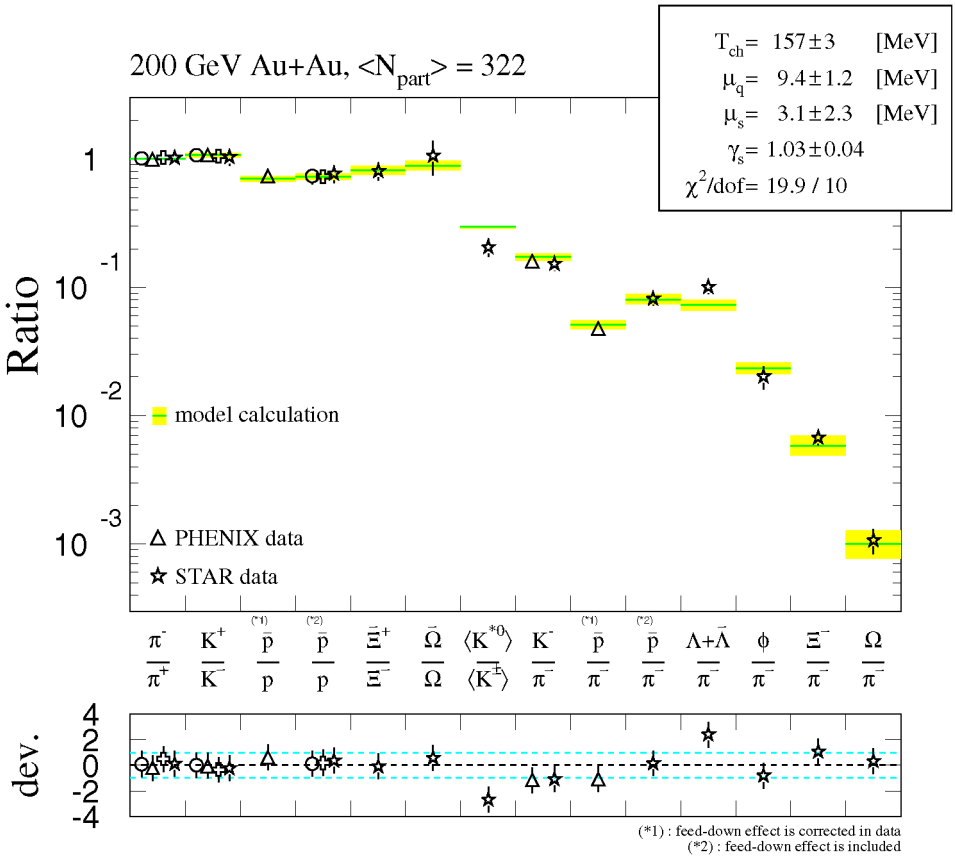

Fig. 10. Comparison of PHENIX (triangles), STAR (stars), BRAHMS (circles), and PHOBOS (crosses) particle ratios from central Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV at mid-rapidity. The thermal model descriptions from Kaneta and Xu [90] are also shown as lines. See Kaneta and Xu [90] for the experimental references.

to $\gamma_s \simeq 0.95$ for central collisions at RHIC. Similar fits to the central RHIC data are obtained by Braun-Munzinger et al., [93] who assume complete chemical equilibration, i.e., $\gamma_s = 1$.

We note that there are differences in the temperature parameter extracted by the different authors. Kaneta and Xu [90] extract $T_{\text{chem}} = 157 \pm 3$ MeV which is lower than that extracted by both Braun-Munzinger et al., [89] of $T_{\text{chem}} = 177 \pm 7$ MeV and Cleymans et al. [91] of $T_{\text{chem}} = 165 \pm 7$ MeV. However, both Braun-Munzinger et al. [89] and Magestro [94] discuss the sensitivity of the extracted temperature to corrections from feed-down from decays. Cleymans et al., [91] estimate that over 70% of π^+ in the thermal model fits come from the decay of resonances.

At lower beam energies there is controversy over whether strangeness is in full chemical equilibrium. Becattini et al. [95] use data that is integrated over the full rapidity and find that strangeness is in partial equilibrium, i.e., at the AGS $\gamma_s = 0.65 \pm 0.07$ and at the SPS $\gamma_s = 0.84 \pm 0.03$. Braun-Munzinger et al. [89] instead use ratios measured at mid-

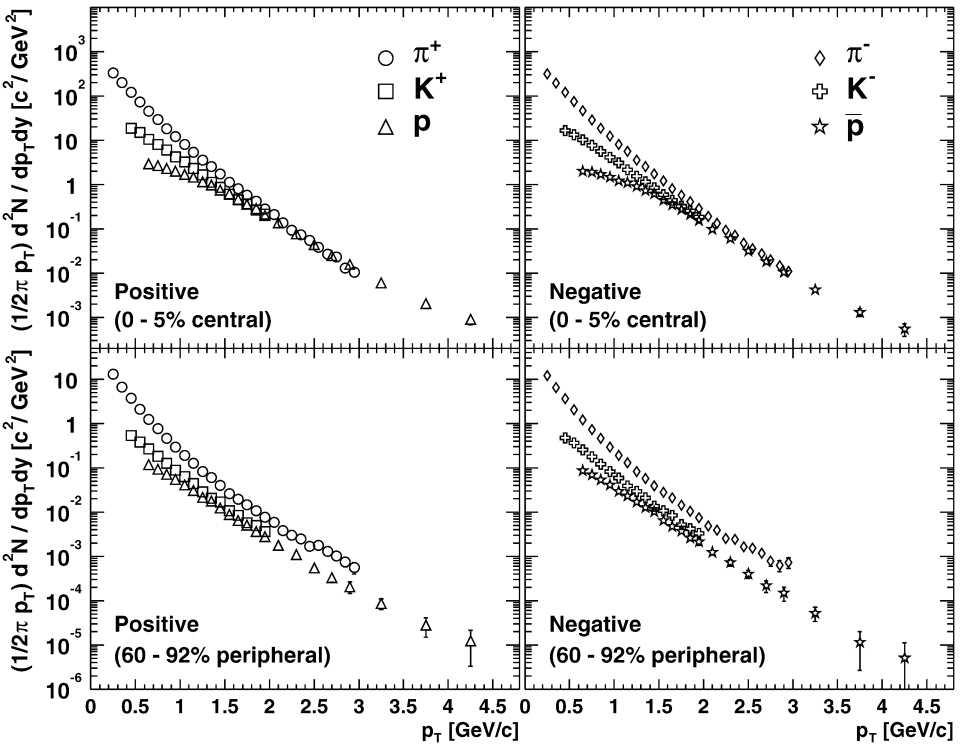

Fig. 11. Transverse momentum distributions for pions, kaons, protons, and antiprotons in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [54].

rapidity which typically have larger strange/nonstrange values, and, hence, they obtain acceptable fits with $\gamma_s = 1$ at both AGS and SPS energies. At RHIC energies thermal model comparisons all use mid-rapidity data; a choice that is motivated in part by the separation between fragmentation regions and central particle production.

In contrast to the controversies at lower beam energies, the observation that strangeness is equilibrated is common to all thermal calculations that reproduce RHIC data. This is consistent with chemical equilibrium being obtained before hadronization, though does not prove that this is the case. An alternative explanation is that scattering in the hadronic phase could increase γ_s to 1, though small interaction cross sections imply that it may be difficult to equilibrate the multi-strange baryons before the hadrons freezeout.

3.2. Spectra

Hadron spectra reflect conditions late in the reaction, as well as the integrated effects of expansion from the beginning of the collision. Fig. 11 shows the p_T distributions for pions, kaons, protons, and antiprotons in both central (top panel) and peripheral collisions (bottom panel) [54]. The pion spectra have a concave shape at low p_T where many of the pions may come from the decay of resonances: Δ, ρ, etc. The kaon spectra are approximately

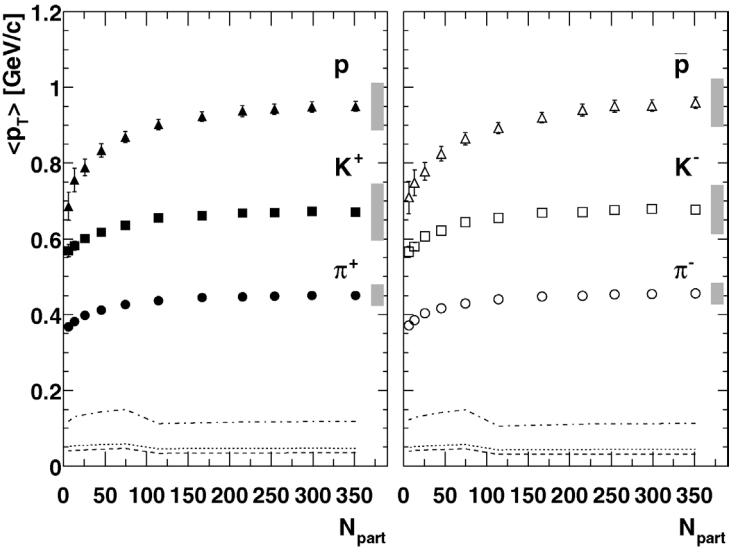

Fig. 12. Mean transverse momentum as a function of N_{part} for pions, kaons, protons and antiprotons in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [54]. The systematic errors from extrapolation, which are scaled by a factor of two for clarity, are shown in the bottom for protons and antiprotons (dashed-dotted lines), kaons (dotted lines), and pions (dashed lines). The shaded bars to the right represent the systematic error.

exponential over the full measured p_T range, whereas the proton spectra flatten at low p_T for the most central collisions. A striking feature is that the proton and antiproton spectra in central collisions become comparable in yield to the pion spectra above 2 GeV/c. This is more fully discussed in Section 7.

One way to characterize the change in spectra as a function of centrality is to calculate $\langle p_T \rangle$ for each spectrum [54] as shown in Fig. 12. The $\langle p_T \rangle$ increases for all particles as a function of centrality with the largest change occurring in peripheral collisions ($N_{\text{part}} < 100$). Across the different particles the increase is largest for protons and antiprotons. This is consistent with a collective expansion velocity that increases with centrality to produce the largest increase in $\langle p_T \rangle$ for the heaviest particles.

The pion, kaon, and proton spectra can all be fit using an ansatz of a thermal, expanding source [48,96] to extract the collective transverse expansion velocity $\langle \beta_T \rangle$ as well as the temperature at freezeout, T_{fo}. Fig. 13 shows $\langle \beta_T \rangle \sim 0.45$ at AGS energies [97,98], which increases to $\langle \beta_T \rangle \sim 0.5$ at the SPS [99–101] and RHIC [48,102]. All the above fits use similar model assumptions of a linear velocity profile and a Woods–Saxon density profile. That the spectra at these beam energies can be reproduced by a thermal source is necessary, but not sufficient, evidence for thermal equilibrium at each of these energies. However, it is difficult to draw strong conclusions from the increase in $\langle \beta_T \rangle$ as a function of beam energy since the parameters $\langle \beta_T \rangle$ and T_{fo} are strongly anticorrelated and their values depend on fit ranges and treatment of decays.

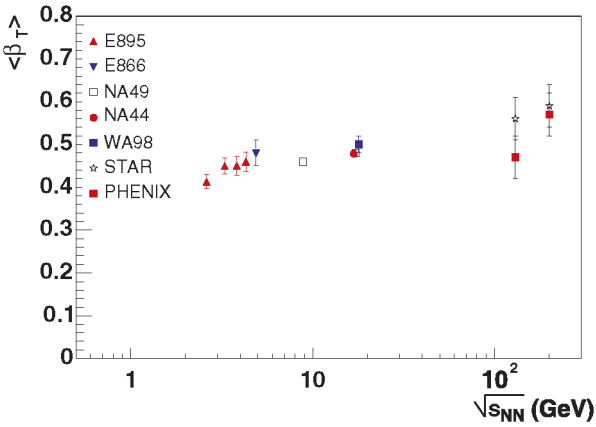

Fig. 13. Beam-energy dependence of the extracted mean transverse expansion velocity as a function of beam energy from simultaneous fits to spectra of different mass [48,97–102].

3.3. *Elliptic flow*

At the beginning of a heavy ion collision, the spatial distribution of the colliding matter resembles an ellipsoid due to the incomplete overlap of the two colliding nuclei. Any strong scattering in this early stage converts the spatial anisotropy to a momentum anisotropy which is observable as an elliptic flow of the emitted hadrons. Elliptic flow is a self-limiting phenomenon, which is readily understood in the thermodynamic limit. If strong scattering is sufficient to establish local thermal equilibrium, then the pressure gradient is largest in the shortest direction of the ellipsoid. This gradient produces higher momenta in that direction, quickly reducing the spatial asymmetry.

The absence of any strong scattering in the early stage of the collision would reduce the amount of elliptic flow that could be created. If the initially produced particles are allowed to initially free stream and reach local equilibrium only after some time delay, then the spatial anisotropy at the start of hydrodynamic evolution will be reduced; the longer the delay, the greater the reduction. Following the prescription of Kolb et al. [78], we plot in Fig. 14 the eccentricity after a time delay Δt compared to its value at formation time, as a function of Au + Au collision centrality. The eccentricity (ε) of the reaction zone is

$$\varepsilon = \frac{\langle y^2 \rangle - \langle x^2 \rangle}{\langle y^2 \rangle + \langle x^2 \rangle}. \tag{7}$$

The eccentricity can be analytically calculated once the density profile of the nuclei is chosen (typically a Woods–Saxon shape). It can also be calculated using Monte Carlo techniques, where the positions of those nucleons that participate in the reaction are used to calculate the averages in Eq. (7). From Fig. 14 we can see that for time delays of 2 fm/c or greater the magnitude of the eccentricity is significantly reduced, and its shape vs. centrality is also altered.

If locally equilibrated hydrodynamics is taken as the mechanism for generating elliptic flow, then the observation of *any* substantial amount of elliptic flow can be taken as

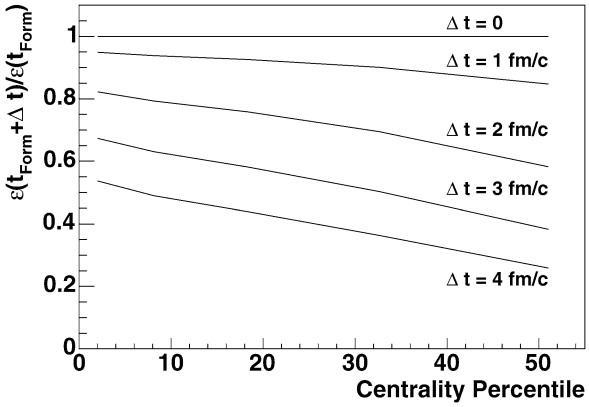

Fig. 14. The ratio of the eccentricity after a time delay Δt compared to its value at formation time, as a function of Au + Au collision centrality. The calculations follow the prescription of [78] where the produced particles are allowed to free-stream at first and reach local equilibrium only after some time delay.

evidence that local thermal equilibrium is achieved on a time scale before the spatial anisotropy would be completely erased. The order of this time-scale would be $t \sim R/c$, where R is the nuclear radius. However, the hydrodynamical calculations we will examine here (see Section 3.5 and Table 1) all require quite short thermalization times, from 0.6–1.0 fm/c, in order to reproduce the magnitude of elliptic flow observed at RHIC.

The azimuthal anisotropy of the spectra can be characterized in terms of Fourier coefficients, which at RHIC are dominated by the elliptic flow, the second Fourier coefficient, $v_2(p_T)$, where

$$\frac{d^2N}{d\phi\, dp_T} = N_0\big(1 + 2v_2(p_T)\cos(2\phi)\big). \tag{8}$$

Both the first Fourier coefficient, v_1, and higher order coefficients have been neglected in the above expression.

The most direct evidence that v_2 is related to spatial asymmetries present early in the reaction is that v_2 at low p_T approximately scales with the initial eccentricity (ε) of the reaction zone. The measured values of v_2 normalized by ε are shown in Fig. 15 vs. centrality for two different p_T ranges [46]. At low momentum v_2/ε is independent of centrality to within 20%. This scaling is increasingly broken at higher p_T.

The measured values of the integrated v_2 at RHIC are larger than those at lower energies, but this is in part due to the fact that $v_2(p_T)$ increases with p_T and $\langle p_T \rangle$ increases as a function of beam energy. To remove this effect we will concentrate on the differential flow, i.e., the shape of $v_2(p_T)$.

To make a uniform comparison between different colliding nuclei (Pb + Pb at SPS and Au + Au at RHIC) as well as different impact parameter selections from the different experiments, we normalize v_2 by the eccentricity, ε, as shown in Fig. 16. The values of ε have been calculated via a Glauber Monte Carlo using Woods–Saxon density distributions for the Au and Pb nuclei. The averages in Eq. (7) are over the participating nucleons, hence ε is calculated at the start of the collision. The pion data in Fig. 16 show that $v_2(p_T)/\varepsilon$

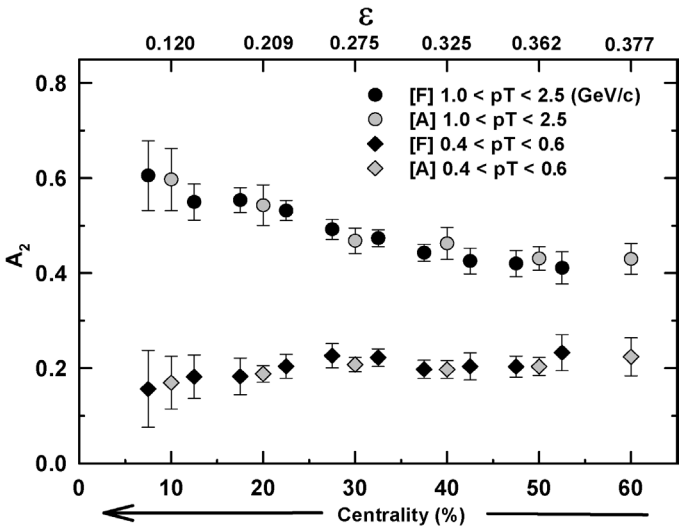

Fig. 15. $A_2 = v_2/\varepsilon$ vs. centrality for Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV [46]. The data points come from two different types of two-particle correlations: "fixed" p_T correlations when both particles are at the same p_T (points are labeled as "F"), and "assorted" p_T correlations when the two particles have different p_T (points are labeled as "A"). In this case the labeled p_T range is for the higher-momentum particle of the pair.

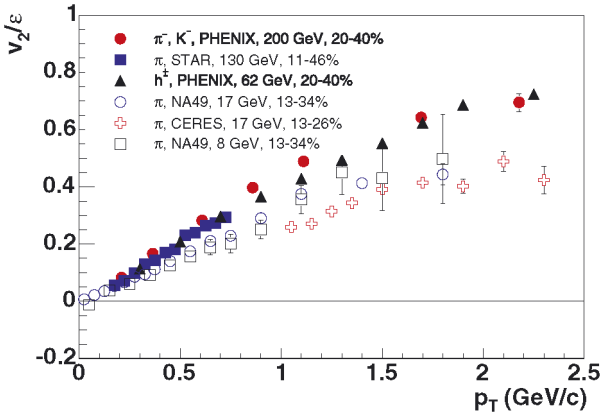

Fig. 16. $v_2(p_T)/\varepsilon$ vs. p_T for mid-central collisions at RHIC (filled symbols) and SPS (open symbols). Dividing by eccentricity removes to first order the effect of different centrality selections across the experiments [50,70, 103–105].

increases approximately linearly with p_T for low p_T. The rate of increase of v_2/ε as a function of p_T is larger at RHIC [50,103] than at SPS [104,105] as can most easily be seen by calculating the slope of v_2/ε below $p_T = 1$ GeV/c (Fig. 17). The slope $(dv_2/dp_T)/\varepsilon$ increases from SPS to RHIC by approximately 50%. Hydrodynamical calculations [106] shown in Fig. 17 reproduce the data both at RHIC and at CERN SPS within one standard deviation. More extensive comparisons with hydro calculations will be discussed in Sec-

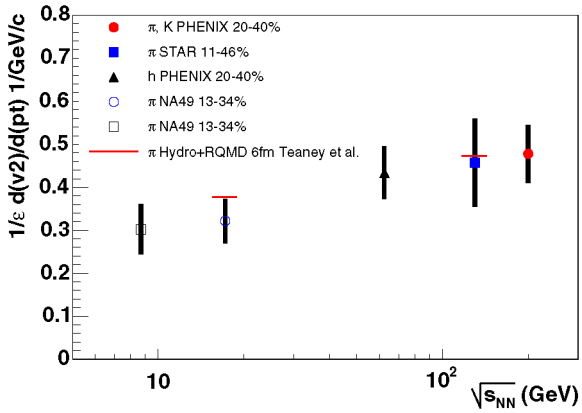

Fig. 17. The slope of the scaled elliptic flow, $(dv_2/dp_T)/\varepsilon$, for mid-central collisions at RHIC (filled symbols) and the SPS (open symbols). The slope is calculated from the data in Fig. 16 for the data $p_T < 1$ GeV/c. The solid error bars represent the total systematic error including the systematic error on v_2 and ε [50,70,103,104].

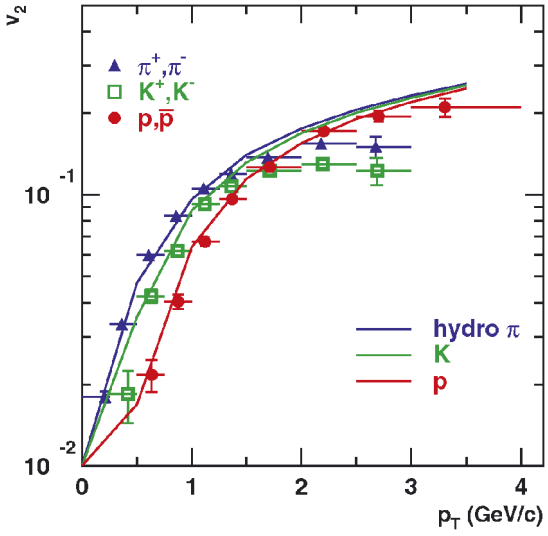

Fig. 18. $v_2(p_T)$ for pions, kaons and protons produced in minimum-bias collisions at RHIC [50] compared to hydro calculations from Huovinen et al. [107].

tion 3.5, while the behavior of v_2 at higher p_T, which follows a scaling with respect to the number of quarks, is discussed in Section 7.

Further insight into the expansion dynamics can be obtained from the mass dependence of $v_2(p_T)$ shown in Fig. 18 for pions, kaons and protons [50] along with a comparison with an early hydrodynamic model calculation [107]. The $v_2(p_T)$ for pions is larger than for kaons and protons at low p_T, and this mass ordering has been explained as resulting from radial expansion [107] that produces a larger distortion of the elliptic flow

induced velocity profile for larger hadron masses. However, as will be discussed in Section 3.5, this calculation fails to reproduce the proton spectra, and attempts to remedy this failure lead to calculations that no longer reproduce the measured v_2 for pions and protons.

3.4. HBT

Bose–Einstein correlations between identical particles provide a measure of the space–time extent of the source at the end of the reaction. Because the extracted source parameters as measured by the HBT technique are driven by space–time correlations, HBT results are sensitive to expansion dynamics integrated throughout the collision. HBT measurements were originally motivated by theoretical predictions of a large source size and/or a long duration of particle emission [108–110]—which would result from the presence of a long-lived mixture of phases in the matter as it undergoes a first-order phase transition from a quark–gluon plasma back to the hadronic phase.

In HBT analyses, multidimensional Gaussian fits are made to the normalized relative momentum distributions yielding fit parameters, R_{long}, R_{side}, R_{out} [111], also referred to as HBT radii, where

$$C_2 = 1 + \lambda \exp\bigl(-R_{\text{side}}^2 q_{\text{side}}^2 - R_{\text{out}}^2 q_{\text{out}}^2 - R_{\text{long}}^2 q_{\text{long}}^2\bigr). \tag{9}$$

The coordinate system is chosen so that the longitudinal direction is parallel to the beam axis, the out direction is in the direction of the pair's total transverse momentum, and the side direction is in the transverse plane perpendicular to the out axis. For dynamic (i.e., expanding) sources, the HBT radii depend on the mean transverse momentum of the particle pairs, $k_T = |\mathbf{p}_{1\text{T}} + \mathbf{p}_{2\text{T}}|/2$, and correspond to lengths of homogeneity: regions of the source which emit particles of similar momentum [112]. Measuring the k_T dependence of HBT radii provides essential constraints on dynamical models [113]. In particular, the ratio $R_{\text{out}}/R_{\text{side}}$ is predicted to be larger than unity for sources which emit particles over a long time.

The measured k_T dependence of all radii [56] and the ratio $R_{\text{out}}/R_{\text{side}}$ are shown in Fig. 19, along with STAR results [114]. The data from PHENIX and STAR are in excellent agreement. Both sets of data have been corrected for Coulomb repulsion between the detected particles.

The measured radii all decrease with increasing k_T as expected for a rapidly expanding source. The ratio $R_{\text{out}}/R_{\text{side}}$ was measured to be 1 within errors, with a slight systematic decrease for increasing k_T. As is discussed in the next section, these data have excluded the validity of a large majority of hydrodynamical models developed to describe Au + Au collisions at RHIC, indicating that in their present form these models do not describe well the space–time evolution of the Au + Au collisions.

3.5. Hydrodynamic model comparisons

Many of the experimental features in the spectra and elliptic flow are consistent with equilibrium being established early in the collision with large pressure gradients that drive

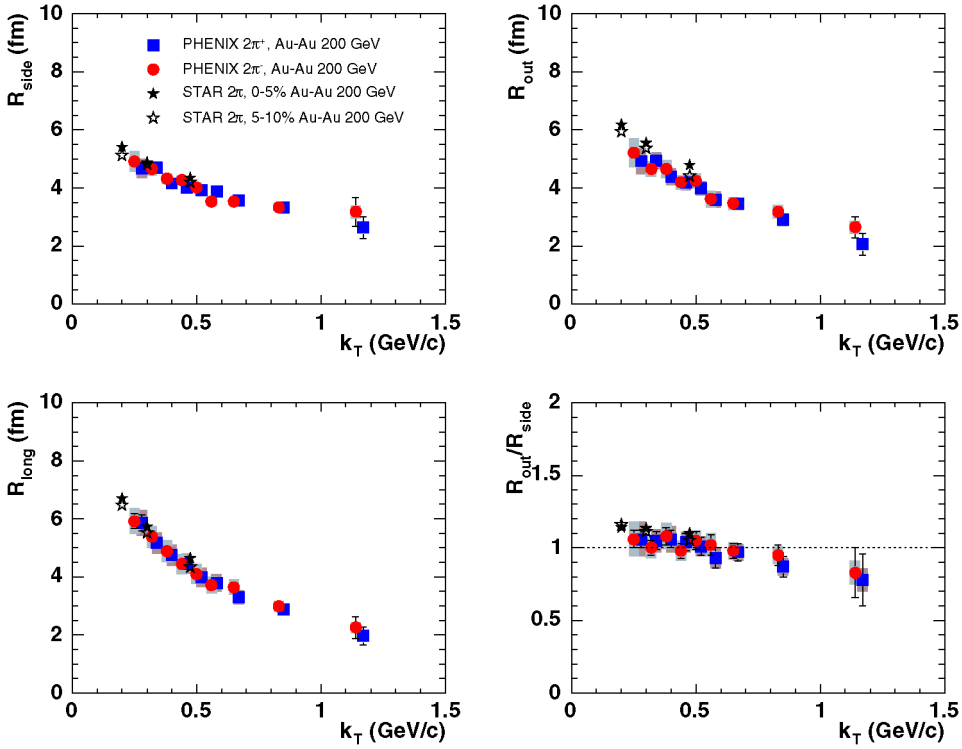

Fig. 19. The k_T dependence of the Bertsch–Pratt parameters for $\pi^+\pi^+$ (blue square) and $\pi^-\pi^-$ (red circle) for 0–30% centrality with statistical error bars and systematic error bands. Results from PHENIX [56] and STAR [114] are overlaid. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

a strong expansion. Moving from a statement of "consistency" to a statement that equilibrium has been "established" is difficult. Some progress can be made by comparing the data to hydrodynamic models that assume full equilibrium early in the collision.

A variety of hydrodynamic models have been published. Our approach is to confront these models with the following broad set of data; $v_2(p_T)$, spectra, and HBT. In this paper we will not compare the data with hydro-inspired parameterized fits, e.g., blast-wave [115] or Buda–Lund [116] models, but will restrict ourselves to dynamical hydro models.

In Figs. 20 and 21, hydro calculations that include a phase transition from the QGP phase to a hadronic phase are shown with solid lines, while hydro calculations that do not include a pure QGP phase at any stage in the dynamics are drawn with dashed lines. The four calculations that include a QGP phase all assume an ideal gas EOS for the QGP phase, a resonance gas for the hadronic phase and connect the two using a first-order phase transition and a Maxwell construction. These calculations use latent heats that range from 0.8 GeV/fm^3 (Teaney et al. [106]) to 1.15 GeV/fm^3 (Huovinen et al. [107] and Kolb et al. [117]), to 1.7 GeV/fm^3 (Hirano et al. [118,119]). For comparison the bag model of the nucleon with external bag pressure $B = (230\ \text{MeV})^4$ and a $T_{\text{crit}} = 164$ MeV produces

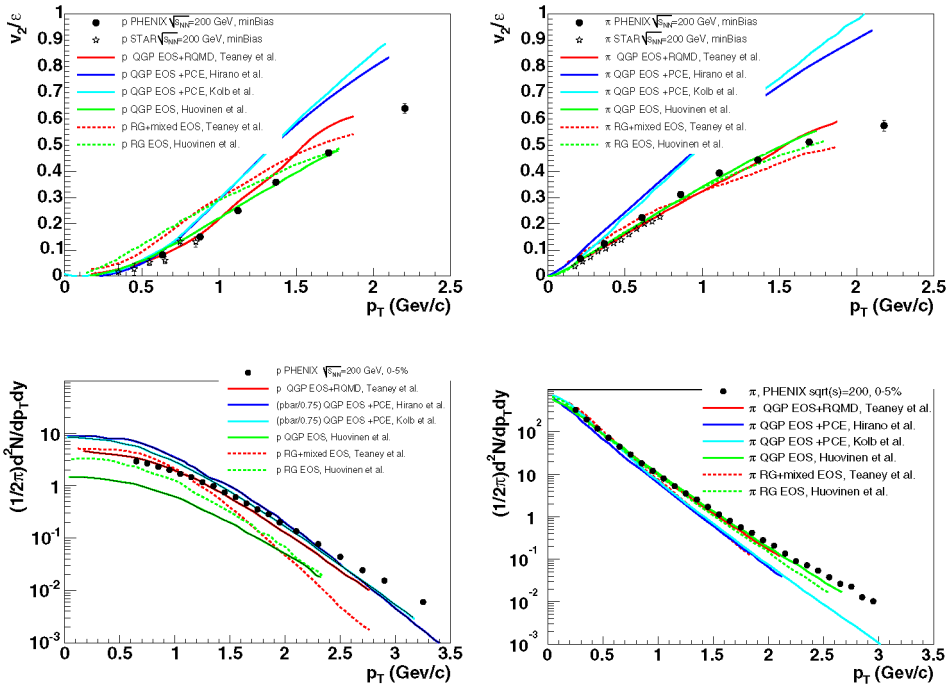

Fig. 20. Top two panels: on the left, proton $\frac{1}{\varepsilon}v_2(p_T)$ vs. p_T for minimum-bias collisions at RHIC [50,103] are compared with hydro calculations [106,107,118,120], and on the right is the same comparison for pions. Bottom two panels: on the left, proton spectra for 0–5% collisions at RHIC [54] are compared with the same hydro calculations and on the right is the same comparison for pions.

a latent heat of 1.15 GeV/fm^3 [120]. The calculations that do not include a QGP phase (dashed lines) either include a hadron phase and a phase mixture by forcing the latent heat of the transition to infinity [106], or use an hadronic resonance gas equation of state, i.e., no mixed or QGP phases [107].

The calculations also differ in how they solve the hydro equations and how they treat the final hadronic phase. The work of Hirano, Tsuda, and Nara cited here are the only calculations in this paper that solve the hydro equations in 3D [118,119]. For the final hadronic stage Teaney [106] uses a hybrid model that couples the hadronic phase to RQMD to allow hadrons to freezeout according to their cross section, i.e., for chemical equilibrium to be broken in the hadronic phase. Hirano [118] and Kolb [120] both allow for partial chemical equilibrium by chemically freezing out earlier than the kinetic freezeout. This has been done in order to reproduce the large proton yield measured at RHIC (see later in this section). In contrast, Huovinen [107] maintains full chemical equilibrium throughout the hadronic phase.

Fig. 20 compares these calculations to the measured minimun-bias proton and pion $v_2(p_T)/\varepsilon$. Minimum-bias results were chosen in order to have the broadest set of data and model calculations for comparison. The four calculations that include a phase transition from the QGP phase to a hadronic phase (solid lines) reproduce the low-p_T proton data

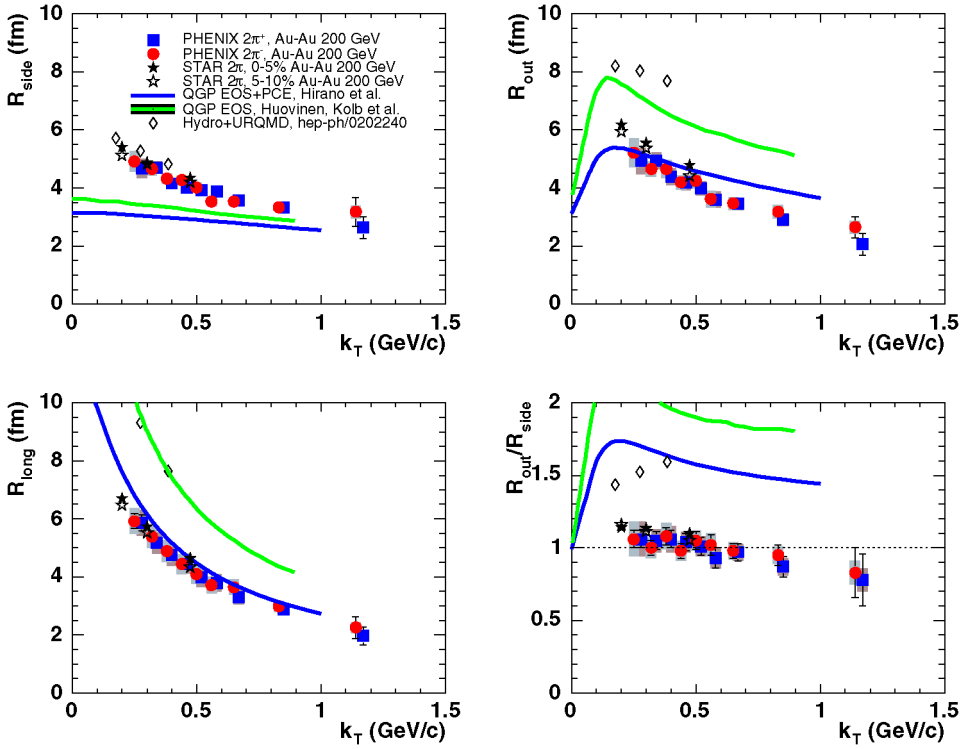

Fig. 21. The k_T dependence of the Bertsch–Pratt parameters for $\pi^+\pi^+$ (blue square) and $\pi^-\pi^-$ (red circle) for 0–30% centrality with statistical error bars and systematic error bands. Results from PHENIX [56], STAR [114] and hydrodynamics models (Hirano [118], Kolb/Huovinen [123] and Soff [130], diamonds) are overlaid. (For interpretation of the references to colour in this figure legend, the reader ir referred to the web version of this article.)

better than the two hydro calculations that do not have a QGP phase at any stage in the dynamics (dashed lines). The presence of the first-order QGP phase transition softens the EOS which reduces the elliptic flow. At higher p_T there is considerable variation between the models. Part of this is due to how the final hadronic stage is modeled. For example, Kolb's (solid light-blue line)[7] and Hirano's (solid dark-blue line) calculations allow for partial chemical equilibrium in the final stage compared to Huovinen (solid green line) which chemically freezes out late in the collision. The difference is observable above $p_T \sim 1\ \mathrm{GeV}/c$.

The same hydro models are compared to the pion $v_2(p_T)/\varepsilon$ measurements from STAR and PHENIX in Fig. 20. The Kolb (solid light-blue line) and Hirano (solid dark-blue line) calculations fail completely by predicting too strong a v_2. These two models have very similar partial chemical equilibrium assumptions in the late hadronic stage. It is worth noting that the Kolb calculation is the same as the Huovinen (solid green line) calculation with the exception of the final hadronic stage.

[7] For interpretation of the references to colour in Fig. 20, the reader is referred to the web version of this article.

All the above models have assumed ideal hydrodynamics, i.e., with no viscosity and zero mean free path. Nonzero viscosity in the QGP reduces v_2 [121,122] and since the early hydro calculations from Teaney and Huovinen reproduced the magnitude of the pion v_2 data, it is often stated that viscosity of the matter at RHIC must be small [24]. However recent calculations from Hirano (3D) (solid dark-blue line) and Kolb (solid light-blue line) overpredict the measured v_2. As these results do not include dissipative effects, such as those resulting from hadronic interactions in the final state, their failure indicates that further work will be necessary before a quantitative determination of the viscosity in the QGP phase is possible. Progress will require both theoretical development and experimental measures that are less sensitive to how the azimuthal asymmetry of the energy–momentum tensor is distributed between different particles in the final stage of the reaction, e.g., the elliptic flow of the total transverse energy.

The same hydro models are now compared to the measured spectra from central collisions. The bottom right panel of Fig. 20 shows that all the hydro models reproduce the pion spectra below $p_T \sim 1$ GeV/c; at higher p_T the particles are less likely to be equilibrated and hydro models are not expected to work well. In the bottom left panel the calculated proton spectra from Huovinen [107] (solid green line) are lower than the data, due to the calculation maintaining chemical equilibrium throughout the hadronic phase. The lower temperature chemical freezeout suppresses the final calculated yield of heavier particles such as protons. Of the two calculations from Teaney [106] the calculation that includes the QGP phase (solid red line) reproduces the proton spectra, presumably because of the increased transverse flow from the stronger early pressure gradients. Hirano's and Kolb's (solid dark and light-blue lines) calculations break chemical equilibrium during the hadronic phase and overpredict the proton spectra at low p_T.

One difficulty is that the spectra comparison with hydrodynamic models is for central collisions while the v_2 comparison is for minimum-bias collisions. It is difficult to use central collisions for the v_2 comparison since the collisions are nearly symmetric and hence v_2 is small. In addition, hydrodyamic calculations that reproduce v_2 values over a broad range of centrality (from 0–45% in Ref. [103]) tend to overpredict the data for more peripheral collisions by approximately 25%, presumably because of a breakdown in the hydrodynamic assumptions. Hence when comparing to minimum-bias data sets, an overprediction of v_2 from the hydro models of less than 20% should be acceptable.

These comparisons between data and hydro models are summarized in Table 1 and in the following conclusions.

- $v_2(p_T, PID)$ is sensitive to all stages of the reaction. Elliptic flow is produced by strong scattering in the initial phase, while the detailed shape of $v_2(p_T)$ and how the momentum asymmetry is distributed to different particles is affected by the transition from a QGP to hadronic phase and scattering in the final hadronic stage.
- The hydro models that reproduce the low-p_T proton v_2 are those that include both a QGP and hadronic phase.
- The hadronic phase critically affects the final values of $v_2(p_T, PID)$. Models (Hirano, Kolb) that include partial chemical equilibrium to reproduce the baryon yield, completely fail on the pion v_2.

Table 1
Summary of various hydro model assumptions and a comparison between measurements and hydro calculations. Two initial energies are tabulated, either the maximum energy density at the center of the collision or the energy density averaged over the transverse profile

	QGP + mixed + RG				mixed + RG	RG

- The only model that survives this comparison with measured v_2 and spectra is Teaney's (solid red line) which includes a strong expansion in a QGP phase, a phase transition to a mixed phase, and then a hadronic cascade in the final hadronic state. There are open questions in this hybrid model, e.g., the sensitivity of the results to the matching conditions between hydro and RQMD. All other models fail in at least one v_2 or spectra comparison, partially due to differences in modeling the final hadronic state.
- Until the model uncertainty in the final state is reduced, it is not yet possible to use the measured splitting between proton and pion $v_2(p_T)$ to extract quantitative information on the EOS during the reaction, including the possible softening of the EOS due to the presence of a mixed phase.

A comparison with the HBT data and some of the hydro models is shown in Fig. 21. It is unfortunate that not all hydro models have been compared to HBT data, e.g., the hydro + RQMD model from Teaney [106] has not been confronted with this observable. The hydro calculation from Kolb, Heinz and Huovinen [123] (solid green line) includes a first-order phase transition which leads to a long lifetime for the system. The source parameter R_{long} is considered most sensitive to the duration of the whole collision, i.e., from initial overlap to final particle emission, and the Kolb/Huovinen hydro calculation [123] (solid green line) overpredicts the measured R_{long} data. Changing to partial chemical equilibrium in the hadronic stage [118], indicated with the dark blue line, reduces the lifetime of the collision which improves the agreement with R_{long}. However the ratio $R_{\mathrm{out}}/R_{\mathrm{side}}$, which is sensitive to the duration over which particles are emitted, is still overpredicted.

There have been many attempts to understand what may be causing the disagreement with data (known collectively as the HBT puzzle).

• Sinyukov et al. [124] and Grassi et al. [125] have suggested that the sharp Cooper–Frye freezeout condition [126] should be replaced by an emission function that decouples hadrons depending on their hadronic cross section.

• However when this has been effectively implemented by using a hadronic cascade (URQMD) for the final hadronic stage, the predicted ratio $R_{\rm out}/R_{\rm side}$ increases and diverges further from the data [127]. Modeling the final stage with a hadronic cascade effectively includes dissipative effects which should increase the duration of emission and produce a larger ratio $R_{\rm out}/R_{\rm side}$.

• One method to reduce the lifetime of the reaction is to change the QGP EOS. Using a crossover instead of a first-order transition reduces the ratio $R_{\rm out}/R_{\rm side}$ by about 50% to $R_{\rm out}/R_{\rm side} \sim 1.5$ [128] which is still larger than the data. Because the calculation was restricted to $\eta = 0$ Zschiesche et al. were unable to compare with the measured values of $R_{\rm long}$.

In summary, model comparisons seem to be closer to the HBT data when the lifetime of the collision is made smaller than the long time resulting from a first-order phase transition. The small values of $R_{\rm out}/R_{\rm side}$ may indicate that there is little to no mixed phase present in the reactions. One possible direction for future comparisons with data is to include a more realistic EOS into the hydro models, e.g., to take the EOS from lattice QCD calculations [129]. Such a calculation needs to be compared with all the available data, including spectra and v_2, as well as HBT.

3.6. Conclusions

In summary we can make the following conclusions.

• The measured yields and spectra of hadrons are consistent with thermal emission from a strongly expanding source.

• Strangeness is fully saturated at RHIC, consistent with full chemical equilibrium.

• The scaling of v_2 with eccentricity shows that collective behavior is established early in the collision.

• Elliptic flow is stronger at RHIC than at the SPS, since the measured slope of $v_2(p_T)$ for pions is 50% larger at RHIC.

• The measured proton $v_2(p_T)$ is less than that for pions at low p_T; the small magnitude of the proton v_2 at low p_T is reproduced by hydro models that include both a QGP and hadronic phase.

• However several of the hydro models that reproduce the proton $v_2(p_T)$ fail for the pion $v_2(p_T)$.

• The HBT source parameters, especially the small value of $R_{\rm long}$ and the ratio $R_{\rm out}/R_{\rm side}$, suggest that the mixed phase is too long-lived in the current hydro calculations.

Hence we currently do not have a consistent picture of the space–time dynamics of reactions at RHIC as revealed by spectra, v_2, and HBT. The lack of a consistent picture of the dynamics means that it is not yet possible to extract quantitative properties of the QGP or mixed phase using the observables v_2, spectra, or HBT.

4. Fluctuations

4.1. Net-charge fluctuations

In the study of the fluctuations of multiplicity as a means to understand the dynamics of charged particle production, one important realization was to use small regions of phase space, where energy–momentum conservation constraints would not be significant [131–133]. Such studies led to the important observation that the distribution of multiplicity, even in small intervals near mid-rapidity, was negative binomial rather than Poisson, which indicated large multiplicity correlations even in small $\delta\eta$ intervals [134]. No such studies are yet available at RHIC.

Based on predictions that event-by-event fluctuations of the net charge in local phase space regions would show a large decrease as a signature of the QGP [135–137], net-charge fluctuations were measured in PHENIX [44]. The idea is that in a QGP composed of fractionally charged quarks, the larger number of fractionally charged particles compared to unit-charged hadrons would result in smaller relative net-charge fluctuations in a QGP than for a pure gas of hadrons and that this original fluctuation would survive the transition back to ordinary hadrons.

It is important to realize that the study of net-charge fluctuations represents the study of fluctuations in a quantity that is conserved over all phase space. Consider $N = N_+ + N_-$ charged particles produced in the full phase space. By charge conservation $N_+ = N_- = N/2$, and the net charge $Q \equiv N_+ - N_-$ is identically zero so that there are no net-charge fluctuations—the variance $V(Q) = 0$, where

$$V(Q) \equiv \left\langle Q^2 \right\rangle - \langle Q \rangle^2. \tag{10}$$

In a smaller region of phase space, where p is the fraction of N observed in a stochastic scenario, the mean and variance of the number of positive n_+ and negative n_- particles are equal, but the variance of Q is no longer identically zero:

$$\langle n_+ \rangle = \langle n_- \rangle = pN/2, \tag{11}$$

$$V(n_+) = V(n_-) = p(1-p)N/2, \tag{12}$$

from which it follows that

$$V(Q) = (1-p)n_{\mathrm{ch}}, \tag{13}$$

where $n_{\mathrm{ch}} = pN$ is the expected number of charged particles on the interval. Thus the normalized variance in Q (normalized to Poisson statistics) is defined as

$$v(Q) = \frac{V(Q)}{n_{\mathrm{ch}}} = (1-p). \tag{14}$$

In the limit $n_{\mathrm{ch}} \gg 0$, the variance of the charge ratio $R = n_+/n_-$ approaches $V(R) = 4(1-p)/n_{\mathrm{ch}}$. However, it is well known in mathematical statistics that moments of the inverse of a stochastic variable, e.g., $1/n_-$, diverge if there is any finite probability, no matter how small, for $n_- = 0$. Thus, the charge ratio is not a stable measure of fluctuations.

The previous arguments are based on fixed N. The results where N varies according to a specified distribution are also interesting. If n_- is Poisson distributed, with mean value

$\mu = N/2$ over the whole phase space, then in the region of phase space with probability p the distribution is also Poisson, with mean $\langle n_- \rangle|_p = \mu_p = pN/2$. If, on the other hand n_- is negative binomial distributed, with mean value $\mu = N/2$ and NBD parameter $\sigma^2/\mu^2 - 1/\mu = 1/k$ for the whole phase space, then in the region of phase space with probability p, the distribution is negative binomial with mean $\langle n_- \rangle|_p = \mu_p = pN/2$ and the same value of $1/k$.

Actually, the binomial division preserves $\sigma_p^2/\mu_p^2 - 1/\mu_p = 1/k$, for any distribution [138]. This appears to indicate that smaller intervals, which tend to have larger values of σ_p^2/μ_p^2 would be less sensitive to the global $1/k$, the long-range correlation. This would be true except for the fact that there are short-range correlations which are better seen on small intervals of phase space. Another important thing to note regarding a binomial split of a negative binomial distribution is that the two subintervals are not statistically independent. The conditional probability distribution on the interval $(1 - p)$ depends upon the outcome on the interval p [139]. It is unfortunate that these elegant arguments cannot be applied to the net-charge fluctuations since $\langle Q \rangle = 0$.

The PHENIX measurement [44] of the normalized variance $v(Q)$ of net-charge fluctuations is shown in Fig. 22 in the interval $-0.35 \leqslant \delta\eta \leqslant +0.35$ as a function of the azimuthal angular interval of reconstructed tracks, either at the detector, $\Delta\phi_d$, or at the vertex, $\Delta\phi_r$, chosen symmetrically around the detector acceptance. For smaller $\Delta\phi_r$ the data agree with the purely stochastic $(1 - p)$ dependence shown as the solid line, but deviate from the stochastic prediction at larger values due to correlations from resonance decay, such as $\rho^0 \to \pi^+ + \pi^-$ as nicely explained by RQMD [140].

Absent new theoretical insight, it is difficult to understand how quark-level net-charge fluctuations in a QGP can be related to net-charge fluctuations of hadrons, where, by definition, strong correlations exist, e.g., in the formation of a meson from a q–$\bar{q}$ pair. Also, the study of the fluctuations of net charge, which is conserved, may not be as useful to detect interesting fluctuations as the study of fluctuations of the total charged multiplicity, which is much less constrained by conservation laws. This has yet to be tried at RHIC.

4.2. Event-by-event average-p_T fluctuations

Fluctuations in the event-by-event average p_T, denoted M_{p_T}, have been measured and provide a severely small limit on possible fluctuations from a sharp phase transition. For events with n detected charged particles with magnitudes of transverse momenta, p_{T_i}, the event-by-event average p_T, denoted M_{p_T} is defined as

$$M_{p_T} = \overline{p_T} = \frac{1}{n} \sum_{i=1}^{n} p_{T_i}. \tag{15}$$

Mixed events are used to define the baseline for random fluctuations of M_{p_T} in PHENIX [45,55]. This has the advantage of effectively removing any residual detector-dependent effects. The event-by-event average distributions are very sensitive to the number of tracks in the event (denoted n or N_{tracks}), so the mixed event sample is produced with the *identical* N_{tracks} distribution as the data. Additionally, no two tracks from the same data event are placed in the same mixed event in order to remove any intra-event correlations in p_T. Finally, $\langle M_{p_T} \rangle$ must exactly match the semi-inclusive $\langle p_T \rangle$.

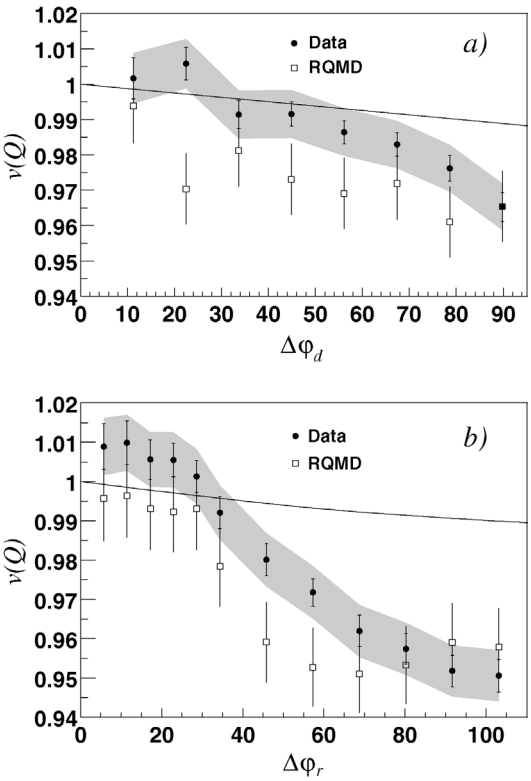

Fig. 22. $v(Q)$ for the 10% most central events in data and RQMD, as a function of the azimuthal interval in degrees of reconstructed tracks, either (a) at the detector, $\Delta\phi_d$, or (b) at the vertex, $\Delta\phi_r$, chosen symmetrically around the detector acceptance. For data, the error band shows the total statistical error, whereas the error bars indicate the uncorrelated part. The solid line shows the expected reduction in $v(Q)$ in the stochastic scenario when global charge conservation is taken into account [44]. Note that the data points are correlated since the data in one bin is a subset of the data in the next bin.

For the case of statistical independent emission, where the fluctuations are purely random, an analytical formula for the distribution in M_{p_T} can be obtained assuming negative binomial distributed event-by-event multiplicity, with gamma distributed semi-inclusive p_T spectra [141]. The formula depends on the four semi-inclusive parameters $\langle n\rangle$, $1/k$, b and p which are derived from the means and standard deviations of the semi-inclusive p_T and multiplicity distributions, $\langle n\rangle$, σ_n, $\langle p_T\rangle$, σ_{p_T}:

$$f(y) = \sum_{n=n_{\min}}^{n_{\max}} f_{\mathrm{NBD}}\big(n, 1/k, \langle n\rangle\big)\, f_{\Gamma}(y, np, nb), \tag{16}$$

where $y = M_{p_T}$. For fixed n, and purely random fluctuations, the mean and standard deviation of M_{p_T} follow the expected behavior, $\langle M_{p_T}\rangle = \langle p_T\rangle$, $\sigma_{M_{p_T}} = \sigma_{p_T}/\sqrt{n}$. In PHENIX, Eq. (16) is used to confirm the randomness of mixed events which are used to define the baseline for random fluctuations of M_{p_T} [45,55].

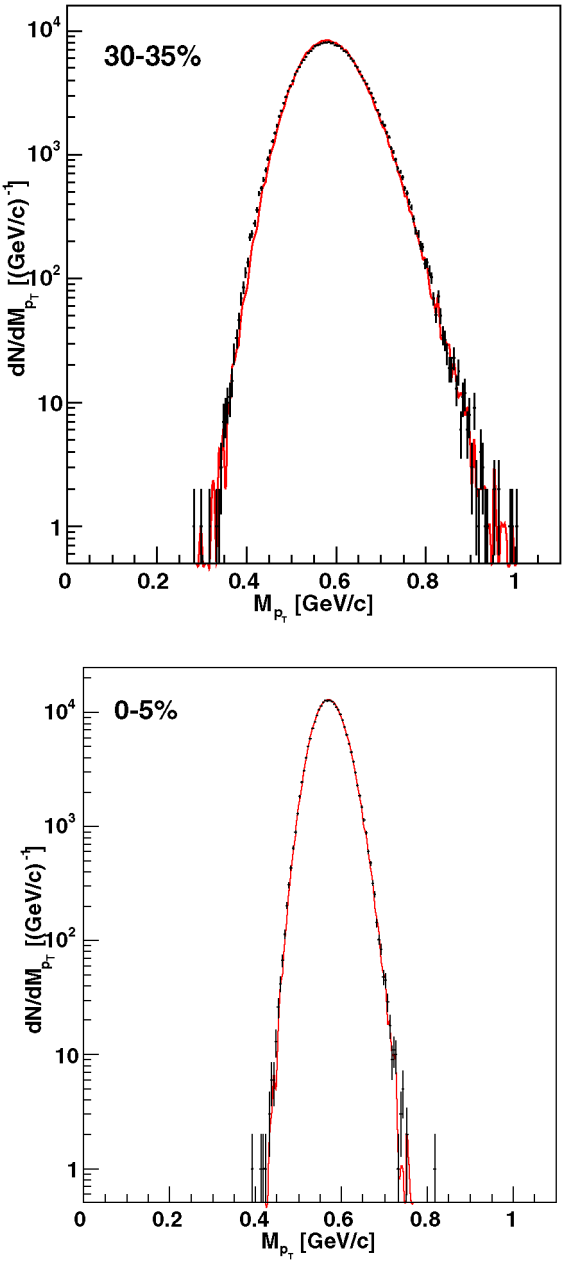

Fig. 23. M_{pT} for 30–35% and 0–5% centrality classes: data (points) mixed events (histogram) [55].

The measured M_{p_T} distributions for the data in two centrality classes for $\sqrt{s_{NN}} =$ 200 GeV Au + Au collisions in PHENIX [55] are shown in Fig. 23 (data points) compared to the mixed-event distributions (histograms). The non-Gaussian, gamma-distribution

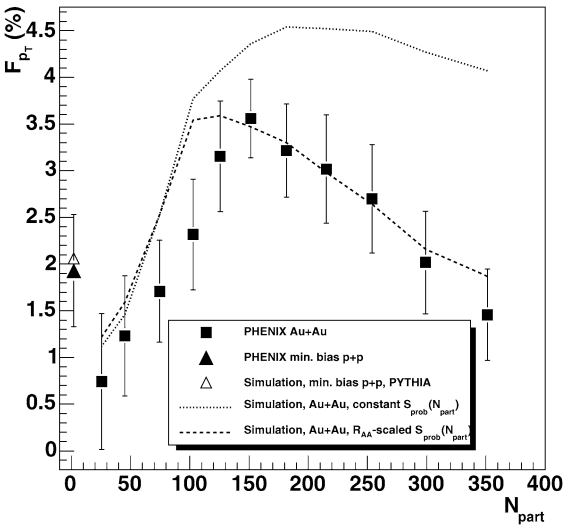

Fig. 24. F_{p_T} vs. centrality, represented as the average number of participants (N_{part}) in a centrality class, compared to jet simulation [55].

shape of the M_{p_T} distributions is evident. The difference between the data and the mixed-event random baseline distributions is not visible to the naked eye. The nonrandom fluctuation is quantified by the fractional difference of ω_{p_T}, the normalized standard deviation of M_{p_T}, for the data and the mixed-event (random) samples:

$$\omega_{p_T} = \frac{\sigma_{M_{p_T}}}{\langle M_{p_T} \rangle}, \tag{17}$$

$$F_{p_T} = \frac{\omega_{p_T,\text{data}} - \omega_{p_T,\text{mixed}}}{\omega_{p_T,\text{mixed}}}. \tag{18}$$

The results are shown as a function of centrality, represented by N_{part} in Fig. 24.

The dependence of F_{p_T} on N_{part} is striking. To further understand this dependence and the source of these nonrandom fluctuations, F_{p_T} was measured over a varying p_T range, $0.2\ \text{GeV}/c \leqslant p_T \leqslant p_T^{\text{max}}$ (Fig. 25), where $p_T^{\text{max}} = 2.0\ \text{GeV}/c$ for the N_{part} dependence.

The increase of F_{p_T} with p_T^{max} suggests elliptic flow or jet origin. This was investigated using a Monte Carlo simulation of correlations due to elliptic flow and jets in the PHENIX acceptance. The flow was significant only in the lowest centrality bin and negligible ($F_{p_T} < 0.1\%$) at higher centralities. Jets were simulated by embedding (at a uniform rate per generated particle, $S_{\text{prob}}(N_{\text{part}})$) $p + p$ hard-scattering events from the PYTHIA event generator into simulated Au + Au events assembled at random according to the measured N_{tracks} and semi-inclusive p_T distributions. This changed $\langle p_T \rangle$ and σ_{p_T} by less than 0.1%. $S_{\text{prob}}(N_{\text{part}})$ was either constant for all centrality classes, or scaled by the measured hard-scattering suppression factor $R_{AA}(N_{\text{part}})$ for $p_T > 4.5\ \text{GeV}/c$ [49]. A value $F_{p_T} = 2.06\%$ for $p + p$ collisions was extracted from pure PYTHIA events in the PHENIX acceptance in agreement with the $p + p$ measurement (Fig. 24). The value of $S_{\text{prob}}(N_{\text{part}})$ was chosen so that the simulation with $S_{\text{prob}}(N_{\text{part}}) \times R_{AA}(N_{\text{part}})$ agreed with

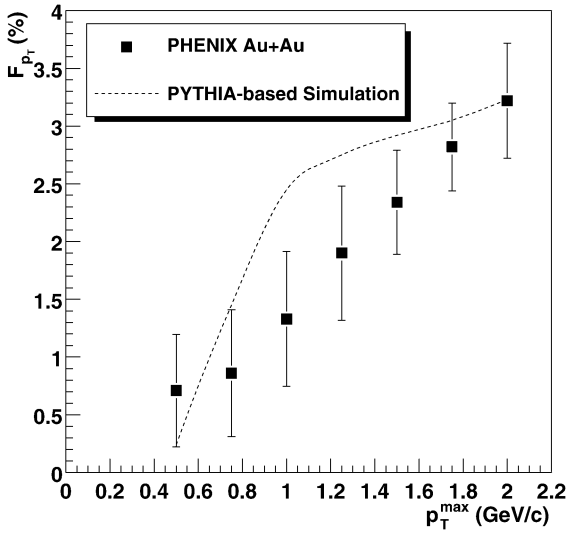

Fig. 25. F_{pT} vs. $p_T^{\max}$ compared to R_{AA}-scaled jet simulation for the 20–25% centrality class ($N_{\text{part}} = 181.6$) [55].

the data at $N_{\text{part}} = 182$. The centrality and $p_T^{\max}$ dependences of the measured F_{pT} match the simulation very well, but only when the R_{AA} scaling is included.

A less experiment-dependent method to compare nonrandom fluctuations is to assume that the entire F_{pT} is due to temperature fluctuations of the initial state, with RMS variation $\sigma_T/\langle T\rangle$ [45,142]. Then,

$$\omega^2_{p_T,\text{data}} - \omega^2_{p_T,\text{mixed}} = \left(1 - \frac{1}{\langle n\rangle}\right)\frac{\sigma_T^2}{\langle T\rangle^2} = 2F_{p_T}\omega^2_{p_T,\text{mixed}}, \tag{19}$$

This yields $\sigma_T/\langle T\rangle = 1.8\%$ for central collisions in PHENIX with similarly small values for the other Relativistic Heavy Ion experiments [143], 1.7% in STAR, 1.3% in CERES, and 0.6% in NA49. These results put severely small limits on the critical fluctuations that were expected for a sharp phase transition, both at SPS energies and at RHIC, but are consistent with the expectation from lattice QCD that the transition is a smooth crossover [12].

Other proposed explanations of the centrality and $p_T^{\max}$ dependences of F_{pT} include: overlapping color strings which form clusters so that the number of sources and $\langle p_T\rangle$ per source is modified as a function of centrality [144]; and near equilibrium p_T correlations induced by spatial inhomogeneity [145].

4.3. Conclusions

Critical behavior near the phase boundary can produce nonrandom fluctuations in observables such as the net-charge distribution and the average transverse momentum distribution. Our search for net-charge fluctuations has ruled out the most naive model of charge fluctuations in a QGP, but it is unclear whether the charge fluctuation signature can survive

hadronization. Our measurement of the event-by-event average p_T distribution shows a nonrandom fluctuation that is consistent with the effect expected from high-p_T jets. This puts a severe constraint on the critical fluctuations that were expected for a sharp phase transition but is consistent with the expectation from lattice QCD that the transition is a smooth crossover [12].

5. Binary scaling

5.1. Hard scattering and pQCD

One way to get a partonic probe into the midst of an $A + A$ collision is to use the high-p_T partons produced by hard scattering. For $p + p$ collisions in the RHIC energy range, hard scattering is considered to be the dominant process of particle production with $p_T \geqslant 2$ GeV/c at mid-rapidity. Typically, particles with $p_T \geqslant 2$ GeV/c are produced from states with two roughly back-to-back jets which are the result of scattering of constituents of the nucleons (partons) as described by pQCD [146].

The overall $p + p$ hard-scattering cross section in "leading logarithm" pQCD is the sum over parton reactions $a + b \to c + d$ (e.g., $g + q \to g + q$) at parton–parton center-of-mass (c.m.) energy $\sqrt{\hat{s}}$:

$$\frac{d^3\sigma}{dx_1\,dx_2\,d\cos\theta^*} = \frac{1}{s}\sum_{ab} f_a(x_1)\,f_b(x_2)\,\frac{\pi\alpha_s^2(Q^2)}{2x_1x_2}\,\Sigma^{ab}\big(\cos\theta^*\big), \tag{20}$$

where $f_a(x_1)$, $f_b(x_2)$, are parton distribution functions, the differential probabilities for partons a and b to carry momentum fractions x_1 and x_2 of their respective protons (e.g., $u(x_2)$), and where θ^* is the scattering angle in the parton–parton c.m. system. The parton–parton c.m. energy squared is $\hat{s} = x_1x_2s$, where $\sqrt{s}$ is the c.m. energy of the $p+p$ collision. The parton–parton c.m. system moves with rapidity $y = 1/2\ln(x_1/x_2)$ in the $p + p$ c.m. system.

Eq. (20) gives the p_T spectrum of outgoing parton c, which then fragments into hadrons, e.g., π^0. The fragmentation function $D_c^{\pi^0}(z,\mu^2)$ is the probability for a π^0 to carry a fraction $z = p^{\pi^0}/p^c$ of the momentum of outgoing parton c. Eq. (20) must be summed over all subprocesses leading to a π^0 in the final state. The parameter μ^2 is an unphysical "factorization" scale introduced to account for collinear singularities in the structure and fragmentation functions [146,147].

In this formulation, $f_a(x_1,\mu^2)$, $f_b(x_2,\mu^2)$ and $D_c^C(z,\mu^2)$ represent the "long-distance phenomena" to be determined by experiment; while the characteristic subprocess angular distributions, $\Sigma^{ab}(\cos\theta^*)$, and the coupling constant, $\alpha_s(Q^2) = \frac{12\pi}{25}\ln(Q^2/\Lambda^2)$, are fundamental predictions of QCD [148–150] for the short-distance, large-Q^2, phenomena. The momentum scale $Q^2 \sim p_T^2$ for the scattering subprocess, while $Q^2 \sim \hat{s}$ for a Compton or annihilation subprocess, but the exact meaning of Q^2 tends to be treated as a parameter rather than a dynamical quantity. The transverse momentum of a scattered constituent is

$$p_T = p_T^* = \frac{\sqrt{\hat{s}}}{2}\sin\theta^*. \tag{21}$$

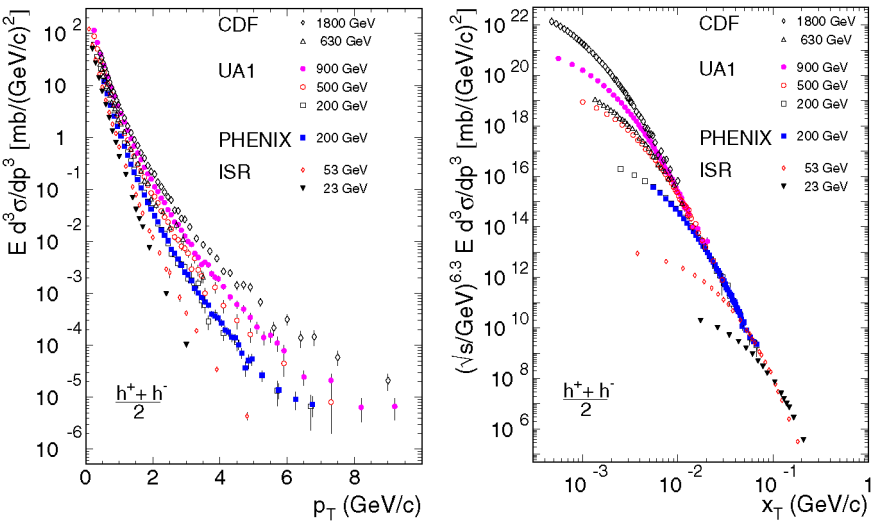

Fig. 26. Left: $E\,d^3\sigma(p_T)/d^3p$ at mid-rapidity as a function of $\sqrt{s}$ in $p+p$ collisions. Right: $(\sqrt{s}/\mathrm{GeV})^{6.3} \times E\,d^3\sigma/d^3p$ vs. $x_T = 2p_T/\sqrt{s}$ [53] (and references therein).

Eq. (20) leads to a general "x_T-scaling" form for the invariant cross section of high-p_T particle production:

$$E\frac{d^3\sigma}{d^3p} = \frac{1}{p_T^n}F(x_T) = \frac{1}{\sqrt{s}^n}G(x_T), \tag{22}$$

where $x_T = 2p_T/\sqrt{s}$. The cross section has two factors, a function $F(x_T)$ ($G(x_T)$) which "scales", i.e., depends only on the ratio of momenta, and a dimensioned factor, $1/p_T^n$ ($1/\sqrt{s}^n$), where n equals 4 in lowest-order (LO) calculations, analogous to the $1/q^4$ form of Rutherford Scattering in QED. The structure and fragmentation functions are all in the $F(x_T)$ ($G(x_T)$) term. Due to higher-order effects such as the running of the coupling constant, $\alpha_s(Q^2)$, the evolution of the structure and fragmentation functions, and the initial-state transverse momentum k_T, n is not a constant but is a function of x_T, $\sqrt{s}$. Measured values of $n(x_T, \sqrt{s})$ in $p+p$ collisions are between 5 and 8.

5.2. *Mid-rapidity p_T spectra from $p+p$ collisions*

The scaling and power-law behavior of hard scattering are evident from the $\sqrt{s}$ dependence of the p_T dependence of the $p+p$ invariant cross sections. This is shown for nonidentified charged hadrons, $(h^+ + h^-)/2$, in Fig. 26 (left). At low $p_T \leqslant 1$ GeV/c the cross sections exhibit a "thermal" $\exp(-6p_T)$ dependence, which is largely independent of $\sqrt{s}$, while at high p_T there is a power-law tail, due to hard scattering, which depends strongly on $\sqrt{s}$. The characteristic variation with $\sqrt{s}$ at high p_T is produced by the funda-

mental power-law and scaling dependence of Eqs. (20), (22). This is best illustrated by a plot of

$$\sqrt{s}^{n(x_T,\sqrt{s})} \times E\frac{d^3\sigma}{d^3p} = G(x_T), \tag{23}$$

as a function of x_T, with $n(x_T, \sqrt{s}) = 6.3$, which is valid for the x_T range of the present RHIC measurements (Fig. 26 (right)). The data show an asymptotic power law with increasing x_T. Data at a given $\sqrt{s}$ fall below the asymptote at successively lower values of x_T with increasing $\sqrt{s}$, corresponding to the transition region from hard to soft physics in the p_T region of about 2 GeV/c.

The PHENIX measurement of the invariant cross section for π^0 production in $p + p$ collisions at $\sqrt{s} = 200$ GeV [60] agrees with NLO pQCD predictions over the range $2.0 \leqslant p_T \leqslant 15$ GeV/c (Fig. 27).

5.3. Scaling hard scattering from $p + p$ to $p + A$ and $A + B$ collisions

Since hard scattering is point-like, with distance scale $1/p_T \leqslant 0.1$ fm, and the hard-scattering cross section factorizes as shown in Eq. (20), the cross section in $p + A$ or $A + B$ collisions, compared to $p + p$, is proportional to the relative number of possible point-like encounters. The number of encounters of point-like constituents of nucleons is then proportional to A (AB), for $p + A$ ($A + B$) minimum-bias collisions. For $A + B$ collisions at impact parameter b, it is proportional to $T_{AB}(b)$, the nuclear thickness function, which is the integral of the product of nuclear thickness over the geometrical overlap region of the two nuclei. In detail, the semi-inclusive invariant yield of, e.g., high-p_T π^0's for $A + B$ inelastic collisions, with centrality f, is related to the $p + p$ cross section by

$$\left.\frac{1}{N_{AB}^{\text{evt}}}\frac{d^2N_{AB}^{\pi^0}}{dp_T dy}\right|_f = \langle T_{AB}\rangle_f \times \frac{d^2\sigma_{pp}^{\pi^0}}{dp_T dy}. \tag{24}$$

Note that

$$\langle T_{AB}\rangle_f = \frac{\int_f T_{AB}(b)\,d^2b}{\int_f (1 - e^{-\sigma_{NN}T_{AB}(b)})\,d^2b} = \frac{\langle N_{\text{coll}}\rangle_f}{\sigma_{NN}}, \tag{25}$$

where $\langle N_{\text{coll}}\rangle_f$ is the average number of binary nucleon–nucleon inelastic collisions, with cross section σ_{NN}, in the centrality class f. This leads to the description of the scaling for point-like processes as binary-collision (or N_{coll}) scaling.

Nuclear medium effects, either in the initial or final state, can modify the expected scaling. These modifications can be quantitatively studied by measurement of the *nuclear modification factor* R_{AB}, which is defined as

$$R_{AB} = \frac{dN_{AB}^P}{\langle T_{AB}\rangle_f \times d\sigma_{NN}^P} = \frac{dN_{AB}^P}{\langle N_{\text{coll}}\rangle_f \times dN_{NN}^P}, \tag{26}$$

where dN_{AB}^P is the differential yield of a point-like process P in a $A + B$ collision and $d\sigma_{NN}^P$ is the cross section of P in $N + N$ collision. If there are no initial- or final-state effects that modify the yield of P in $A + B$ collisions, the process P scales with $\langle T_{AB}\rangle_f$

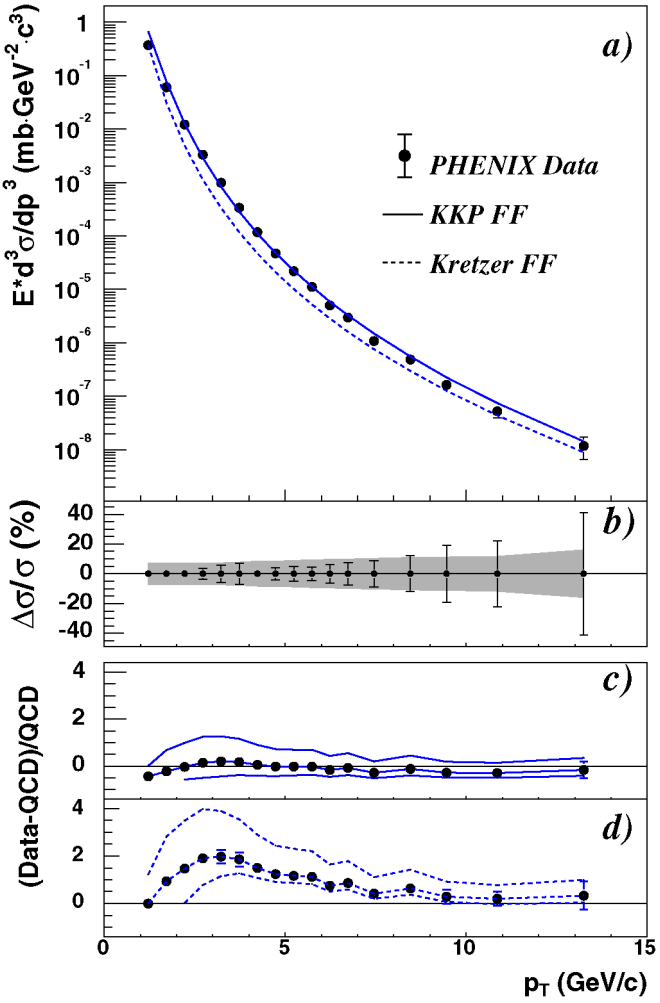

Fig. 27. PHENIX π^0 invariant cross section at mid-rapidity from $p+p$ collisions at $\sqrt{s} = 200$ GeV, together with NLO pQCD predictions from Vogelsang [151,152]. (a) The invariant differential cross section for inclusive π° production (points) and the results from NLO pQCD calculations with equal renormalization and factorization scales of p_T using the "Kniehl–Kramer–Pötter" (solid line) and "Kretzer" (dashed line) sets of fragmentation functions. (b) The relative statistical (points) and point-to-point systematic (band) errors. (c), (d) The relative difference between the data and the theory using KKP (c) and Kretzer (d) fragmentation functions with scales of $p_T/2$ (lower curve), p_T, and $2p_T$ (upper curve). In all figures, the normalization error of 9.6% is not shown [60].

and $R_{AB} = 1$. Sometimes, the central to peripheral ratio, R_{CP}, is used as an alternative to R_{AB}. The central to peripheral ratio is defined as

$$R_{CP} = \frac{dN^{\text{Central}}/\langle N_{\text{coll}}^{\text{Central}}\rangle}{dN^{\text{Peripheral}}/\langle N_{\text{coll}}^{\text{Peripheral}}\rangle}, \tag{27}$$

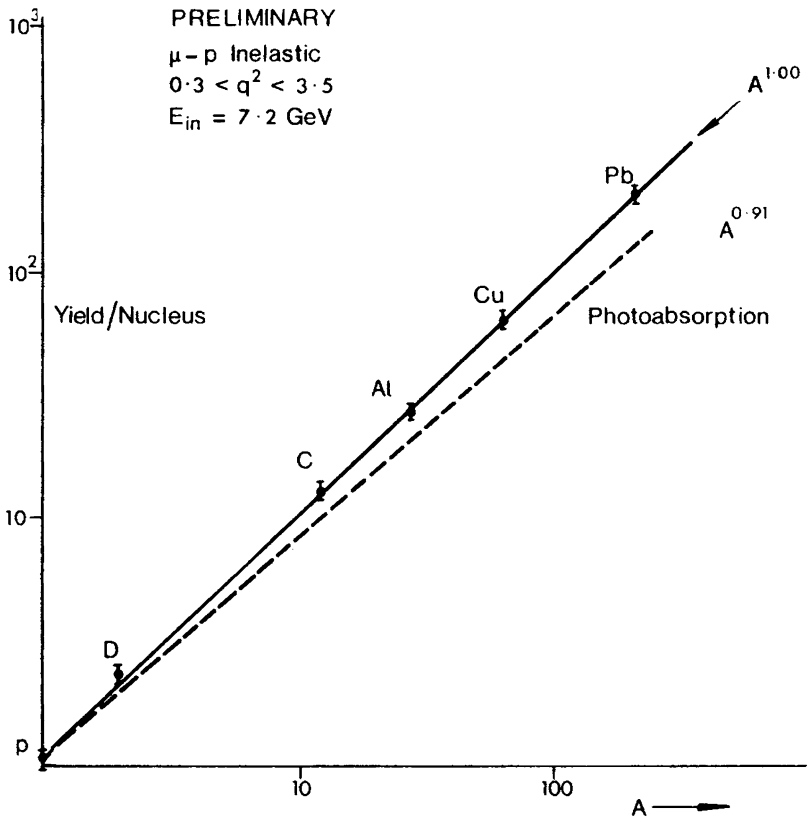

Fig. 28. μ–A cross section vs. A [156].

where dN^{Central} and $dN^{\text{Peripheral}}$ are the differential yield per event of the studied process in a central and peripheral collision, respectively. If the yield of the process scales with the number of binary collisions, $R_{CP} = 1$.

5.4. Binary scaling in $l + A$, $p + A$, and low-energy $A + A$

In deeply inelastic lepton scattering, where hard scattering was discovered [153–155], the cross section for $\mu + A$ collisions is indeed proportional to $A^{1.00}$ (Fig. 28). This indicates that the structure function of a nucleus of mass A is simply A times the structure function of a nucleon (with only minor deviations, $\leqslant 10\%$ for $0.02 \leqslant x \leqslant 0.50$ [157]), which means that the nucleus acts like an incoherent superposition of nucleons for hard scattering of leptons.

The situation is rather different in $p + A$ collisions: the cross section at a given p_T also scales as a power law, $A^{\alpha(p_T)}$ (Fig. 29), but the power $\alpha(p_T)$ is greater than 1. This is called the "Cronin effect" [158]. The enhancement (relative to $A^{1.00}$) is thought to be due to the multiple scattering of the incident partons while passing through the nucleus A before the collision [159,160], which smears the axis of the hard scattering relative to the axis of the

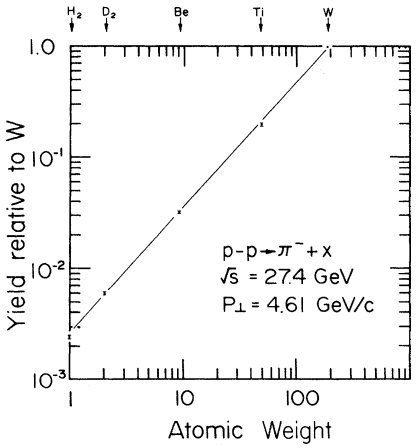

Fig. 29. Cronin effect in $p + A$, for π^- with $p_T = 4.61$ GeV/c. $\alpha(p_T) = 1.148 \pm 0.010$ [158].

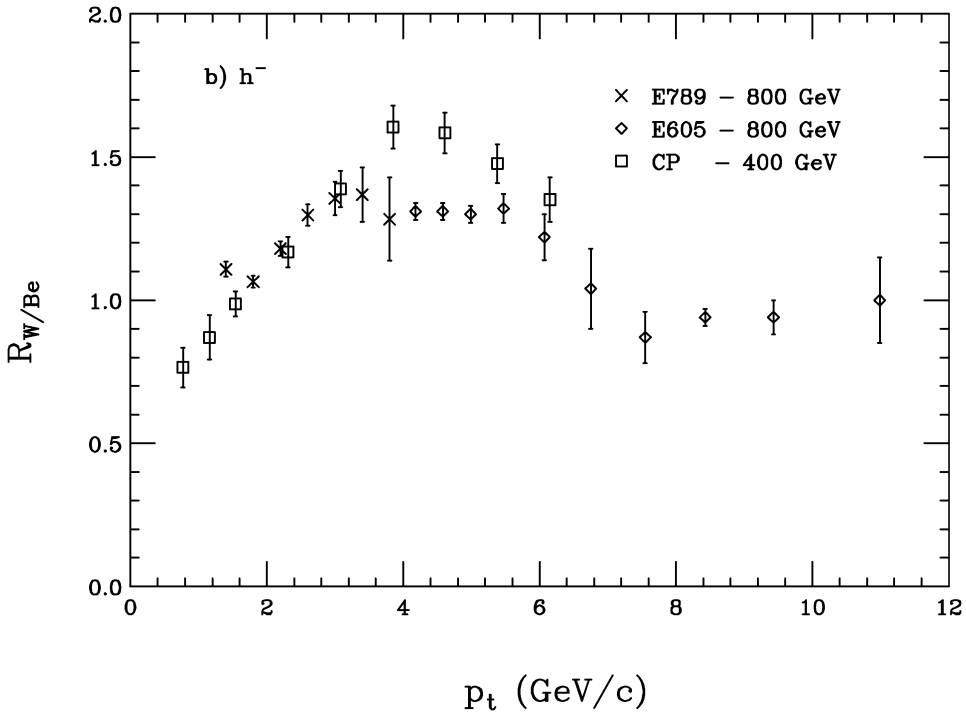

Fig. 30. Cronin effect at fixed target energies expressed as $R_{\mathrm{W/Be}}$, the ratio of the point-like scaled cross sections in $p + \mathrm{W}$ and $p + \mathrm{Be}$ collisions vs. p_T [161].

incident beam, leading to the characteristic "Cronin effect" shape for $R_A(p_T)$ (Fig. 30). At low $p_T < 1$ GeV/c, the cross-section is no longer point-like, so the scattering is shadowed ($\propto A^{2/3}$), thus $R_A < 1$. At larger $p_T > 2$ GeV/c, as the hard-scattering, power-law p_T

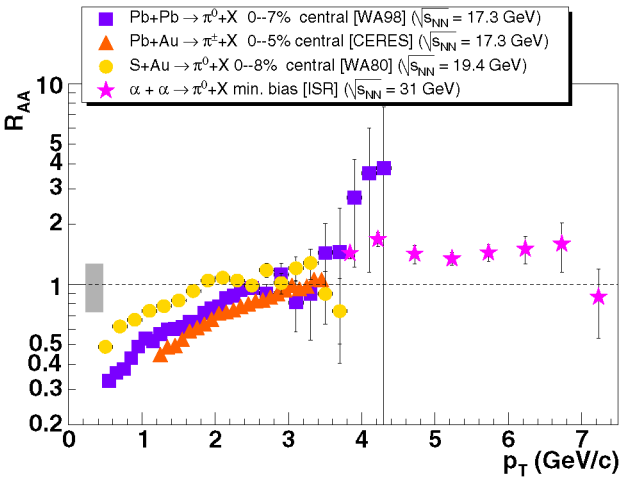

Fig. 31. Nuclear modification factors for π^0 production at the CERN-ISR in minimum-bias $\alpha + \alpha$ reactions at $\sqrt{s_{NN}} = 31$ GeV [162] and for pion production at the CERN-SPS in central Pb + Pb [163], Pb + Au [164], and S + Au [165] reactions at $\sqrt{s_{NN}} \approx 20$ GeV. The R_{AA} from SPS are obtained using the $p + p$ parametrization proposed in Ref. [166]. The shaded band around $R_{AA} = 1$ represents the overall fractional uncertainty of the SPS data (including in quadrature the 25% uncertainty of the $p + p$ reference and the 10% error of the Glauber calculation of N_{coll}). There is an additional overall uncertainty of ±15% for the CERES data not shown in the plot [164].

spectrum begins to dominate, the multiple scattering smears the spectrum to larger p_T leading to an enhancement relative to binary-scaling which dissipates with increasing p_T as the influence of the multiple scattering diminishes.

Previous measurements of high-p_T particle production in $A + A$ collisions at $\sqrt{s_{NN}} \leqslant 31$ GeV (Fig. 31) and in $p + A$ (or $d + A$) collisions (Fig. 30) including measurements at RHIC [64] at mid-rapidity (Fig. 32) all show binary scaling or a Cronin effect.

This establishes that the initial condition for hard scattering at RHIC at mid-rapidity is an incoherent superposition of nucleon structure functions, including gluons, where multiple scattering before the hard collision smears the p_T spectrum of scattered particles to be somewhat above the simple point-like binary (N_{coll}) scaling.

An alternative view of the initial state of a nucleus at RHIC is provided by the color glass condensate (CGC), in which the gluon population at low x is not an incoherent superposition of nucleon structure functions but is limited with increasing A by nonlinear gluon–gluon fusion resulting from the overlap of gluons from several nucleons in the plane of the nucleus transverse to the collision axis [168]. A Cronin effect in $d + A$ collisions, as shown in Fig. 32, can be reproduced in the CGC with a suitable choice of initial state parameters, which must also reproduce quantitatively the observed binary scaling of the direct photon production and total charm production in Au + Au collisions to be shown below (Figs. 33, 34). However, at this writing, no detailed quantitative description of the CGC initial state which satisfies these three conditions has been published.

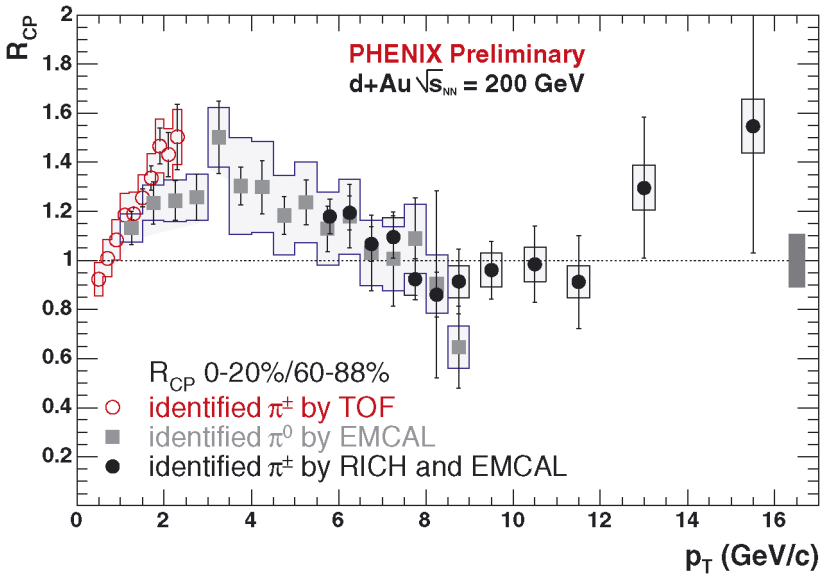

Fig. 32. Cronin effect in R_{CP}, the ratio of point-like scaled central to peripheral collisions for pions in $d + \mathrm{Au}$ at $\sqrt{s_{NN}} = 200$ GeV [167]. Data points for low p_T are $\pi^{\pm}$ identified by Time of Flight (TOF). Data at medium p_T are for π^0 identified by reconstruction in the Electromagnetic Calorimeter (EMCAL). Highest p_T data are for $\pi^{\pm}$ identified by a count in the Ring Imaging Cerenkov Counter (RICH) and a deposited energy/momentum and shower shape in the EMCAL inconsistent with those of a photon or electron. The shaded band on the right represents the overall fractional systematic uncertainty due to N_{coll}.

5.5. *Binary scaling in Au + Au collisions at RHIC—direct photons and charm yield*

The production of hard photons in Au + Au collisions at RHIC via the constituent reactions (e.g., $g + q \to \gamma + q$) is a very important test of QCD and the initial state, because the photons only interact electromagnetically, hence hardly at all, with any final-state medium produced. The direct-photon cross section and centrality dependence should then reflect only the properties of the initial state, notably the product of the gluon and quark structure functions of the Au nuclei.

The first measurement of direct photon production in Au + Au collisions at RHIC has been reported by the PHENIX Collaboration (Fig. 33) [73]. The data exhibit pure point-like (N_{coll}) scaling as a function of centrality relative to a pQCD calculation for $p + p$ collisions. The statistical and systematic errors still leave some room for a small Cronin effect and/or some thermal photon production. The observation of direct photon production establishes the importance of gluon degrees of freedom at RHIC.

PHENIX measured the single-electron yield from nonphotonic sources in Au + Au collision at 130 GeV [42] and 200 GeV [57]. Since semi-leptonic decay of charm is the dominant source of the nonphotonic electrons at low p_T ($p_T \leqslant 3\ \mathrm{GeV}/c$), the total yield of charm can be determined from the integrated yield of nonphotonic electrons in the low-p_T region. Fig. 34 shows the yield of nonphotonic electrons ($0.8 < p_T < 4.0\ \mathrm{GeV}/c$) per NN collision in Au + Au reactions at $\sqrt{s_{NN}} = 200$ GeV as a function of N_{coll} [57]. The N_{coll}

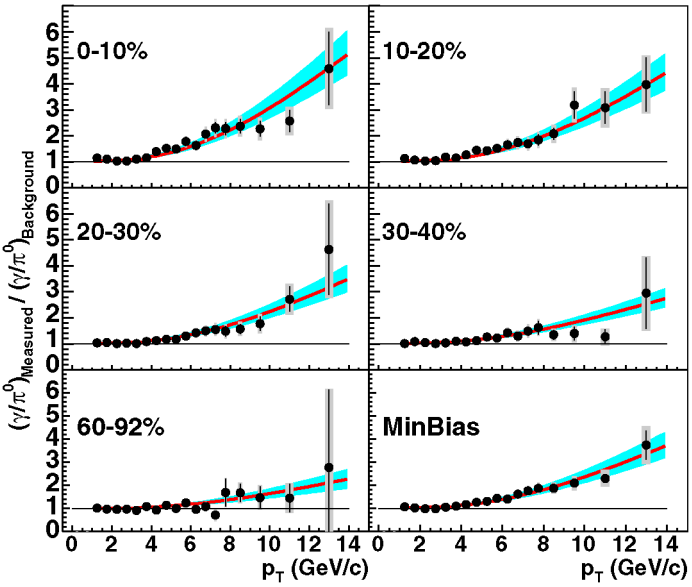

Fig. 33. PHENIX direct photon measurements relative to the background for minimum bias and for five centralities of Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV (0–10% is the most central). Statistical and total errors are indicated separately on each data point by the vertical bar and shaded region, respectively. The curves represent a pQCD calculation of direct photons in $p + p$ collisions from Vogelsang [169–172] scaled to Au + Au assuming pure point-like ($N_{\rm coll}$) scaling, with no suppression. The shaded region around the curves indicate the variation of the pQCD calculation for scale changes from $p_T/2$ to $2p_T$, plus the $\langle N_{\rm coll}\rangle$ uncertainty [73].

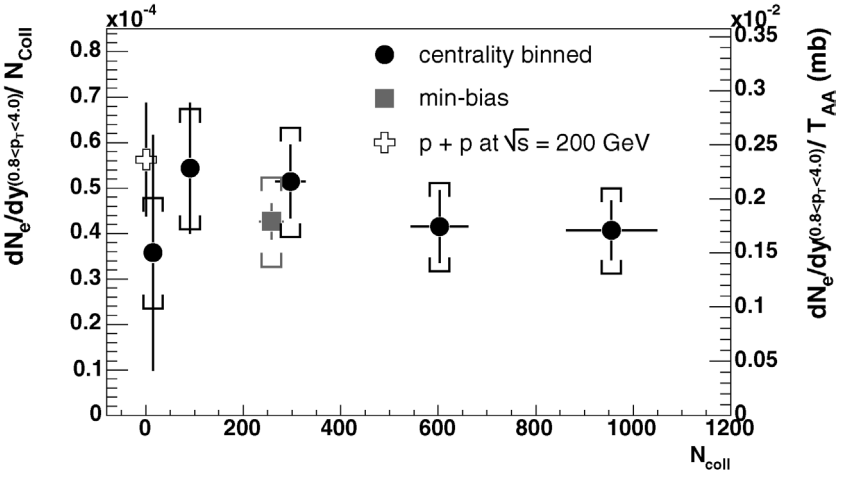

Fig. 34. Nonphotonic electron yield ($0.8 < p_T < 4.0$ GeV/c), dominated by semi-leptonic charm decays, measured in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV scaled by $N_{\rm coll}$ as a function of $N_{\rm coll}$. The right-hand scale shows the corresponding electron cross section per NN collision in the above p_T range. The yield in $p + p$ collision at 200 GeV is also shown [57].

dependence of the yield is fit to $N_{\rm coll}^{\alpha}$, where $\alpha = 1$ is the expectation for binary scaling. We find $\alpha = 0.938 \pm 0.075(\text{stat.}) \pm 0.018(\text{sys.})$, showing that the total yield of charm-decay electrons is consistent with binary scaling. It should be noted that medium effects, such as energy loss of charm in the dense hot medium, can only influence the momentum distribution of charm, and have little effect on the total yield of charm. Initial-state effects, such as shadowing, and other effects, such as thermal production of charm, are believed to be very small for charm production at RHIC energy. Therefore, the observation of binary scaling of the total charm yield in Au + Au collisions at RHIC may also be considered as an experimental verification of the binary scaling of a point-like pQCD process.

5.6. Conclusions

In this section evidence has been presented to show that the initial condition for hard-scattering at RHIC at mid-rapidity is an incoherent superposition of nucleon structure functions, including gluons, where multiple scattering before the hard collision can smear the p_T spectrum of scattered particles to be somewhat above the simple point-like binary ($N_{\rm coll}$) scaling. This was demonstrated using the reactions: pion production in d + Au collisions, where there is no final-state medium, and direct photon production in Au + Au collisions, where the outgoing photons interact electromagnetically, hence hardly at all, with any final-state medium produced. The total charm yield in Au + Au, a reaction dominated by the subprocess $g + g \to c + \bar{c}$, and which is not sensitive to final-state medium effects for the total yield of $c + \bar{c}$ pairs, also exhibits binary scaling. The latter two measurements provide experimental evidence for the binary scaling of point-like pQCD processes in Au + Au collisions.

The color glass condensate (CGC) provides an alternative view of the initial state of a nucleus at RHIC in which coherence of gluons due to nonlinear gluon–gluon fusion can produce a Cronin-like effect, depending on the initial conditions and the kinematic range covered. However, at the present writing, there is no CGC description of the initial state nuclear structure function which reproduces the observed Cronin effect for pions in d + Au collisions and the observed binary scaling for both direct photon production and the total charm yield in Au + Au collisions.

6. Number density and high p_T suppression

To study the initial properties of the matter created in heavy ion collisions we need a probe that is already present at the earliest times and that is directly sensitive to the properties of the medium. Partons resulting from hard scatterings during the initial crossing of the two nuclei in $A + A$ collisions provide such a probe. Energetic partons propagating through a dense medium are predicted to lose energy [173–181] thus producing a suppression in the yield of high-p_T hadrons produced from the fragmentation of these partons. Initial measurements from RHIC Run 1 [39,47,182] and Run 2 [49,53,183,184] demonstrated such a suppression, and the results of d + Au measurements [64,66–68] showed that the suppression was not due to initial-state effects. Further measurements have in-

dicated a modification of dijet angular correlations [68] that has also been attributed to in-medium parton energy loss [185,186].

While the energy loss of hard-scattered partons was originally proposed as a signature of the quark–gluon plasma and deconfinement, it has been argued recently that the energy loss is sensitive only to the density of unscreened color charges and not directly to deconfinement [177–181,187,188]. Ideally, a measurement of initial parton densities together with constraints on initial energy density might allow an estimate of the temperature of the medium. As will be seen below, the current high-p_T measurements and theoretical tools for interpreting the experimental data are not yet sufficient to take such a step. Instead, the energy loss results are currently being used to provide estimates of the initial energy density. The remainder of this section summarizes PHENIX experimental data related to high-p_T suppression, discusses the current state of theoretical understanding of the energy loss process and concludes with a statement of estimates for initial parton number and energy densities that currently can be made.

6.1. Single particle spectra, R_{AA}

As described in Section 5, in the absence of modifications due to initial-state or final-state effects, the rate for the production of particles through hard-scattering processes in nucleus–nucleus collisions is expected to be given by the equivalent $p+p$ hard-scattering cross section multiplied by T_{AB}. Fig. 35 shows PHENIX π^0 spectra, $d^2N/dp_T\,dy$, measured in $\sqrt{s_{NN}}$ GeV [49] peripheral (80–92%) and central (0–10%) Au + Au collisions compared to measured [60] $p+p$ cross sections multiplied by the peripheral and central T_{AB} values estimated using the procedure described in Section 5. The error bands on the $p+p$ data points reflect both the systematic errors on the $p+p$ cross sections and the uncertainties in the T_{AB} values. As the figure clearly demonstrates, the central Au + Au π^0 yields are strongly suppressed relative to the "expected" yields over the entire measured p_T range. In contrast, the peripheral yields compared to the T_{AB}-scaled $p+p$ cross sections show little or no suppression. The results incontrovertibly demonstrate that there is a strong and centrality-dependent suppression of the production of high-p_T pions relative to pQCD-motivated expectations. This is quite different from measurements of R_{AA} in Pb + Pb collisions at $\sqrt{s_{NN}} = 17.3$ GeV where in semi-peripheral Pb + Pb collisions there is a nuclear enhancement increasing with p_T similar to the well-known Cronin effect, while in central collisions the Cronin enhancement appears to be weaker than expected (see Fig. 31).

To better demonstrate quantitatively the suppression in central collisions indicated in Fig. 35, we show in Fig. 36 $R_{AA}(p_T)$ for mid-rapidity π^0's in central and peripheral 200 GeV Au + Au collisions. We also show the values obtained from minimum-bias 200 GeV d + Au collisions [64] which provide a stringent test of the possible contribution of initial-state nuclear effects to the observed suppression in Au + Au collisions. The error bands on the data indicate combined statistical and point-to-point systematic errors and the bars shown next to the different data sets indicate common systematic errors due to uncertainties in the $p+p$ cross section normalization and T_{AB}.

Fig. 36 shows that the central Au + Au π^0 suppression changes only slightly over the measured p_T range and reaches an approximately p_T-independent factor of 5 ($R_{AA} \approx 0.2$)

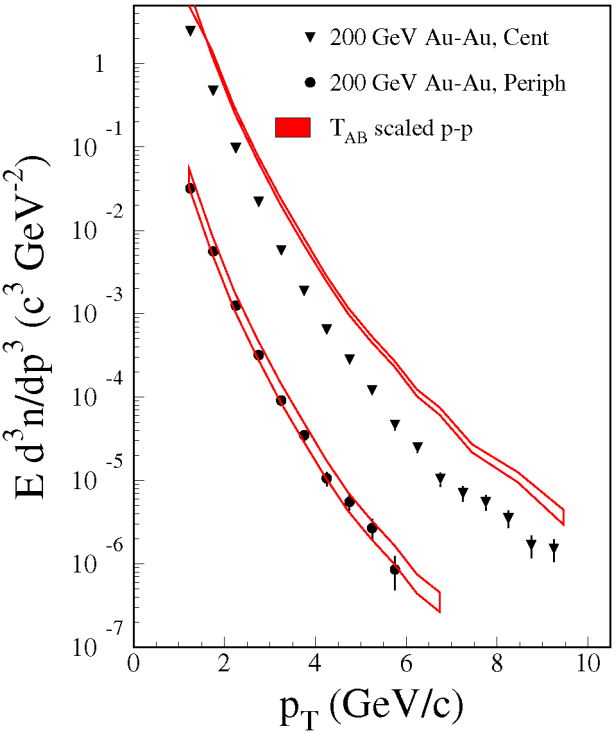

Fig. 35. π^0 p_T spectra in 200 GeV Au + Au collisions [49] compared to a T_{AB} scaling of the 200 GeV $p+p$ π^0 differential cross section [60]. The central data were obtained with a 0–10% centrality cut while the peripheral data were obtained with an 80–92% cut.

for $p_T > 4$–5 GeV/c. The peripheral Au + Au R_{AA} values are consistent with one after taking into account systematic errors but we cannot rule out a slight suppression suggested by the peripheral R_{AA} values. In all of the data sets R_{AA} decreases with decreasing p_T for $p_T < 2$ GeV/c. This decrease, known since the original measurements of the A dependence of particle production in $p+A$ collisions is due to contributions of soft hadronic processes at low p_T that are expected to increase more slowly than proportional to T_{AB}. The $d+$Au R_{dA} values are also consistent with one within systematic uncertainties, but in contrast to the Au + Au results, the data suggest a slight enhancement. The $d+$Au R_{dA} values above 2 GeV/c exceed one for nearly the entire experimentally covered p_T range. As shown previously in Fig. 32, only for $p_T \gtrsim 6$ GeV/c does the $d+$Au pion yield return to the T_{AB}-scaling expectation. Such a small enhancement is consistent with expectations based on prior measurements of the Cronin effect [189,190], and it is also quantitatively consistent with calculations incorporating the initial-state multiple scattering that is thought to produce the Cronin effect [191–197]. Therefore the Cronin effect at RHIC is small and cannot mask a strong suppression of high p_T particle production due to initial-state parton saturation as suggested by Ref. [198].

To better demonstrate the systematic behavior of the high-p_T suppression we show in Fig. 37 π^0 [49] and unidentified charged particle R_{AA} values [53] as a function of p_T for

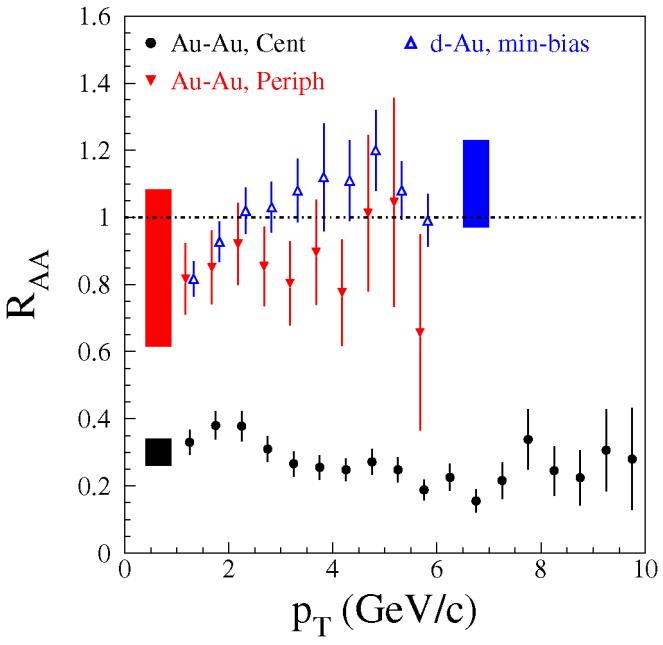

Fig. 36. π^0 $R_{AA}(p_T)$ for central (0–10%) and peripheral (80–92%) Au + Au collisions [49] and minimum-bias d + Au collisions [64]. The shaded boxes on the left show the systematic errors for the Au + Au R_{AA} values resulting from overall normalization of spectra and uncertainties in T_{AB}. The shaded box on the right shows the same systematic error for the d + Au points.

various centrality bins. While for moderate p_T values ($2 < p_T < 5$ GeV/c) total charged particle production is suppressed less than pion production, the charged particle and π^0 R_{AA} values become equal, within errors, at high p_T. This evolution in the charged particle suppression is related to contributions from the (anti)protons that will be discussed further below. Despite the differences resulting from the protons, the charged particles and π^0's exhibit very similar trends in the suppression vs. p_T and vs. centrality. The suppression increases smoothly with centrality though the change in R_{AA} values at high p_T is most rapid in the middle of the centrality range. Fig. 37 also shows that the suppression is approximately constant as a function of p_T for $p_T > 4.5$ GeV/c in all centrality bins. We take advantage of this feature of the data to better illustrate the centrality dependence of the suppression by integrating both the Au + Au spectra and the reference $p + p$ cross sections over $p_T > 4.5$ GeV/c and using these integrated quantities to determine an average suppression factor, R_{AA} for $p_T > 4.5$ GeV/c. We plot the charged particle and π^0 R_{AA} values vs. N_{part} in Fig. 38 (top). This figure suggests that the suppression evolves smoothly with N_{part}, showing no abrupt onset of suppression. The charged particles and π^0's exhibit similar evolution of suppression with N_{part}. In the most central collisions we obtain R_{AA} values of 0.24 ± 0.04 (total) and 0.23 ± 0.05 (total) for charged particles and π^0's, respectively. In peripheral collisions, R_{AA} approaches one, but the systematic errors on the most peripheral T_{AB} values are sufficiently large that we cannot rule out $\sim 20\%$ deviations of the peripheral Au + Au hard-scattering yields from the T_{AB}-scaled $p + p$ cross sections.

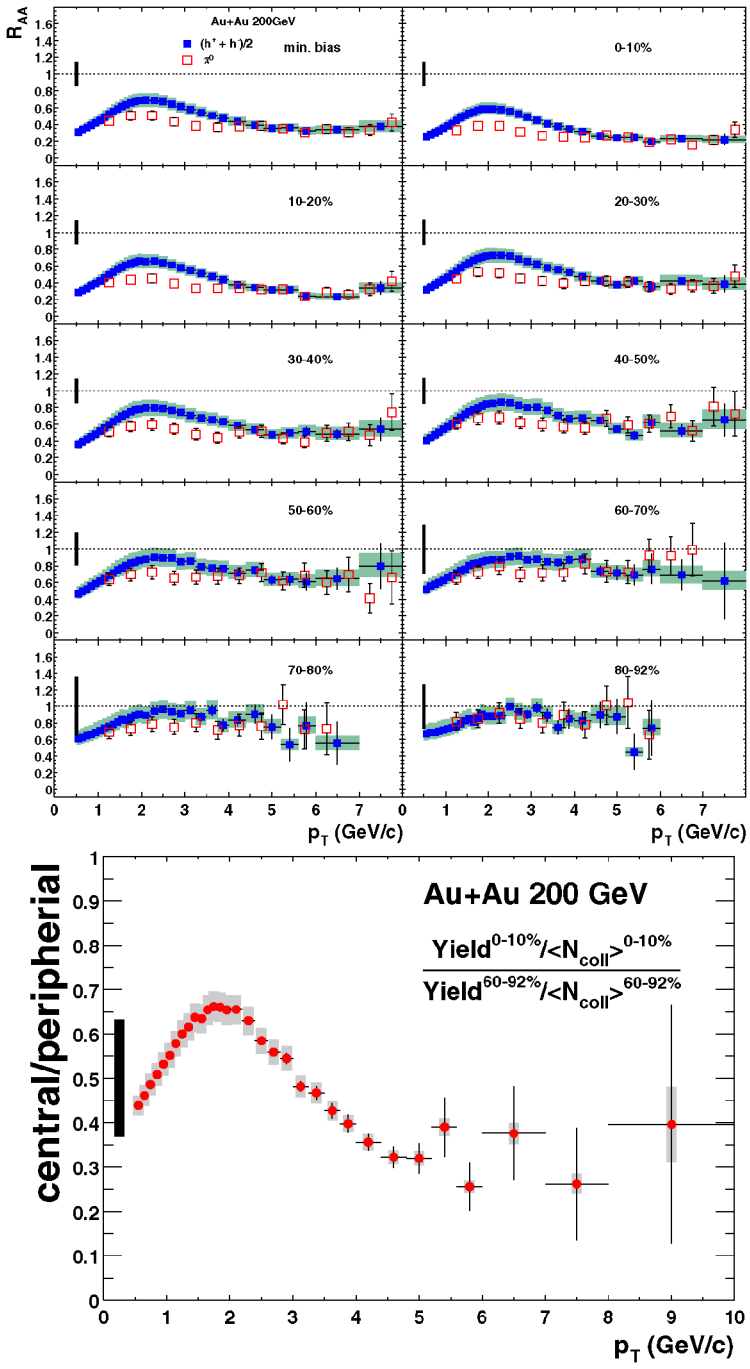

Fig. 37. Centrality and p_T dependence of nuclear modification factors in 200 GeV Au + Au collisions [53]. Top panel: π^0 and charged particle $R_{AA}(p_T)$ for ten centrality bins. Bottom panel: charged particle R_{CP} vs. p_T.

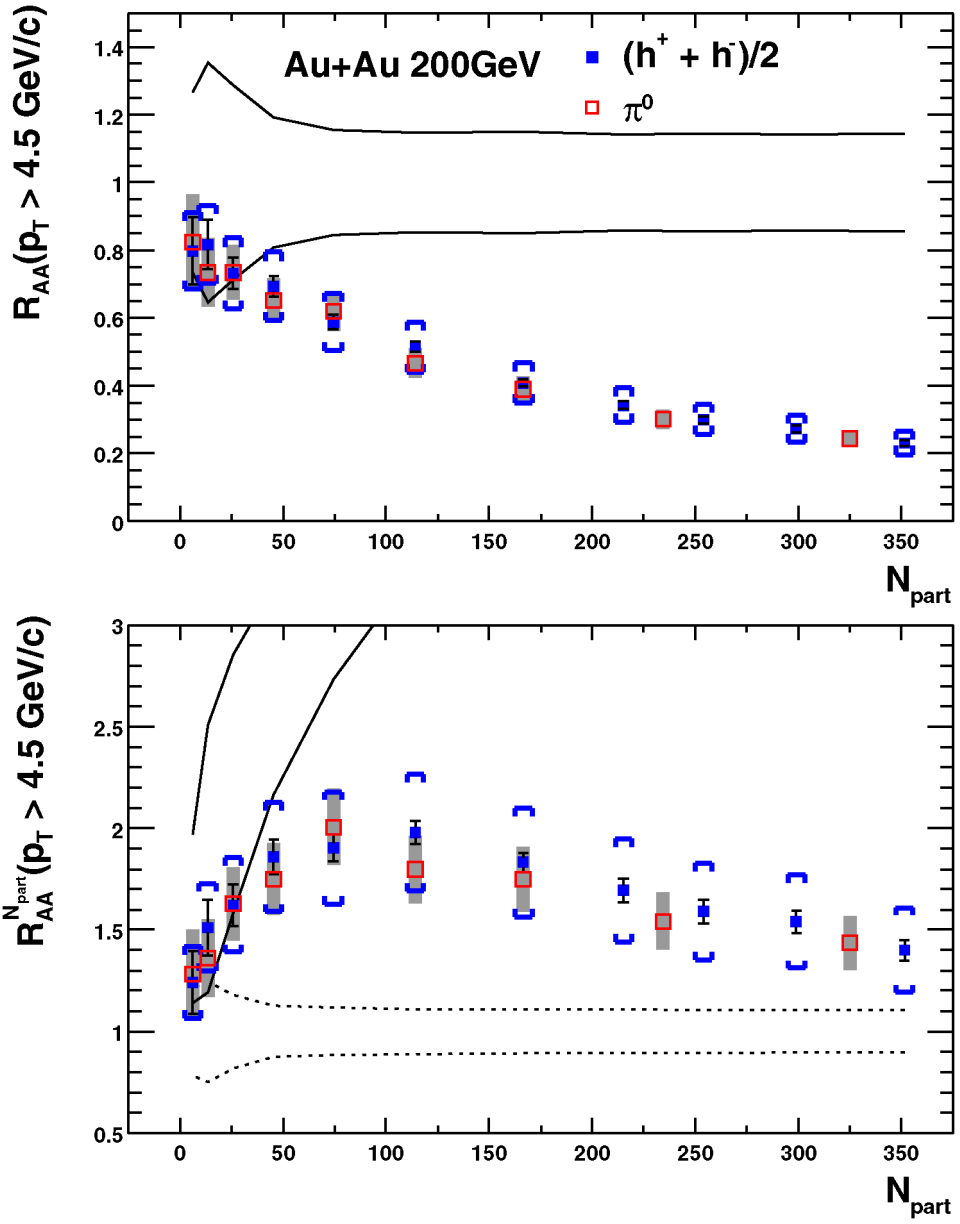

Fig. 38. Top panel: R_{AA} vs. N_{part} obtained from p_T-integrated ($p_T > 4.5$ GeV/c) Au + Au π^0 and charged-hadron spectra. The band indicates the systematic error bands on a hypothetical T_{AB} scaling of the $p + p$ p_T-integrated cross section. Bottom panel: π^0 and charged hadron yield per participant vs. N_{part} divided by the same quantity in $p + p$ collisions ($R_{AA} N_{\text{part}}$). The solid band shows the same band as in the top panel expressed in terms of yield per participant pair while the dashed band indicates the systematic error bands around a hypothetical N_{part} scaling. Both plots are from [53].

An alternative method for evaluating the evolution of the high-p_T suppression with centrality is provided in Fig. 38 (bottom) which presents the charged and π^0 yields per participant integrated over $p_T > 4.5$ GeV/c as a function of $N_{\rm part}$ [53] divided by the same quantity in $p+p$ collisions. Also shown in the figure are curves demonstrating the $N_{\rm part}$ dependence that would result if the π^0 and charged particle yields exactly T_{AB} scaled and what an $N_{\rm part}$ scaling from $p+p$ collisions would imply. As Fig. 38 demonstrates, the high-p_T yields of both charged hadrons and π^0's *per participant* increase proportional to T_{AB} for small $N_{\rm part}$ but level off and then decrease with increasing $N_{\rm part}$ in more central collisions. The PHENIX measurements do not naturally support an approximate $N_{\rm part}$ scaling of high-p_T particle production suggested in an analysis of PHOBOS data [184]. The PHENIX $R_{AA}^{N_{\rm part}}$ values decrease from mid-peripheral ($N_{\rm part} \approx 75$) to central collisions by an amount larger than the systematic errors in the measurement. For more peripheral collisions, $R_{AA}^{N_{\rm part}}$ increases with $N_{\rm part}$ consistent with the modest suppression of high-p_T production shown for peripheral collisions in the top panel of Fig. 38. The initial rise and subsequent decrease of $R_{AA}^{N_{\rm part}}$ with increasing $N_{\rm part}$ suggests that the high-p_T hadron yield in Au + Au collisions has no simple dependence on $N_{\rm part}$. The observation that the high-p_T yields initially increase proportional to T_{AB} demonstrates that in the most peripheral Au + Au collisions the hard-scattering yields are consistent with point-like scaling. However, the deviation from T_{AB} scaling sets in rapidly, becoming significant by $N_{\rm part} = 50$. By $N_{\rm part} = 100$ the high-p_T suppression is so strong that high-p_T yields grow even more slowly than proportional to $N_{\rm part}$.

6.2. x_T scaling in Au + Au collisions at RHIC

If the production of high-p_T particles in Au + Au collisions is the result of hard scattering according to pQCD, then x_T scaling should work just as well in Au + Au collisions as in $p+p$ collisions and should yield the same value of the exponent $n(x_T, \sqrt{s})$. The only assumption required is that the structure and fragmentation functions in Au + Au collisions should scale, in which case Eq. (23) still applies, albeit with a $G(x_T)$ appropriate for Au + Au. In Fig. 39, $n(x_T, \sqrt{s_{NN}})$ in Au + Au is derived from Eq. (23), for peripheral and central collisions, by taking the ratio of $E\,d^3\sigma/dp^3$ at a given x_T for $\sqrt{s_{NN}} = 130$ and 200 GeV, in each case. The π^0's exhibit x_T scaling, with the same value of $n = 6.3$ as in $p+p$ collisions, for both Au + Au peripheral and central collisions, while the nonidentified charged hadrons x_T-scale with $n = 6.3$ for peripheral collisions only. Notably, the $h^{\pm}$ in Au + Au central collisions exhibit a significantly larger value of n, indicating different physics, which will be discussed below. The x_T scaling establishes that high-p_T π^0 production in peripheral and central Au + Au collisions and $h^{\pm}$ production in peripheral Au + Au collisions follow pQCD as in $p+p$ collisions, with parton distributions and fragmentation functions that scale with x_T, at least within the experimental sensitivity of the data.

6.3. Two-hadron azimuthal-angle correlations

We argued in Section 5 that the production of hadrons at high-p_T results predominantly from hard scattering followed by fragmentation of the outgoing parton(s). While

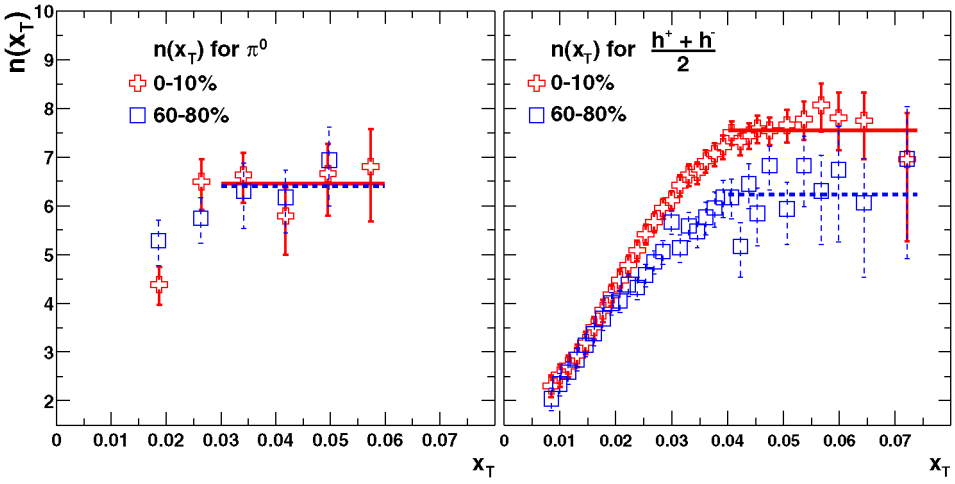

Fig. 39. Power-law exponent $n(x_T)$ for π^0 and h spectra in central and peripheral Au + Au collisions at $\sqrt{s_{NN}} = 130$ and 200 GeV [53].

this result is well established in $p(\bar{p}) + p$ collisions, it might not be true in Au + Au collisions when the yield of high-p_T particles is modified so dramatically compared to expectations. Since a hard-scattered parton fragments into multiple particles within a restricted angular region (i.e., a jet) a reasonable way to check the assumption that high-p_T hadron production in Au + Au collisions is due to hard scattering is to directly observe the angular correlations between hadrons in the jets. None of the experiments at RHIC are currently capable of reconstructing jets in the presence of the large soft background of a Au + Au collision. However, both STAR [199,200] and PHENIX [201,202] have directly observed the presence of jets by studying two-hadron azimuthal-angle correlations. Fig. 40 shows preliminary distributions [201] of the relative azimuthal angle ($\Delta\phi$) between pairs of charged particles detected within the PHENIX acceptance in d + Au collisions and peripheral (60–90%) and central (0–10%) Au + Au collisions after the subtraction of combinatoric background. The pairs of particles are chosen such that one particle lies within a "trigger" p_T range ($2.5 < p_{T\,\mathrm{trig}} < 4$ GeV/c) while the other "associated" particle falls within a lower p_T window $1.0 < p_T < 2.5$ GeV/c. The distributions show the differential yield per $\Delta\phi$ of associated particles per detected trigger particle within the given p_T ranges and within the η acceptance of the PHENIX central arms ($-0.35 < \eta < 0.35$).

The peaks observed at $\Delta\phi = 0$ (near side) reflect the correlation between hadrons produced within the same jet while the broader peaks observed at $\Delta\phi = \pi$ (away side) reflect the correlations between hadrons produced in one jet and hadrons produced in the "balance" jet. In the Au + Au cases, a $\cos 2\Delta\phi$ modulation underlies the jet angular correlations due to the elliptic flow of particles in the combinatoric background and possibly also in part due to azimuthal anisotropies in the jets themselves (see below). Nonetheless, the $\cos 2\Delta\phi$ contribution has little effect on the narrow same-jet (near-side) peak in the $\Delta\phi$ distribution.

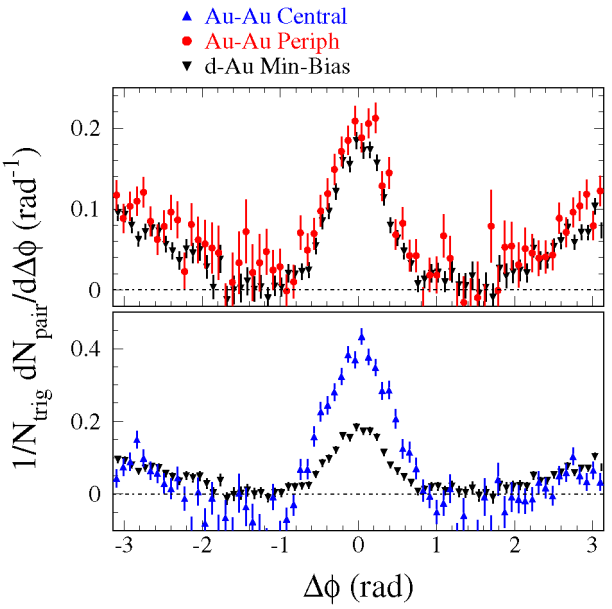

Fig. 40. Differential yields per $\Delta\phi$ and per trigger particle of pairs of charged hadrons in $d+\mathrm{Au}$, peripheral $\mathrm{Au}+\mathrm{Au}$ and central $\mathrm{Au}+\mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV [201]. The pairs were selected with the higher-momentum "trigger" particle in the range $2.5 < p_T < 4.0$ GeV/c and the lower-momentum "associated" particle in the range $1.0 < p_T < 2.5$ GeV/c. A constant background has been subtracted for all three distributions.

We observe that the angular widths of the same-jet correlations are the same within errors in all three data sets in spite of the factor of two larger yield of associated hadrons in central $\mathrm{Au}+\mathrm{Au}$ collisions compared to $d+\mathrm{Au}$ and peripheral $\mathrm{Au}+\mathrm{Au}$ collisions. This result is demonstrated more quantitatively in Fig. 41 which shows the centrality dependence of the Gaussian widths of the same-jet peaks in the $\mathrm{Au}+\mathrm{Au}$ $\Delta\phi$ compared to the jet widths extracted from $d+\mathrm{Au}$ collisions [201]. We see that the $\mathrm{Au}+\mathrm{Au}$ two-hadron correlation functions show peaks with the same jet width as $d+\mathrm{Au}$ collisions. Since this width is a unique characteristic of the parton fragmentation process, we conclude that high-p_T hadrons in $\mathrm{Au}+\mathrm{Au}$ collisions result from hard scattering followed by jet fragmentation regardless of any medium modifications of the fragmentation multiplicity.

6.4. High-p_T suppression and energy loss

The suppression of the production of high-p_T hadrons in heavy ion collisions at RHIC had been predicted long before RHIC started running [173–179,203]. It is now generally accepted that partons propagating in colored matter lose energy predominantly through medium-induced emission of gluon radiation [204,205]. An energetic parton scatters off color charges in the high-parton-density medium and radiates gluon bremsstrahlung. The reduction in the parton energy translates to a reduction in the average momentum of the fragmentation hadrons, which, in turn, produces a suppression in the yield of high-p_T

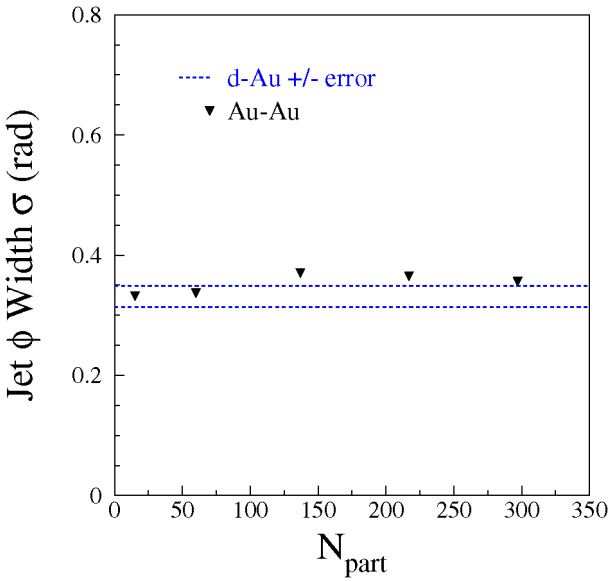

Fig. 41. The azimuthal angle width of jets in 200 GeV Au + Au collisions extracted as the σ's of Gaussian fits to the 0° peak in the two-charged-hadron azimuthal-angle ($\Delta\phi$) correlation functions [201]. The correlation functions were formed from pairs with trigger hadron in the p_T range $2.5 < p_T < 4.0$ GeV/c and the associated hadron in the range $1.0 < p_T < 2.5$ GeV/c. The dashed lines show the $\pm 1\sigma$ range of the jet widths in d + Au collisions using the same momentum bins. In the Au + Au data, the effect of the elliptic flow has been subtracted in the extraction of the jet width.

hadrons relative to the corresponding yield in $p + p$ collisions. The power-law spectrum for $p_T \geqslant 3$ GeV/c implies that a modest reduction in fragmenting parton energy can produce a significant decrease in the yield of hadrons at a given p_T. Thus, the suppression of the yield of high-p_T hadrons is generally believed to provide a direct experimental probe of the density of color charges in the medium through which the parton passes [188,194, 206]. However, before proceeding to an interpretation of our results, we briefly discuss the theoretical understanding of the radiative energy loss mechanism and limitations in that understanding.

The dominant role of radiative gluon emission was identified early on [175], but it took several years and much effort before rigorous calculations of the energy loss taking into account Landau–Pomeranchuk–Migdal suppression [176] and the time evolution of the medium were available. Initial estimates of the radiative energy loss suggested an approximately constant $\Delta E/\Delta x$ [174,176], but later calculations [177,180,181,207] showed that the quantum interference can produce a loss of energy that grows faster than linearly with the propagation path length, L, of the parton in the medium. However, this ideal growth of $\Delta E/\Delta x$ with increasing path length is never realized in heavy ion collisions due to the rapid decrease of the energy density and the corresponding color charge density with time [179,185,188,194]. Generally, all energy loss calculations predict that the fractional energy loss of a propagating parton decreases with increasing parton energy. However, the precise evolution with parton energy depends on the assumptions in the energy loss models and on

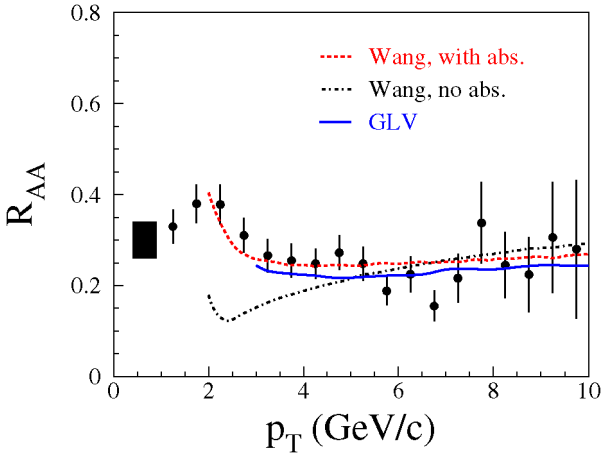

Fig. 42. Comparisons of energy loss calculations [185,212] used to extract estimates for the initial parton number or energy density (see text for details) to the central 200 GeV Au + Au π^0 $R_{AA}(p_T)$ measured by PHENIX. The Wang curves compare results with and without energy absorption from the medium.

the treatment of details like kinematic limits and nonleading terms in the radiation spectrum [204,205]. There are many different calculations of medium-induced energy loss currently available based on a variety of assumptions about the thickness of the medium, the energy of the radiating parton, and the coherence in the radiation process itself (see [204,205,208] for recent reviews). The p_T dependence of the PHENIX π^0 R_{AA} values has ruled out the possibility of a constant (energy independent) $\Delta E/\Delta x$ [203] and the original BDMS energy loss formulation (which the authors argued should not be applied at RHIC energies). In fact, the only detailed energy loss model that *predicted* the flat p_T dependence of R_{AA} over the p_T range covered by RHIC data was the GLV prescription [181,194,209–211]. In the GLV formulation, the fractional energy loss for large jet energies varies approximately as $\log(E)/E$ but the authors observe that below 20 GeV the full numerical calculation of the energy loss produces a nearly constant $\Delta E/E$ [205]. However, the same authors argue that the flat $R_{AA}(p_T)$ observed at high p_T at 200 GeV also requires an accidental cancellation of several different contributions including the separate p_T dependences of the quark and gluon jet contributions, the p_T dependence of the Cronin enhancement, and shadowing/EMC effect. A comparison of the GLV results for the p_T dependence of the π^0 suppression to the PHENIX data is shown in Fig. 42.

One of the most critical issues in the energy loss calculation is the treatment of the time evolution of the energy density of the matter through which the radiating parton is propagating. Even if transverse expansion of the created matter is ignored, the longitudinal expansion produces a rapid reduction in the energy density as a function of time. Most energy loss calculations assume that the color charge density decreases as a function of proper time as $\rho(\tau) = \rho_0\tau_0/\tau$ in which case the measured R_{AA} can be used to infer the product $\rho_0\tau_0$. Here τ_0 represents the formation time of the partons from which the medium is composed and ρ_0 the initial number density of those partons. Since the gluons have the largest cross section for scattering with other partons, the initial color-charge density is

interpreted as the gluon density. Making the usual assumption that the produced partons are spread over a longitudinal spatial width $\delta z = \tau_0 \delta y$, the GLV authors relate the product $\rho_0 \tau_0$ to the initial dn_g/dy and e obtain $dn_g/dy = 1000 \pm 200$ from the PHENIX π^0 R_{AA} values [194]. The sensitivity of the GLV calculations to the details of the description of the transverse parton density and the transverse expansion of the matter has been tested by using the results of hydrodynamic calculations of the energy density as a function of position and time [213]. The average energy loss for partons in central Au + Au collisions evaluated under dramatically different assumptions was shown to be remarkably insensitive to details of the description of the parton density. The GLV results are also potentially sensitive to a "screening mass" that determines both the transverse momentum distributions of the virtual gluons absorbed from the medium in the bremsstrahlung process and an energy cutoff for the radiated gluons. This mass is related to the local energy density using lattice QCD calculations of the plasma screening mass [194]. However, it was shown by the authors that a factor of two change in the screening mass produces only a 15% change in the dn_g/dy needed to describe the data.

An alternative analysis of parton energy loss [214] starts from explicit calculation of higher-twist matrix elements for $e + A$ collisions that account for coherent rescattering of the struck quark in the nucleus. The contributions of these higher-twist terms can be incorporated into modified jet fragmentation functions, producing an effective energy loss. This calculation can reproduce [188] the HERMES measurements of modified jet fragmentation in nuclear deep-inelastic scattering [215]. By relating the modified fragmentation functions from the higher-twist calculation to energy-loss results obtained from the leading term in an opacity expansion calculation (e.g., GLV) of medium-induced energy loss the parameters describing the rescattering in the nucleus in $e + A$ collisions can be related to the parameters describing the medium in an explicit energy-loss calculation. By relating the two sets of parameters, the parton density in the hot medium can be related to the parton density in a cold nucleus [188]. Results of this analysis are shown in Fig. 42 for parameters that give an initial energy loss per unit length of 13.8 ± 3.9 GeV/fm when the HIJING [79] parameterization of shadowing is used [185] (Note: this result is a factor of two larger that in [188] which was based on analysis of the 130 GeV results). However, an alternative (EKS) [216] shadowing description results in an initial energy loss of 16.1 ± 3.9 GeV/fm [185] in the same calculation indicating at least a 25% systematic error in the energy loss estimates due to uncertainties in the description of nuclear shadowing. Nonetheless, these initial-energy-loss values are much larger than the time-averaged energy loss extracted from the calculation, 0.85 ± 0.24 GeV/fm for HIJING shadowing [185], due to the assumed $1/\tau$ decrease in the color-charged density. In fact, the average energy loss per unit path length in central Au + Au collisions [188] is comparable to the value for cold nuclear matter extracted from HERMES data [188]. However, the initial energy loss is estimated by Wang to be a factor of ~ 30 larger than that in a cold nucleus [185] implying that the initial Au + Au parton density is larger by a factor > 30 than in cold nuclear matter [217].

As shown in Fig. 42 the Wang higher-twist calculation predicts a suppression that varies strongly with p_T over the range where the experimental $R_{AA}(p_T)$ values are flat. However, Wang and Wang have argued that absorption of energy from the medium needs to be accounted for in calculating the energy loss of moderate-p_T partons [187]. They provide a formula which incorporates both parton energy loss and "feedback" from the medium that

can reproduce the shape of the observed high-p_T suppression as shown by the lower curve in Fig. 42. This formula, then, provides the energy loss estimate given above. This explanation for the observed p_T independence of R_{AA}, a crucial feature of the experimental data, is disquieting, however, because it contradicts the explanation provided by the GLV model which provides a consistent estimate of the initial energy density. The feedback of energy from the medium is *not* included in the GLV calculations and if this contribution is significant, then the agreement of the GLV predictions with the π^0 $R_{AA}(p_T)$ over the entire p_T range would have to be considered "accidental". Also, the variation of the suppression in the Wang higher-twist calculation with p_T reflects the $\Delta E \propto \log E$ variation of parton energy loss naturally obtained from approximations to the full opacity expansion [205]. As noted above, the GLV approach finds that incorporating nonleading terms in the opacity expansion produces $\Delta E \propto E$. Thus, while the absorption of energy from the medium in the Wang et al. approach may only be significant below $p_T = 5$ GeV/c, the differences between the variation of energy loss with parton energy in the two approaches will not be confined to low p_T.

One source of uncertainty in the interpretation of the high-p_T suppression is the role of possible inelastic scattering of hadrons after fragmentation. It was originally argued that final-state inelastic scattering of hadrons could produce all of the observed suppression [218]. The persistence of the jet signal with the correct width in Au + Au collisions would be difficult to reconcile with this hypothesis. Indeed, more recent analyses [219] discount the possibility that hadronic re-interaction could account for the observed high-p_T suppression and indicate that only $\sim 1/3$ of fragmentation hadrons undergo final-state inelastic scattering [219]. Wang has also argued [220] that the complete pattern of high-p_T phenomena observed in the RHIC data cannot be explained by hadronic rescattering. However, this leaves open the question of whether hadronic re-interactions after jet fragmentation can be partially responsible for the observed high-p_T suppression. There are a number of other open issues with the quantitative interpretation of the observed high-p_T suppression. The calculations all assume that the jets radiate by scattering off static color charges while the typical initial gluon p_T is often assumed to be ~ 1 GeV. Also the radiated gluons are assumed to be massless though a plasmon cutoff equal to the screening mass is applied. The systematic errors introduced by these and other assumptions made in the current energy loss calculations have not yet been evaluated though the gluon screening mass is being included in analyses of heavy-quark energy loss.

6.5. *Empirical energy loss estimate*

The observation that the suppression of high-p_T particle production is approximately independent of p_T above 4 GeV/c and that the $p + p$ p_T spectra are well described by a pure power-law function in the same p_T range allows a simple empirical estimate of the energy loss of hard-scattered partons in the medium. The π^0 invariant cross section measured by PHENIX in $p + p$ collisions [60] is found to be well described by a power law

$$E\frac{d^3n}{dp^3} = \frac{1}{2\pi}\frac{d^2n}{p_T\,dp_T\,dy} = \frac{A}{p_T^n} \tag{28}$$

for $p_T > 3.0$ GeV/c with an exponent $n = 8.1 \pm 0.1$. If we assume that none of the hard-scattered partons escape from the medium without losing energy, then the approximately p_T-independent suppression above 4.5 GeV/c can be interpreted as resulting from an average fractional shift in the momentum of the final-state hadrons due to energy loss of the parent parton. The suppressed spectrum can be evaluated from the unsuppressed $(p + p)$ spectrum by noting that hadrons produced in Au + Au collisions at a particular p_T value, would have been produced at a larger p_T value $p'_T = p_T + S(p_T)$ in $p + p$ collisions. If the energy loss is proportional to p_T then we can write $S(p_T) = S_0 p_T$ so $p'_T = (1 + S_0) p_T$ Then, the number of particles observed after suppression in a given Δp_T interval is given by

$$\frac{dn}{dp_T} = \frac{dn}{dp'_T}\frac{dp'_T}{dp_T} = \frac{A}{(1+S_0)^{(n-2)}\, p_T^{(n-1)}}. \tag{29}$$

We note that the factor $\frac{dp'_T}{dp_T}$ accounts for the larger relative density of particles per measured p_T interval due to the effective compression of the p_T scale caused by the induced energy loss; this factor is necessary for the total number of particles to be conserved. The nuclear modification factor then can be expressed in terms of S_0,

$$R_{AA}(p_T) = \frac{1}{(1+S_0)^{(n-2)}}. \tag{30}$$

Using this very simple picture, we can estimate the fraction of energy lost by hard-scattered partons in the medium from our measured R_{AA} values. First we obtain S_0 from Eq. (30)

$$S_0 = \frac{1}{R_{AA}^{1/(n-2)}} - 1. \tag{31}$$

Then we observe that the hadrons that would have been produced in $p + p$ collisions at a momentum $(1 + S_0) p_T$ were actually produced at p_T, implying a fractional energy loss

$$S_{\rm loss} = 1 - 1/(1 + S_0) = 1 - R_{AA}^{1/(n-2)}. \tag{32}$$

Fig. 43 shows the centrality dependence of $S_{\rm loss}$ obtained from the p_T-averaged R_{AA} values shown in Fig. 38. For the most central Au + Au collisions at 200 GeV we obtain $S_{\rm loss} = 0.2$, which naively implies that an average 20% reduction in the energy of partons in the medium will produce the suppression observed in the π^0 spectra above 4.5 GeV/c. The extracted $S_{\rm loss}$ values are well described by an $N_{\rm part}^{2/3}$ dependence using the most central bin to fix the proportionality constant. This result agrees with the GLV prediction for the centrality dependence of the medium-induced energy loss.

It has been shown previously [221,222] that fluctuations in the radiation process can distort an estimate of parton energy loss using the procedure described above. Because of the steeply falling p_T spectrum, the partons that lose less energy dominate the yield at a given p_T so our determination of $S_{\rm loss}$ will significantly underestimate the true energy loss. However, it has also been observed that this distortion can largely be compensated by a single multiplicative factor of value ~ 1.5–2.0 [221]. While we cannot use the empirically extracted energy loss to estimate an initial gluon density, we can evaluate the consistency of our results with estimates of $\langle dE/dx \rangle$ in the medium. If we take into account the factor

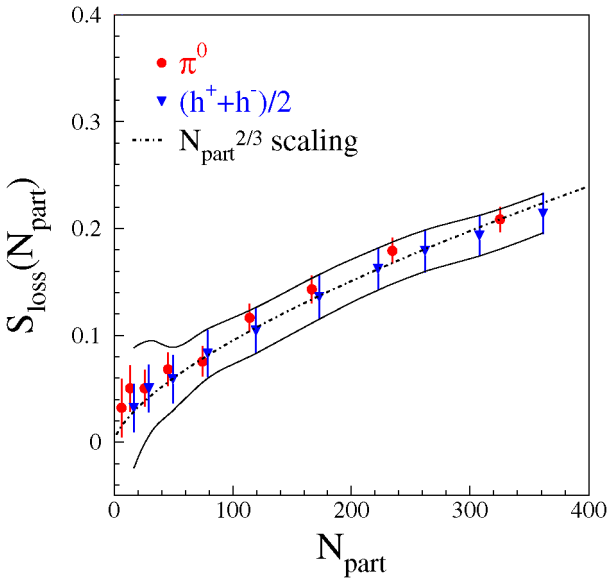

Fig. 43. Calculated energy loss shift factor, S_{loss} vs. N_{part} for π^0 and charged hadron production in 200 GeV Au + Au collisions. The band around the values indicates systematic errors resulting from uncertainties in T_{AB} and the normalization of the $p + p$ spectrum. The dot-dashed curve shows an $N_{\text{part}}^{2/3}$ scaling of S_{loss} using the most central bin to fix the proportionality constant.

of 1.5–2.0 renormalization of S_{loss}, we estimate that 10 GeV partons lose $\sim$ 3–4 GeV of energy. If the typical path length of these partons is on the order of the nuclear radius then we can infer a $\Delta E/\Delta x \sim 0.5$ GeV/fm which is in good agreement with the estimate from Wang [188]. We can also use the above empirical energy loss approach to evaluate possible systematic errors in the estimate of the initial gluon density. For example, if one third of the observed suppression were a result of final-state hadronic interactions in the medium, then the suppression due to energy loss would be a factor of 1.5 smaller than that implied by the measured R_{AA} values, assuming that every fragmentation hadron that interacts effectively "disappears" by being shifted to much lower momentum. As a result, S_0 in central Au + Au collisions would be reduced from 0.25 to 0.17, implying 30% reduction in the estimated energy loss. If this energy loss is indeed proportional to the initial gluon density then the uncertainty in the effect of the final-state hadronic interactions would introduce a 30% systematic error in dn_g/dy.

6.6. Conclusions

The observed suppression of high-p_T particle production at RHIC is a unique phenomenon that has not been previously observed in any hadronic or heavy ion collisions at any energy. The suppression provides direct evidence that Au + Au collisions at RHIC have produced matter at extreme densities, greater than ten times the energy density of normal nuclear matter and the highest energy densities ever achieved in the laboratory. Medium-induced energy loss, predominantly via gluon bremsstrahlung emission, is the

only currently known physical mechanism that can fully explain the magnitude and p_T dependence of the observed high-p_T suppression. This conclusion is based on evidence provided above that we summarize here:

- Observation of the x_T scaling of the high-p_T hadron spectra and measurements of two-hadron azimuthal-angle correlations at high p_T confirm the dominant role of hard scattering and subsequent jet fragmentation in the production of high-p_T hadrons.
- $d+\mathrm{Au}$ measurements demonstrate that any initial-state modification of nuclear-parton distributions has little effect on the production of hadrons with $p_T > 2$ GeV/c at mid-rapidity.
- This conclusion is further strengthened by preliminary PHENIX measurements showing that the yield of direct photons with $p_T > 5$ GeV/c is consistent with a T_{AB} scaling of a pQCD-calculated $p+p$ direct-photon spectrum.
- Analyses described above indicate that final-state hadronic interactions can only account for a small fraction of the observed high-p_T suppression.

Interpreted in the context of in-medium energy loss, the high-p_T suppression data rule out the simplest energy loss prescription—a jet energy independent $\Delta E/\Delta x$. The approximately flat $R_{AA}(p_T)$ was predicted by the GLV energy loss model from which the most explicit estimates of the initial gluon-number density, $dn_g/dy = 1000 \pm 200$ and a corresponding initial energy density $\varepsilon_0 \approx 15$ GeV/fm^3 [194], have been obtained. An alternative estimate from the analysis of Wang et al. [188] yields a path-length-averaged energy loss of 0.5 GeV/fm. Assuming a $1/\tau$ time evolution of the energy density a much larger initial energy loss of 13–16 GeV/fm is obtained. That estimate combined with the estimated 0.5 GeV/fm energy loss of partons in cold nuclear matter yields an initial $\mathrm{Au}+\mathrm{Au}$ gluon density > 30 times larger than that in nuclei [217]. From this result, Wang concludes that the initial energy density is a factor of ~ 100 times larger than that of a nucleus which would correspond to 16 GeV/fm^3 [217]. While this conclusion is consistent with the independent estimate from GLV, we note that the two models provide completely different explanations for the nearly p_T-independent R_{AA}—the most unique feature of the single-particle high-p_T suppression—and the differences between the approaches may not be confined to low p_T. An empirical analysis of the parton energy loss suggests that the Wang estimate of > 0.5 GeV/fm for the average parton $\Delta E/\Delta x$ is consistent with the measured R_{AA} values in central $\mathrm{Au}+\mathrm{Au}$ collisions. However, some outstanding issues with current energy loss calculations and the interpretation of high-p_T suppression were noted above. Most notably, rescattering of hadrons after parton fragmentation could affect the observed high-p_T suppression even if such rescattering cannot explain the pattern of jet quenching observations. Using results from [219] and our empirical energy loss analysis, we estimated that hadronic interactions *could* modify extracted values for initial parton densities by only 30%. However, we cannot evaluate the potential systematic error in extracted parton densities due to other untested assumptions of the energy loss calculations. Therefore, to be conservative we interpret the extracted initial gluon number and energy densities as order-of-magnitude estimates. Even then, the 15 GeV/fm^3 estimated by Gyulassy and Vitev from the central 200 GeV $\mathrm{Au}+\mathrm{Au}$ π^0 $R_{AA}(p_T)$ measurements indicates that the

matter produced in central Au + Au collision has an energy density greater than 10 times normal nuclear matter density.

7. Hadron production

Descriptions of heavy ion collisions have provided an understanding of early energy densities of production rates and medium effects of hard partons, and of collective flow of matter. However, hadronization—the process by which partons are converted into hadrons—is not well understood. The process of hadronization is particularly important since it includes both the dressing of the quarks from their bare masses, i.e., the breaking of approximate chiral symmetry, and the confinement of quarks into colorless hadrons. One could conclude that a quark–gluon plasma had been formed if one had conclusive evidence of hadronization occurring from a thermal distribution of quarks and gluons.

Hadronization processes have been studied over many years in proton–proton and electron–positron reactions. Hadron formation, by its very nature a nonperturbative process, has often been parameterized from data (e.g., fragmentation functions $D(z)$) or phenomenologically described (e.g., string models) [223]. From QCD one expects that hadron production at high transverse momentum is dominated by hard scattering of partons followed by fragmentation into "jets" or "mini-jets" of hadrons. Following the assumptions of collinear factorization, the fragmentation functions should be universal. This universality has proved a powerful tool in comparing e^+e^- annihilation to hadron-hadron reactions. One feature of jet fragmentation is that baryons and antibaryons are always suppressed relative to mesons at a given p_T [224,225]. Phenomenologically this can be thought of as a large penalty for creating a diquark–antidiquark pair for baryon formation vs. a quark–antiquark pair for meson formation.

In hadron–hadron reactions, hard scattering followed by fragmentation is considered to be the dominant process of hadron production for particles with $p_T \geqslant 2$ GeV/c at mid-rapidity. At low transverse momentum, where particles have $p_T < 2$ GeV/c, particle interactions are often referred to as "soft". In small momentum transfer reactions the effective wavelength of interactions is longer than the spacing of individual partons in a nucleon or nucleus. Thus coherence effects are expected to result in large violations of factorization and universality of fragmentation functions. Hadron formation mechanisms in this "soft" regime are poorly understood. We are particularly interested in the study of hadron formation in the region of $p_T \approx 2$–5 GeV/c, where production is expected to make the transition from "soft" to "hard" mechanisms.

7.1. Baryons and antibaryons

One of the most striking and unexpected observations in heavy ion reactions at RHIC is the large enhancement of baryons and antibaryons relative to pions at intermediate $p_T \approx 2$–5 GeV/c. As shown in Fig. 44, the (anti)proton to pion ratio is enhanced by almost a factor

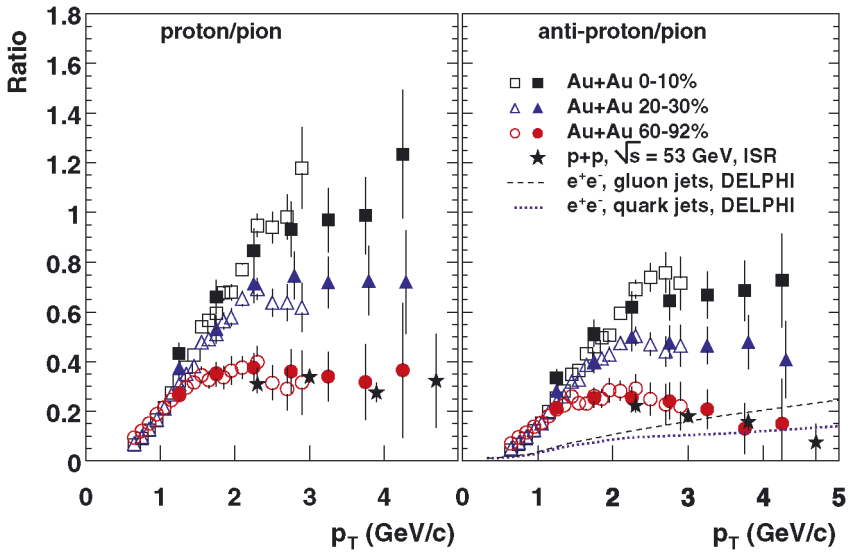

Fig. 44. p/π (left) and $\bar{p}/\pi$ (right) ratios for central (0–10%), mid-central (20–30%) and peripheral (60–92%) Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [52]. Open (filled) points are for $\pi^{+/-}$ (π^0), respectively. Data from $\sqrt{s} = 53$ GeV $p + p$ collisions [224] are shown with stars. The dashed and dotted lines are $(\bar{p} + p)/(\pi^+ + \pi^-)$ ratio in gluon and in quark jets [225].

of three when one compares peripheral reactions to the most central gold-gold reactions [52].[8] This of course is in sharp contrast to the suppression of pions in this region.

We can study this (anti)baryon excess at much higher p_T by comparing our inclusive charged spectra (primarily pions, kaons and protons) with our neutral pion measurements [52]. Shown in Fig. 45 is the charged hadron to π^0 ratio as a function of transverse momentum in ten centrality bins. We observe a significant increase of the $(h^+ + h^-)/\pi^0$ ratio above 1.6 in the p_T range 1–5 GeV/c that increases as a function of collision centrality. The ratio of $h/\pi = 1.6$ is the value measured in $p + p$ reactions [224], and is thought to arise from jet fragmentation. In Au + Au central reactions, above $p_T \approx 5$ GeV/c, h/π returns to the $p + p$ measured baseline. This implies that the (anti)baryon excess occurs only in the limited p_T window $\approx$ 2–5 GeV/c, and then returns to the universal fragmentation function expectation.

As discussed in Section 6, pions in this p_T range are suppressed by almost a factor of five relative to binary collision scaling for central Au + Au reactions. Thus, one possible interpretation of the large (anti)proton to pion ratio is that somehow the baryons are not suppressed in a manner similar to the pions. Fig. 46 shows that in fact (anti)proton production appears to follow binary collision scaling over the transverse momentum range $p_T = 2$–5 GeV/c [52]. However, the h/π^0 ratios shown in Fig. 45 imply that above $p_T > 5$ GeV/c, the (anti)protons must be as suppressed as the pions.

[8] All PHENIX (anti)proton spectra shown in this section are corrected for feed down from weak decays.

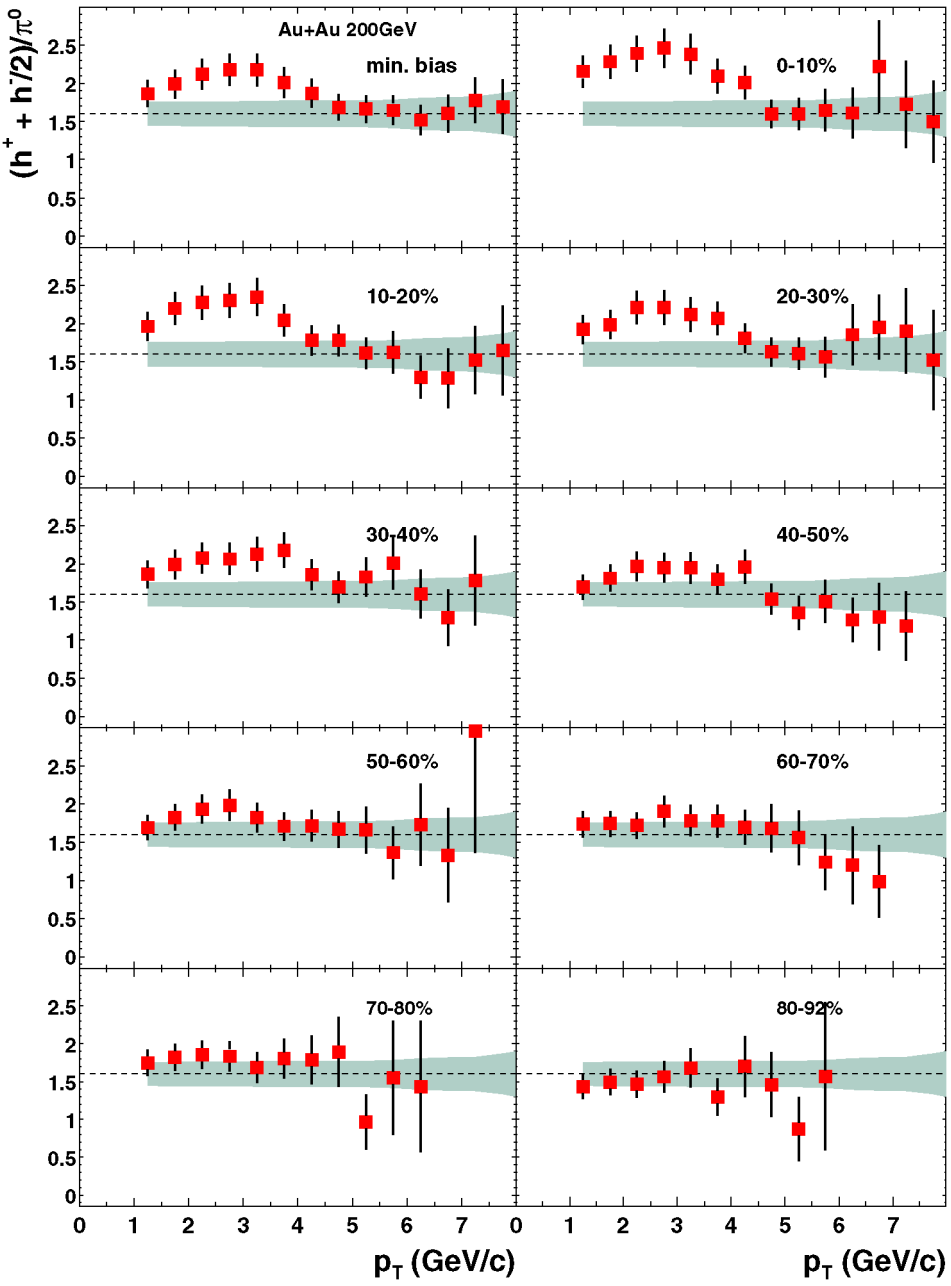

Fig. 45. Charged hadron to π^0 ratio for different centrality classes for Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [53]. Error bars represent the quadratic sum of statistical and point to point systematic errors. The shaded band shows the normalization error common to all centrality classes. The line at 1.6 is the h/π ratio measured in $p + p$ collisions at $\sqrt{s} = 53$ GeV [224] and in $e^+ + e^-$ collisions [225].

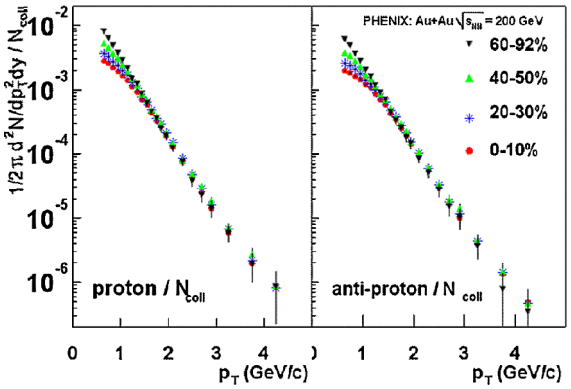

Fig. 46. p and $\bar{p}$ invariant yields scaled by $N_{\rm coll}$ in Au + Au collision at $\sqrt{s_{NN}} = 200$ GeV [52]. Error bars are statistical. Systematic errors on $N_{\rm coll}$ range from $\approx 10\%$ for central to $\approx 28\%$ for 60–92% centrality. Multiplicity dependent normalization errors are $\approx 3\%$.

Characteristics of the intermediate p_T (anti)protons are:

- A large enhancement of the p/π and $\bar{p}/\pi$ ratios in central Au + Au collisions.
- A ratio in peripheral collisions which is in agreement with that from $p + p$ collisions.
- A smooth increase from peripheral to central Au + Au collisions.
- A similar effect for protons and antiprotons.
- Approximate scaling of (anti)proton production at $p_T \approx 2$–4 GeV/c with the number of binary nucleon–nucleon collisions.
- Suppression relative to binary collision scaling similar for (anti)protons and pions for $p_T > 5$ GeV/c.

Large proton to pion ratios have also been observed in heavy ion collisions at lower energies. Fig. 47 shows p_T distributions of protons, antiprotons, and pions in central Pb + Pb collisions at the SPS and in central Au + Au collisions at the AGS. The p/π ratio in central Pb + Pb collisions at the SPS is greater than unity for $p_T \geqslant 1.3$ GeV/c. At the AGS, the proton spectrum crosses pion spectra at $p_T \sim 0.5$ GeV/c, and the p/π ratio is about 20 at $p_T = 1.6$ GeV/c. The p/π ratios in the low-energy heavy-ion collisions are also enhanced compared with $p + p$ collisions at the same energy.

Most of the protons in these lower-energy heavy-ion collisions are not produced in the collision. Rather they are protons from the beam or target nucleus (Pb or Au) that are transported to large p_T at mid-rapidity. As discussed in Section 3, a strong radial flow with velocity $\beta_T \sim 0.5$ is produced in heavy ion collisions at AGS and SPS energies. The large p/π ratio can be interpreted as a result of this radial flow. Since the proton is heavier, a fixed velocity boost results is a larger momentum boost than for pions, and thus enhances p/π ratio at higher p_T. In contrast, at RHIC energies, most of protons are produced particles [40]. The anomalously large antibaryon-to-meson ratio $\bar{p}/\pi \sim 1$ at high $p_T \geqslant 2$ GeV/c is a unique result from RHIC. Such a large $\bar{p}/\pi$ ratio has not been observed in any other collision system. Fig. 47 shows that $\bar{p}/\pi$ is less than ~ 0.1 at the SPS, and it is less than $1/100$ at the AGS. It should also be noted that the measurements from the

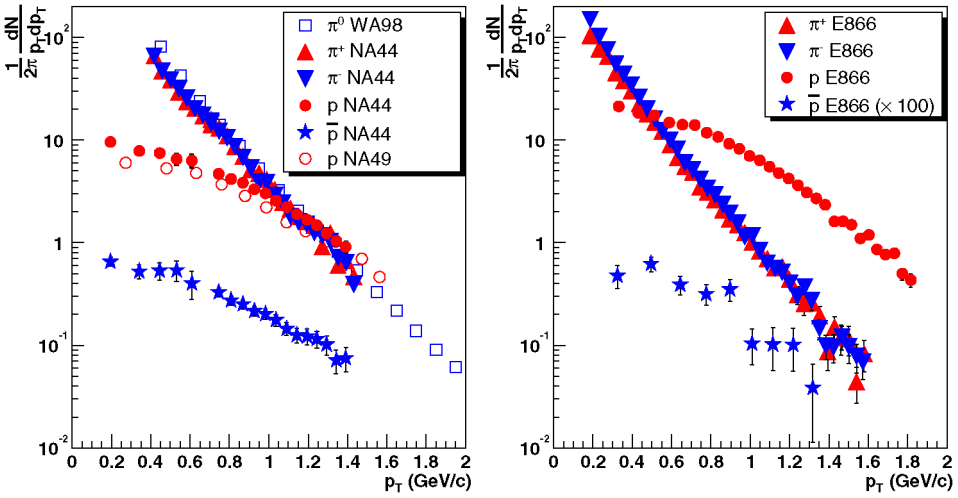

Fig. 47. Invariant yields of p, $\bar{p}$, and π as function of p_T in central Pb + Pb collisions at the SPS ($\sqrt{s_{NN}} = 17$ GeV) (left panel) and in central Au + Au collisions at the AGS ($\sqrt{s_{NN}} = 5$ GeV) (right panel). The $\bar{p}$ spectrum from the AGS is scaled up by a factor 100. All data are at mid-rapidity ($y - y_{\rm cm} \approx 0$) and are from W98 [163], NA44 [226], NA49 [227], and E866 [228,229].

AGS/SPS are limited to lower p_T ($p_T < 2$ GeV/c), where soft physics is still dominant, while at RHIC we observe a large $p(\bar{p})/\pi$ ratio in $p_T \approx 2$–5 GeV/c where hard processes are expected to be the dominant mechanism of particle production.

7.2. The ϕ meson

We have extended our identified hadron studies to include the ϕ vector meson as measured in the K^+K^- decay channel. The ϕ is a meson, and is in that sense similar to the pion with a valence quark and antiquark, yet its mass is comparable to that of the proton.

Fig. 48 shows R_{CP}, the ratio of production in central to peripheral Au + Au collisions scaled by binary collisions, for protons, pions and ϕ mesons detected via its KK decay channel [69] in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. A large suppression of pions at $p_T > 2$ GeV/c is observed (as detailed in Section 6), and a lack of suppression for the protons and antiprotons as expected from Fig. 46. The ϕ follows the suppression pattern of the pions within errors, indicating that the surprising behavior of the protons is not followed by the ϕ. Fig. 49 shows a comparison between the p_T spectral shape for protons and the ϕ in central and peripheral Au + Au reactions. The two spectra agree with each other within errors for the most central events. Thus, although the yields are evolving differently with collision centrality, giving rise to the deviation from unity of R_{CP}, the p_T distributions appear quite similar.

7.3. Jet correlations

A crucial test of the origin for the enhanced (anti)proton to pion ratio is to see if baryons in this intermediate p_T regime exhibit correlations characteristic of the structure

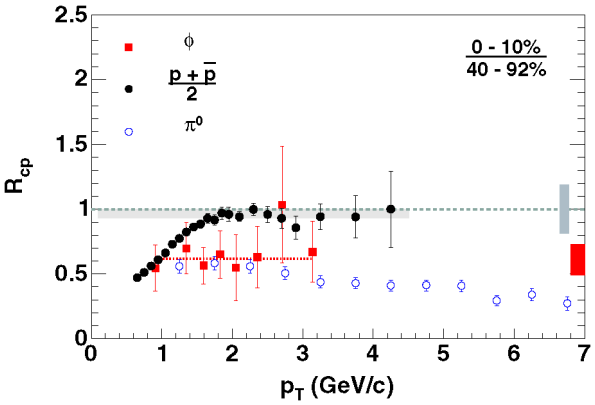

Fig. 48. The R_{CP} of the ϕ as measured in the KK channel, compared to the protons and pions for Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [69].

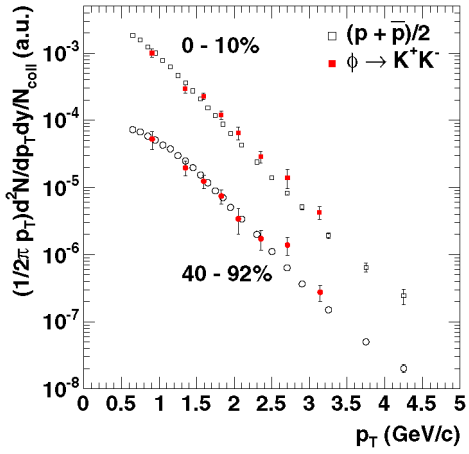

Fig. 49. $(p + \bar{p})$ and ϕ invariant yield as a function of transverse momentum for central 0–10% and peripheral 40–92% Au + Au reactions at $\sqrt{s_{NN}} = 200$ GeV. The two distributions for each centrality class are given an arbitrary relative normalization to allow for comparison of the p_T dependent shapes. Data are from [69].

of jets from hard-scattered partons. Particles which exhibit these correlations are termed "jet-like". Fig. 50 shows the associated partner particle yield within the relative angular range $0.0 < \phi < 0.94$ radians on the same side as trigger baryons and mesons [71]. Correlated pairs are then formed between the trigger particle and other particles within the above mentioned angular range. Mixed events are used to determine the combinatorial (i.e., non-jet-like) background distribution, which is subtracted after accounting for modulation according to the measured v_2.

The partner yield increases for both trigger baryons and mesons by almost a factor of two from deuteron–gold to peripheral and mid-central Au + Au reactions. We then observe a decrease in the jet-like correlations for baryons relative to mesons for the most

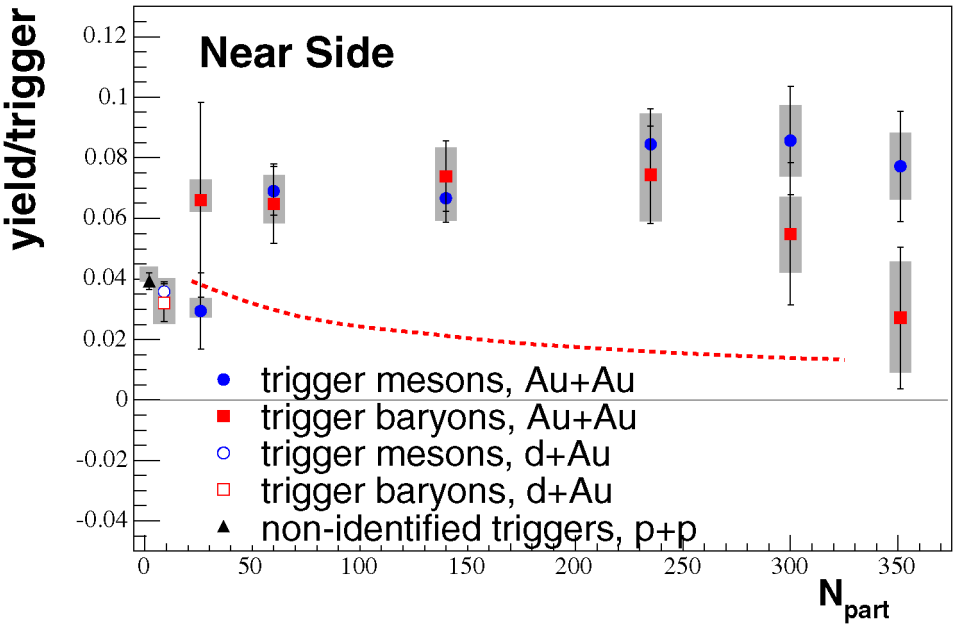

Fig. 50. Centrality dependence of associated charged hadron yield ($1.7 < p_T < 2.5$ GeV/c) above combinatorial background for trigger baryons and trigger mesons in the p_T range 2.5–4.0 GeV/c in a 54° cone around the trigger particle in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [71]. The error bars are statistical errors and the gray boxes are systematic errors. The dashed line represents an upper limit of the centrality dependence of the near-side partner yield from thermal recombination (see text).

central collisions. We note that this observation is of limited significance within our current statistical and systematic errors. Over a broad range of centrality 10–60% the partner yield is the same for protons and pions within errors. This is notable since the (anti)proton to pion ratio has already increased by a factor of two for mid-central Au + Au relative to proton–proton reactions, with the implication that the increase in the p/π ratio is inclusive of the particles with jet-like correlations.

The dashed line in Fig. 50 shows the expected centrality dependence of partners per baryon if all the "extra" baryons which increase the p/π over that in $p + p$ collisions were to arise solely from soft processes. Baryons from thermal quark recombination should have no jet-like partner hadrons and would dilute the per-trigger conditional yield. Because this simple estimate does not allow for meson production by recombination, which must also occur along with baryon production, it represents an upper limit to the centrality dependence of jet partner yield from thermal recombination. The data clearly disagree with both the centrality dependence and also the absolute yields of this estimation, indicating that the baryon excess has the same jet-like origin as the mesons, except perhaps in the highest centrality bin.

The characteristics of the jet-like particles are compared to inclusive hadrons in Fig. 51, which shows the centrality dependence of the p_T distributions of jet-like partners and inclusive hadrons. One can see that, within the available statistics, the slopes of the associated

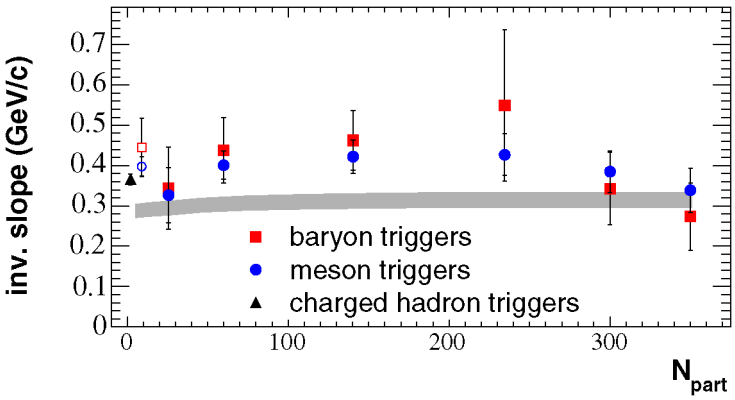

Fig. 51. The inverse slopes for the momentum distributions of the associated particles shown in Fig. 50. The gray band is the inverse slope of the momentum distribution of the inclusive hadrons from Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [71].

particle spectra in $p + p$, $d +$ Au, peripheral and mid-central Au + Au collisions are very similar for both trigger mesons and trigger baryons. The partner spectra are harder than the inclusive hadron spectra, as expected from jet fragmentation. In the most central collisions, the number of particles associated with trigger baryons is very small, resulting in large statistical error bars. However, the inverse slopes of the jet-like partners and inclusive hadron distributions agree better in central collisions than in peripheral collisions.

We can then make the following general observations.

- Trigger (anti)protons and mesons have comparable near-side associated-particle yields over a broad range in centrality, indicating a significant jet-like component for both.
- There is an indication that the proton partner yield tends to diminish for the most central collisions, unlike for leading mesons.
- Within the limited statistics available for the measurement, the inverse slopes of the associated particles are similar for both mesons and baryons. These are harder than for the inclusive spectra.
- Trigger particles in Au + Au collisions appear to have *more* associated particles than in $d +$ Au collisions. This is true for all centralities aside from the most peripheral, and except for leading baryons in central collisions.

7.4. Soft physics

As previously noted, hard scattering followed by fragmentation is considered to be the dominant process of hadron production with $p_T \geqslant 2$ GeV/c in hadron–hadron reactions at mid-rapidity. However, as detailed Section 3, there is strong evidence for explosive collective motion of particles in the medium. If the mean free path for particles in the medium is small, then all particles must move with a common local velocity as described by hydrodynamics. Therefore, heavier particles receive a larger momentum boost than lighter

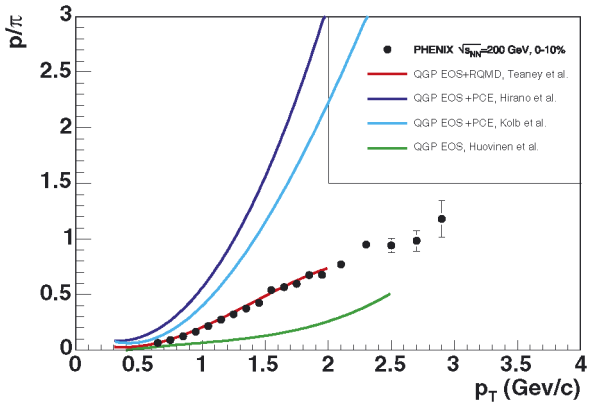

Fig. 52. p/π ratios for central (0–10%) Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [52] compared to hydrodynamic models [106,107,117–119].

particles. This effective shifting of particles to higher p_T results in a "shoulder-arm" shape for the (anti)proton p_T spectra, visible in Fig. 49.

7.4.1. Hydrodynamics

Is it possible that this soft hadron production extends to higher p_T for baryons than mesons? Hydrodynamic boosting of "soft" physics for heavier particles into the $p_T > 2$ GeV/c offers a natural explanation for the enhanced p/π and $\bar{p}/\pi$ ratios [106].

As seen in Section 3, some hydrodynamical models can describe both the proton and the pion spectra. Consequently, the p/π ratio is also reproduced (Fig. 52). It is clear that the description of the p/π ratio is not unique and different calculations yield quite different results. Above some p_T, hydrodynamics should fail to describe the data and fragmentation should dominate. Pure hydrodynamics predicts that this ratio would continue to increase essentially up to $p_T \to \infty$. However, these particles cannot have a zero mean free path in the medium. Any finite mean free path and a finite volume will limit the number of p_T "kicks" a particle can receive. For this reason many of the hydrodynamic calculations are not extended into the p_T region 2–5 GeV/c in which we are interested.

Hydrodynamic calculations do not specify the quanta that flow; rather they assume an equation of state. When applied at RHIC, most calculations start with a quark–gluon-plasma equation of state and transition to a resonance gas. The mapping of the fluid onto hadrons is somewhat ad hoc, and often uses the Cooper–Frye freezeout [126], giving the typical hierarchies of momenta one sees where heavier particles receive a larger boost.

As mentioned previously, this generic feature of a transverse velocity boost yielding an increase in the baryon to meson ratio relative to proton–proton reactions is not unique to RHIC as shown in Fig. 47. However, a major difference between lower-energy results and those at $\sqrt{s_{NN}} = 200$ GeV is that at these highest energies there is a significant hard-process contribution. If the source of the excess baryons is the transport of soft baryons to the intermediate p_T range, then it is purely coincidental that the baryons scale with binary collisions. More importantly, we should expect a significant decrease in the jet-like partner yield for baryons relative to mesons. Although there may be a hint of this for the

most central reactions, one expects this decrease to follow the centrality dependence of the increase in p/π ratio. Thus, this effect should already reduce the partner yield by a factor of two in mid-central Au + Au reactions. This is ruled out by the data.

7.4.2. Recombination models

The quark recombination or coalescence model is a different physics framework in which baryons receive a larger p_T boost than mesons. These models were frequently invoked in the 1970s [230,231] in an attempt to describe the rapidity distribution of various hadronic species in *hadron–hadron* reactions. More recently, these models have been applied to describe the forward charm hadron production in *hadron–nucleus* reactions at Fermilab [232]. In this case they calculate a significant probability for D meson formation from a hard-scattering-created charm quark with a light valence quark in the projectile. The quark coalescence mechanisms have some similarities to light nuclei coalescence. However, wave functions are relatively well determined for light nuclei, whereas the hadron wave functions are neither easily described by partons nor directly calculable from QCD.

Recently, quark recombination has been successfully applied to describe a number of features of heavy ion collisions [233,234] (Duke model). In this picture, quarks in a densely populated phase space combine to form the final-state hadrons. This model uses the simplifying assumption that the mass is small relative to the momentum giving a prediction largely independent of the final hadron wave function.[9] The coalescing parton distribution was assumed to be exponential, i.e., thermal, and recombination applied for hadrons where $m^2/p_T^2 \ll 1$. At very high p_T particles are assumed to arise from fragmentation of hard partons with a standard power law distribution; the relative normalization of the thermal source with respect to this process is an important external parameter to the model. A crucial component of recombination models is the assumption that the partons which recombine carry a mass which is essentially equal to the mass of the dressed constituent quarks.[10] If all observables of intermediate p_T hadrons can be explained by recombination of only thermal quarks, this would essentially prove the existence of a quark–gluon plasma in the early stage of the collisions.

Three essential features are predicted by recombination models. First, baryons at moderate p_T are greatly enhanced relative to mesons as their transverse momentum is the sum of 3 quarks rather than 2. Recombination dominates over parton fragmentation in this region, because, for an exponential spectrum recombination is a more efficient means of producing particles at a particular p_T. This enhancement should return to its fragmentation values at higher p_T. In the intermediate range, all mesons should behave in a similar manner regardless of mass, as should all baryons. Secondly, recombination predicts that the collective flow of the final-state hadrons should follow the collective flow of their constituent quarks. Finally, recombination causes thermal features to extend to higher transverse momentum, $p_T \gg T_C$ than one might naively expect since the underlying thermal spectrum of the con-

[9] The recombination model prediction of these models is independent of the final hadron wave function with an accuracy of about 20% for protons and 10% for pions.

[10] The actual source of this mass is under discussion. It may be that the chiral phase transition is slightly above the deconfinement transition. In this case, the mass would be from the dressing of the quarks. Another possibility is that the mass is a thermal mass which happens to be similar to the constituent quark mass.

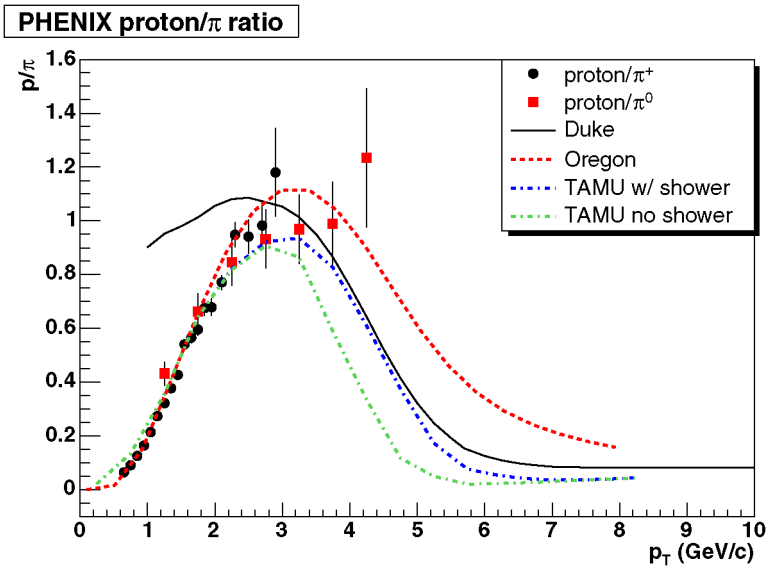

Fig. 53. The proton to pion ratio measured by PHENIX for Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV [52]. Several comparisons to recombination models as mentioned in the text are shown.

stituents gets a multiplication factor of essentially 3 for baryons and 2 for mesons. A last general feature which is true for the simplest of the models, but may not necessarily be true for more complex models, is that at intermediate p_T, recombination is the dominant mechanism for the production of hadrons—particularly of baryons.

Other recombination calculations have relaxed the assumptions previously described, at the cost of much more dependence on the particular form of the hadronic wave function used. One such calculation [235,236] (Oregon model) uses a description of hadronization which assumes that all hadrons—including those from fragmentation—arise from recombination. Hard partons are allowed to fragment into a shower of partons, which can in turn recombine—both with other partons in the shower and partons in the thermal background. Another model [237] (TAMU model) uses a Monte Carlo method to model the production of hadrons allowing recombination of hard partons with thermal partons, and includes particle decays, such as $\rho \to 2\pi$ which produces low-p_T pions.

Fig. 53 shows several recombination model calculations compared to the p/π ratio from PHENIX. The general features at $p_T > 3$ GeV/c are reasonably reproduced—that is the protons show a strong enhancement at moderate p_T which disappears at $p_T > 5$ GeV/c consistent with the measured h/π ratio shown in Fig. 45. The more complicated models do a better job, as one might expect in the $p_T < 3$ GeV/c region, where the assumptions made by the Duke model begin to break down. Since the recombination model's essential ingredient is the number of constituent quarks in a hadron, the similarity of R_{CP} for the ϕ and pions is nicely explained.

Fig. 54 shows the fraction of hadrons arising from recombination of only thermal quarks, as a function of p_T. For p_T between 2.5 and 4 GeV/c the fraction of protons from recombination is greater than 90% for all impact parameters, and is essentially 100%

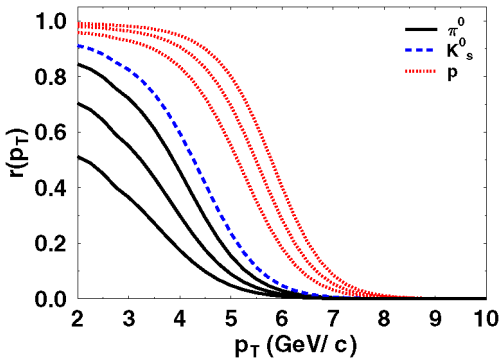

Fig. 54. The ratio $r(P_T) = R/(R+F)$ of recombined hadrons to the sum of recombination (R) and fragmentation (F) for pions (solid), K^0s (dashed) and p (dotted lines) [234] in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. For protons and pions different impact parameters $b = 0$, 7.5 and 12 fm (from top to bottom) are shown. K^0s is for $b = 0$ fm only.

for the most central collisions. For pions the value is between 40 and 80%, depending on the centrality. This is contradicted by the data in Fig. 50 which clearly shows jet-like correlations for both pions and protons in mid-central collisions. It should be noted that the yield of particles associated with baryons in very central collisions appears to decrease, indicating a possible condition where the simple picture of recombination of purely thermal quarks may apply.

One can examine the general prediction for the elliptic flow of identified particles by rescaling both the v_2 and the transverse momentum by the number of constituent quarks as shown in Fig. 55. This scaling was first suggested by Voloshin [238]. Above p_T/n of 1 GeV/c (corresponding to 3 GeV/c in the proton transverse momentum) all particles essentially plateau at a value of about 0.35 presumably reflecting the elliptic flow of the underlying partons. Interestingly, even at lower values of the transverse momentum, all particles also fall on the same curve aside from pions.

It is clear from the jet correlations observed that the majority of moderate p_T baryons in peripheral and mid-central collisions cannot arise from a purely thermal source, as that would dilute the per-trigger partner yield. The jet structure and collision scaling indicate that at least some of the baryon excess is jet-like in origin. The relatively short formation time for baryons of such momenta suggests that allowing recombination of fragmentation partons with those from the medium may solve the problem and better reproduce the data. Both the Oregon and TAMU models have mechanisms to do this. However, such modification of the jet fragmentation function must also modify the elliptic flow, and could break the quark scaling needed to reproduce the observed v_2 trends. Hence, the jet structure of hadrons at 2–5 GeV/c p_T presents a challenge to models of the hadron formation.

Fig. 56 shows a comparison of the elliptic flow calculated by the TAMU model [241] with PHENIX data from Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The model includes the recombination of hard and soft partons, as well as the decay of resonances such as the ρ. In this model, at least, the agreement of v_2 with the data is preserved—in addition a simple explanation is given for the excess of pion v_2 at low p_T. A similar conclusion in shown

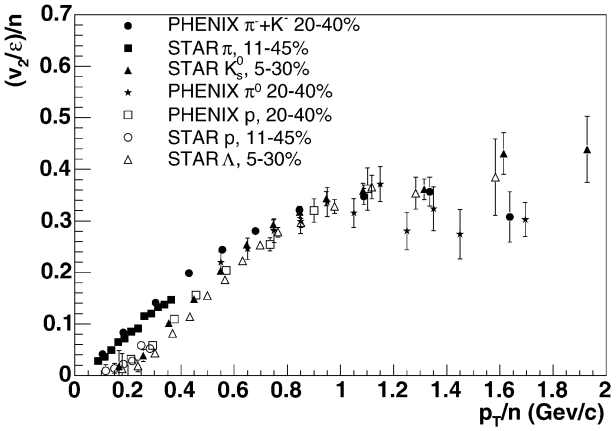

Fig. 55. v_2 as a function of transverse momentum for a variety of particles for Au + Au collisions where both v_2 and p_T have been scaled by the number of constituent quarks in the particle. The meson data are shown with filled symbols; $\pi^- + K^-$ from PHENIX at $\sqrt{s_{NN}} = 200$ GeV [50] (filled circles), charged π from STAR at $\sqrt{s_{NN}} = 130$ GeV [103] (filled squares), K_s^0 from STAR at $\sqrt{s_{NN}} = 200$ GeV [239] (filled triangles), and π^0 from PHENIX at $\sqrt{s_{NN}} = 200$ GeV [240] (filled stars). While the baryons are shown with open symbols; p from PHENIX at $\sqrt{s_{NN}} = 200$ GeV [50] (open squares), p from STAR at $\sqrt{s_{NN}} = 130$ GeV [103] (open circles), and Λ from STAR at $\sqrt{s_{NN}} = 200$ GeV [239] (open triangles).

in [242]. This would seemingly attribute all the elliptic flow to the partonic phase leaving no room for additional flow to be produced in the later, hadronic stage—which may be in contradiction to hydrodynamic interpretations of the hadronic state as demanded by a variety of signatures such as the p_T spectra of the protons and pions (see Section 3). It is clear that a more comprehensive comparison of observables should be undertaken to check the validity of these models. Higher-statistics jet studies with different identified particles by PHENIX in Run-4 will help clarify the situation.

7.5. Hadron formation time

In the discussion of the suppression of pions for $p_T > 2$ GeV/c, we treat the pions as resulting from the fragmentation of hard-scattered quarks and gluons. The explanation of this suppression in terms of partonic energy loss assumes that the hadronic wave function only becomes coherent outside the medium. Protons have a different hadronic structure and larger mass, and so may have a different, shorter time scale for coherence.

Following [220], we can estimate the formation time for the different mass hadrons at moderate p_T in two different ways. According to the uncertainty principle, the formation time in the rest frame of the hadron can be related to the hadron size, R_h. In the laboratory frame, the hadron formation time is then given by

$$\tau_f \approx R_h \frac{E_h}{m_h}, \tag{33}$$

where R_h is taken to be 0.5–1 fm. For a 10 GeV/c pion, this gives a formation time of 35–70 fm/c. For the $p_T = 2.5$ GeV/c pions considered in this section, the formation time

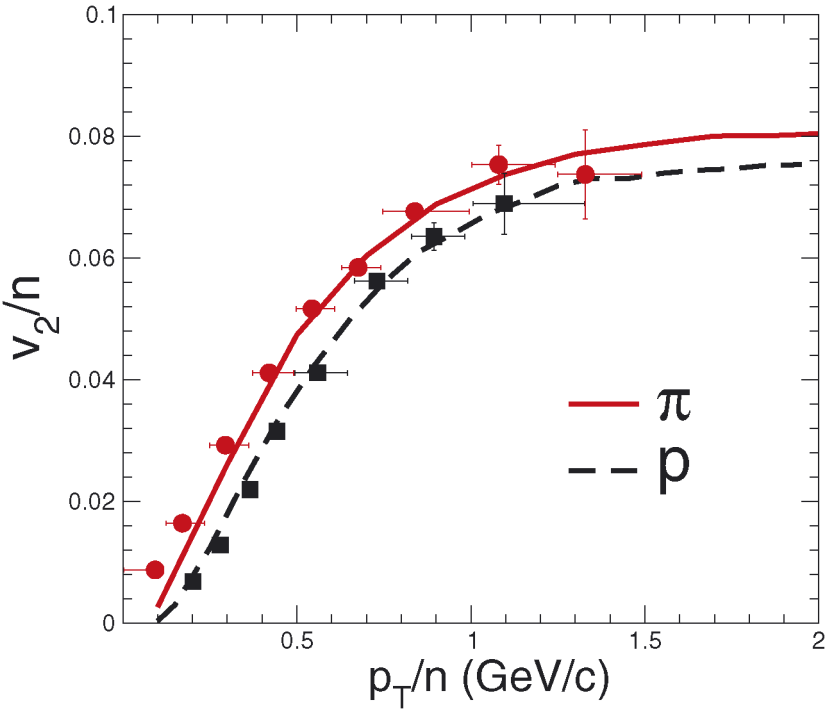

Fig. 56. v_2/n in the TAMU model, where n is the number of constituent quarks in a particle for protons and pions [241]. Scaled pion (dashed line) and proton (dotted line) results from the TAMU model are shown in addition to charged pion and proton measurements from the PHENIX experiment from minimum bias Au + Au reactions at $\sqrt{s_{NN}} = 200$ GeV [50]. This model allows for the recombination of hard partons and soft partons, as well as the decay of resonances such as the two pion decay of the ρ meson. One sees that, at least in this calculation, the addition of processes which mix hard and soft partons do not destroy the agreement for the model with v_2/n which is presumably a soft process.

is 9–18 fm/c, well outside the collision region. However for $p_T = 2.5$ GeV/c protons, the corresponding formation time is only 2.7 fm/c in the vacuum, suggesting the possibility that the hadronization process may begin inside the medium. However the formation of such heavy particles would presumably be delayed in a deconfined medium until the entire system began to hadronize.

If quarks and antiquarks from gluon splitting are assumed to combine into dipole color singlets leading to the final hadrons, the formation time may be estimated from the gluon emission time. Then the formation time for a hadron carrying a fraction z of the parton energy is given by

$$\tau_f \approx \frac{2E_h(1-z)}{k_T^2 + m_h^2}. \tag{34}$$

If z is 0.6–0.8 and $k_T \approx \Lambda_{\mathrm{QCD}}$, proton formation times in the range of 1–4 fm result [220]. Such values again imply formation of the proton within the medium. Thus, it is possible that differing (and perhaps complicated) interactions with the medium may produce differ-

ent scalings of proton and pion production and result in modified fragmentation functions in Au + Au collisions. However, most expectations are that this should lead to greater suppression rather than less. In fact, modified fragmentation functions measured in electron deep-inelastic scattering on nuclei by the HERMES experiment are often interpreted in terms of additional suppression for hadrons forming in the nuclear material.

7.6. Hard-scattering physics

If the dominant source of (anti)protons at intermediate p_T is not soft physics, is the explanation a medium-modified hard-process source? The near-side partner yields indicate that a significant fraction of the baryons have jet-like partners. However, in the parton energy loss scenario as described in Section 6, hard-scattered partons lose energy in medium prior to hadronization. Thus one would expect the same suppression for baryons and mesons. Furthermore, we know that the (anti)protons are as suppressed above $p_T = 5$ GeV/c in a manner similar to pions. Hence for this explanation to be correct, there must exist a mechanism by which only partons leading to baryons between 2 and 5 GeV/c in p_T escape suppression.

Another key piece of information is that the elliptic flow v_2 for protons is large for p_T in the range 2–4 GeV/c. At low p_T this collective motion is attributed to different pressure gradients along and perpendicular to the impact parameter direction in semi-central collisions. At higher p_T it has been hypothesized that one could observe a v_2 due to smaller partonic energy loss for partons traveling along the impact parameter direction (shorter path in the medium) as opposed to larger partonic energy loss in the perpendicular direction (larger path in the medium). However, the data suggest that the pions have a large energy loss (a factor of five suppression in central Au + Au reactions), while the protons do not. In this case one might expect that if the source of proton v_2 were energy loss, then proton v_2 would be significantly less than the v_2 for the pions. In fact, the opposite is experimentally observed: for $p_T > 2$ GeV/c, the proton v_2 is always larger than the pion v_2.

The contradictions the data create for both the “soft”- and “hard”-physics explanations may indicate that the correct physics involves an interplay between the two.

7.7. Conclusions

The anomalous enhancement of (anti)protons relative to pions at intermediate $p_T = 2$–5 GeV remains a puzzle. At lower transverse momentum particle production is a long-wavelength “soft” process and the transport of these hadrons and their precursor partons is reasonably described by hydrodynamics. As observed at lower energies, soft particles emitted from an expanding system receive a collective velocity boost to higher p_T resulting in an enhanced p/π and $\bar{p}/\pi$ ratio relative to proton–proton reactions at the same energy. We observe a similar phenomena at RHIC, for which the (anti)proton spectra and v_2 are roughly described in some hydrodynamic models up to approximately 2 GeV/c. Another class of calculations, referred to as recombination models, also boosts soft physics to higher p_T by coalescence of “dressed” partons. In the hydrodynamic models the quanta which are flowing are initially partons and then hadrons. The recombination models de-

scribe comoving valence partons which coalesce into hadrons, and do not reinteract. These two points of view may not be entirely contradictory, since both include a flowing partonic phase. In fact, it may be that the recombination models provide a mechanism by which hydrodynamics works to a much higher p_T than one might expect. The simplifying assumption of hadrons which do not interact is most probably an oversimplification and further refinement of the models will include this, though it may be that the hadronic phase will not modify the spectra as much as the hydrodynamic models might predict.

In both models, the (anti)proton enhancement as a function of centrality can be tuned to reproduce the apparent binary collision scaling observed in the data. An important distinction between the two is that in one case this enhancement is mass dependent and in the other it comes from the combination of quark momenta and thus distinguishes between baryons and mesons.[11] R_{CP} for the ϕ is similar to other mesons despite the fact that they are more massive than protons. This scaling with quark content, as opposed to mass, favors recombination models.

Further investigations into these intermediate p_T baryons reveals a near-angle correlation between particles, in a fashion characteristic of jet fragmentation. The near-angle associated particle yield increases by almost a factor of two in going from proton–proton and deuteron–gold reactions to gold–gold peripheral collisions. In addition, the partner yield is similar for trigger pions and protons, except in the most central gold–gold reactions. This appears to indicate a hard process source for a significant fraction of these baryons in contrast to the previous mentioned physics scenarios. Quantifying the precise contribution is an important goal for future measurements.

The large (anti)baryon to pion excess relative to expectations from parton fragmentation functions at intermediate $p_T = 2$–5 GeV/c remains one of the most striking unpredicted experimental observations at RHIC. The data clearly indicate a new mechanism other than universal parton fragmentation as the dominant source of baryons and antibaryons at intermediate p_T in heavy ion collisions. The boosting of soft physics, that dominates hadron production at low p_T, to higher transverse momentum has been explored with the context of hydrodynamic and recombination models. However, investigations into these intermediate p_T baryons reveals a near-angle correlation between particles, in a fashion characteristic of jet fragmentation. If instead these baryons have a partonic hard scattering followed by fragmentation source, this fragmentation process must be significantly modified. It is striking that these baryons have a large v_2 (typically 20%) indicative of strong collective motion and also a large "jet-like" near-side partner yield. At present, no theoretical framework provides a complete understanding of hadron formation in the intermediate p_T region.

8. Future measurements

The previous sections have documented the breadth and depth of the PHENIX data from the first three years of RHIC operations, along with the physics implications of those

[11] A caveat to this fact is that in the recombination models, it is the constituent-quark mass that is important, thereby giving a slightly larger mass to the strange quark.

results. Here we describe those measurements required to further define and characterize the state of matter formed at RHIC. In particular, we note that the study of penetrating probes, which are the most sensitive tools in this endeavor, is just beginning. The PHENIX experiment was specifically designed to address these probes with capabilities that are unique within the RHIC program and unprecedented in the field of relativistic heavy ion physics.

One can distinguish two broad classes of penetrating probes.

(1) Hard probes created at the very early stage of the collision which propagate through, and could be modified by, the medium. These are the QCD hard-scattering probes and the main observables are high-p_T particles coming from the fragmentation of jets, hidden charm (J/ψ production), open charm and eventually also bottom quark and Υ production.
(2) Electromagnetic probes (either real or virtual photons) which are created by the medium. Due to their large mean free path these probes can leave the medium without final-state interaction thus carrying direct information about the medium's conditions and properties. The main observables here are low-mass e^+e^- pairs and the thermal radiation of the medium.

By their very nature, penetrating probes are also rare probes and consequently depend on the development of large values of the integrated luminosity. In the present data set the reach for high-p_T particles in PHENIX extends to roughly 10 GeV/c, and lower-cross-section measurements such as charmonium are severely limited. The dramatic improvement of the machine performance in the year 2004 run provides confidence that both this data set and those from future RHIC runs will dramatically extend our reach in the rare probes sector.

As part of a decadal planning of the RHIC operation, PHENIX has prepared a comprehensive document that outlines in great detail its scientific goals and priorities for the next 10 years together with the associated detector upgrade program needed to achieve them. The decadal plan [243] is centered around the systematic study of the penetrating probes listed above. The program is broad and can accommodate additions or modifications provided that a compelling physics case can be made. Measurements are mainly planned in Au + Au collisions at the full RHIC energy but they will be supplemented by other measurements varying the energy and/or the species and by the necessary reference measurements of $p + p$ and $p + A$ collisions. A short summary is given below.

8.1. High-p_T suppression and jet physics

The most exciting results to date at RHIC are the discovery of high-p_T suppression of mesons, interpreted in terms of energy loss of quarks in a high-density medium, and the nonsuppression of baryons or equivalently, the anomalously high p/π ratio which still awaits a clear explanation. These two topics were extensively discussed in Sections 6 and 7, respectively.

The data collected so far are superb. However, they suffer from limited reach in transverse momentum, limited particle identification capabilities and limited statistics in par-

ticular for detailed studies of jet correlations. PHENIX has a program for further studies of the high-p_T-suppression phenomena and jet physics which aims at overcoming these limitations.

It will be necessary to trace the suppression pattern to much higher p_T to determine whether (and if so, when) the suppression disappears and normal perturbative QCD behavior sets in. High-luminosity runs will be needed, with at least a factor of 50 more statistics. PHENIX is particularly able to perform these measurements with its excellent capability of triggering on high-momentum π^0's.

PHENIX has performed several particle correlation analyses and has demonstrated that the experiment's aperture at mid-rapidity is sufficient to conduct these studies. Currently, these analyses are limited by the available statistics. Again, increasing the data sample by a factor of 50–100 will allow a variety of correlation studies using trigger particles with much-higher-momentum than studied to date. A particularly interesting case is the study of high-momentum γ-jet correlations, which have vastly reduced trigger bias, since the trigger photons propagate through the medium with a very long mean free path.

To further elucidate the baryon puzzle, additional data is required with better separation between baryons and mesons. An upgrade consisting of an aerogel Cerenkov counter and a high-resolution TOF detector is expected to be completed in time for the year 2006. A portion of this aerogel counter was already installed prior of the year 2004 run and performed according to expectations. Once completed, this high-p_T detector will allow identification of π, K/p to beyond 8 GeV/c in p_T.

8.2. J/ψ production

Suppression of heavy quarkonia is one of the earliest and most striking proposed signatures of deconfinement. The suppression mechanism follows directly from the Debye screening expected in the medium, which reduces the range of the potential between charm quark and antiquark pairs [244]. The NA38 and NA50 experiments have carried out a systematic study of J/ψ and ψ' at the CERN-SPS in $p+p$, $p+A$, light ion, and Pb + Pb collisions providing some of the most intriguing results of the relativistic heavy ion program for more than ten years. The NA50 experiment observed an anomalous suppression of J/ψ in central Pb + Pb collisions at $\sqrt{s_{NN}} = 17.2$ GeV [245]. The suppression, which is of the order of 25% with respect to the normal suppression in nuclear matter, has been interpreted by the NA50 authors as evidence for deconfinement of quarks and gluons. Although this interpretation is not universally shared [246,247], the results of NA38 and NA50 demonstrate the utility and great interest in understanding the fate of charmonium in dense nuclear matter.

The theoretical expectations at RHIC energies are not at all clear. They range from total suppression in the traditional Debye screening scenario to enhancement in coalescence models [248–250] and in statistical hadronization models [251,252], of c and $\bar{c}$ quarks. Although some versions of the coalescence model seem disfavored from our very limited data set [51], a more conclusive statement on these models has to await the much larger data set of the year 2004 run.

PHENIX has unprecedented capabilities for the study of the J/ψ in Au + Au collisions. The J/ψ can be measured via its $\mu^+\mu^-$ decay channel at forward and backward

rapidities in the muon spectrometers and via its e^+e^- decay channel at mid-rapidity in the central arm spectrometers. From the recorded luminosity of the year 2004 run, we expect several thousand and ~ 500 J/ψ in the muon and central arms, respectively. This data set will allow us a first look at the J/ψ production pattern at RHIC. However, it could well be marginal for a complete characterization as a function of centrality and p_T, so that it is likely that further higher-luminosity runs will be required. Also the $p + p$ and $d +$ Au baseline measurements performed in the year 2001–2003 runs have large statistical uncertainties, and higher-statistics versions for these colliding species will be needed. A high-luminosity $p + p$ run is planned in the year 2005 and high-luminosity $d + A$ or $p + A$ are still to be scheduled in the next years.

8.3. Charm production

Charm quarks are expected to be produced in the initial hard collisions between the incoming partons. The dominant mechanism is gluon fusion and thus the production cross section is sensitive to the gluon density in the initial state. The $c\bar{c}$ production cross section is sizable at RHIC energies with a few $c\bar{c}$ pairs and therefore several open charm mesons per unit of rapidity in central Au + Au collisions. As a result, charm observables become readily accessible at RHIC and offer additional and extraordinarily valuable diagnostic tools. For example, it is vitally important to perform measurements of charm flow and to determine the energy loss of charm quarks in the medium. Such measurements will determine if the bulk dynamics observed for light quarks extend to charm quarks, which could in fact have very different behavior due to their much larger mass. Again the potential of PHENIX in this domain is unique with its capability of measuring open charm in a broad rapidity range, in the central and muon arms, via both the electron and muon decay channels. An additional unique feature is the possibility to measure correlated semileptonic charm decays by detecting e–μ coincidences from correlated $D\bar{D}$ decays. Such a measurement is particularly interesting for the study of charm-quark energy loss which may differ significantly from that observed for lighter quarks [253–255]. A first study of e–μ coincidences should be feasible with the year 2004 data.

To date PHENIX has measured charm production cross section in an indirect way through high-p_T single electrons [42,57] assuming that all electrons (after measuring and subtracting the contributions from light hadrons and photon conversions) originate from the semileptonic decays of charm quarks. Although the charm cross section has large uncertainties, the centrality dependence of the charm rapidity density demonstrates that charm production follows binary scaling as shown in Fig. 34. Improvements and additional information are expected from the much higher statistic of the year 2004 data.

A qualitatively new advance for PHENIX in the charm and also the beauty sector will be provided by the implementation of the silicon vertex detector. An upgrade project is underway to install in the next five years a silicon vertex tracker, including a central arm barrel and two end caps in front of the two muon spectrometers. The vertex tracker will allow us to resolve displaced vertices and therefore to directly identify open charm mesons via hadronic, e.g., $D \to K\pi$, as well as semi-leptonic decays. The heavy-quark physics topics accessible with the vertex tracker include production cross section and energy loss

of open charm and open beauty, and spectroscopy of charmonium and bottomonium states, each of which should provide incisive new details on the properties of the created medium.

8.4. Low-mass dileptons

Low-mass dileptons are considered the most sensitive probe of chiral symmetry restoration primarily through ρ meson decays. Due to its very short lifetime ($\tau = 1.3$ fm/c) compared to that of the typical fireball of ~ 10 fm/c, most of the ρ mesons decay inside the medium providing an unique tool to observe in-medium modifications of its properties (mass and/or width) which could be linked to chiral symmetry restoration. The situation is somewhat different but still interesting for the ω and ϕ mesons. Because of their much longer lifetimes ($\tau = 23$ fm/c and 46 fm/c for the ω and ϕ, respectively) they predominantly decay outside the medium, after regaining their vacuum properties, with only a small fraction decaying inside the medium. Since the measurement integrates over the history of the collision, this may result in a small modification of the line shape of these two mesons which PHENIX might be able to observe with its excellent mass resolution. PHENIX also has the unprecedented capability of simultaneously measuring within the same apparatus the ϕ meson decay through e^+e^- and K^+K^- channels. The comparison of the branching ratios to these two channels provides a very sensitive tool for in-medium modifications of the ϕ and K mesons.

The CERES experiment at CERN has confirmed the unique physics potential of low-mass dileptons [256–258]. An enhancement of electron pairs was observed in the mass region $m = 0.2$–0.6 GeV/c^2 in Pb + Au collisions at $\sqrt{s_{NN}} = 17.2$ GeV with respect to $p + p$ collisions. The results have triggered a wealth of theoretical activity and can be explained by models which invoke in-medium modification of the ρ meson (dropping of its mass and/or broadening of its width) [259]. The precision of the CERES data has been so far insufficient to distinguish between the different models. Results with higher statistics and better mass resolution are expected from the NA60 experiment that is studying the production of low-mass dimuons in In + In collisions [260]. Theoretical calculations [261] show that the enhancement should persist at RHIC energies and that PHENIX with its excellent mass resolution has an unique opportunity to do precise spectroscopy of the light vector mesons and to shed more light on the origin of the enhancement of the low-mass-pair continuum.

The measurement of low-mass electron pairs is however a very challenging one. The main difficulty stems from the huge combinatorial background created by the pairing of e^+ and e^- tracks from unrecognized π^0 Dalitz decays and γ conversions. PHENIX is developing a novel Cerenkov detector that, in combination with the recently installed coil which makes the magnetic field zero close to the beam axis, will effectively reduce this combinatorial background by almost two orders of magnitude [262]. The detector, operated in pure CF_4, consists of a 50-cm-long radiator directly coupled, in a windowless configuration, to a triple GEM detector which has a CsI photocathode evaporated on the top face of the first GEM foil and pad read out at the bottom of the GEM stack [263]. The R&D phase to demonstrate the validity of the concept is nearing completion. The detector construction phase is starting now with installation foreseen in time for the year 2006–2007. With this detector PHENIX will have the unprecedented ability to perform high-quality measure-

ments over the whole dilepton mass range from the π^0 Dalitz decay up to the charmonium states.

8.5. Thermal radiation

A prominent topic of interest in the field of relativistic heavy-ion collisions is the identification of the thermal radiation emitted by the system and in particular the thermal radiation emitted by the quark–gluon plasma via $q\bar{q}$ annihilation. Such radiation is a direct fingerprint of the matter formed and is regarded as a very strong signal of deconfinement. Its spectral shape should provide a direct measurement of the plasma temperature.

In principle the thermal radiation can be studied through real photons or dileptons, since real and virtual photons carry basically the same physics message. In practice the measurements are extremely challenging. The thermal radiation is expected to be a small signal compared to the large background from competing processes, hadron decays for real photons and Dalitz decays and γ conversions for dileptons, the former being larger by orders of magnitude compared to the latter. But in both cases, a very precise knowledge of all these sources is an absolutely necessary prerequisite. After subtracting these sources, one still needs to disentangle other contributions which might be comparable or even stronger, mainly the contributions of initial hard-parton scattering to direct photons and of semileptonic decays of charm mesons to dileptons.

Theoretical calculations have singled out the dilepton mass range $m = 1$–3 GeV$/c^2$ as the most appropriate window where the QGP radiation could dominate over other contributions [264,265]. Measurements in this intermediate mass range carried out at the CERN SPS by HELIOS and NA50 have revealed an excess of dileptons, but this excess could be explained by hadronic contributions [266].

There is no conclusive evidence for QGP thermal photons from the CERN experiments (for a recent review see [267]). From the theoretical point of view it is clear that in the low-p_T region ($p_T < 2$ GeV$/c$) the real photon spectrum is dominated by hadronic sources and the thermal radiation from the hadron gas. It is only in the high-p_T region where one might have a chance to observe the thermal radiation from the QGP.

PHENIX has measured direct real photons at $p_T > 4$ GeV$/c$ from the initial hard scatterings [73]. The errors are relatively large leaving room for a comparable contribution of thermal photons. The high statistics of the year 2004 run will provide the first real opportunity to search for the QGP thermal radiation in PHENIX both in the dilepton and real photon channels. However, the search for this elusive signal might take some time as it will probably require equally-high-statistics runs of reference data in $p + p$ and $p + A$ collisions for a precise mapping of all the other contributions (hadronic + pQCD for real photons and hadronic + charm for dileptons).

9. Summary and conclusions

The PHENIX data set from the first three years of RHIC operation provides an extensive set of measurements, from global variables to hadron spectra to high-p_T physics to heavy-flavor production. From this rich menu we have reviewed those aspects of the present data

that address the broad features of the matter created in Au + Au collisions at RHIC, namely, energy and number density, thermalization, critical behavior, hadronization, and possible deconfinement.

We first investigated whether the transverse energy and multiplicity measurements of PHENIX demonstrate that a state of high-energy-density matter is formed in Au + Au collision at RHIC. We estimated from our $dE_T/d\eta$ measurement that the peak energy density in the form of created secondary particles is at least 15 GeV/fm^3. If we use a thermalization time of 1 fm/c provided by the hydrodynamic models from the elliptic flow, then the value of the energy density of the first thermalized state would be in excess of 5 GeV/fm^3. These values are well in excess of the ~ 1 GeV/fm^3 obtained in lattice QCD as the energy density needed to form a deconfined phase. Naïve expectations prior to RHIC turn-on that $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ could be factorized into a "soft" and a pQCD jet component are not supported by the data. Results from a new class of models featuring initial-state gluon saturation compare well with RHIC multiplicity and E_T data.

We then examined our data and various theoretical models to investigate the degree to which the matter formed at RHIC appears to be thermalized. The measured yields and spectra of hadrons are consistent with thermal emission from a strongly expanding source, and the observed strangeness production is consistent with predictions based on complete chemical equilibrium. The scaling of the strength of the elliptic flow v_2 with eccentricity shows that a high degree of collectivity is built up at a very early stage of the collision. The hydro models which include both hadronic and QGP phases reproduce the qualitative features of the measured $v_2(p_T)$ of pions, kaons, and protons. These hydro models require early thermalization ($\tau_{\rm therm} \leqslant 1$ fm/c) and high initial energy density $\varepsilon \geqslant 10$ GeV/fm^3. These points of agreement between the data and the hydrodynamic and thermal models can be interpreted as strong evidence for formation of high-density matter that thermalizes very rapidly.

However several of the hydro models fail to reproduce the $v_2(p_T)$ of pions, protons, and spectra of pions and protons simultaneously. Given this disagreement it is not yet possible to make an unequivocal statement regarding the presence of a QGP phase based on comparisons to hydrodynamic calculations. The experimentally measured HBT source parameters, especially the small value of $R_{\rm long}$ and the ratio $R_{\rm out}/R_{\rm side} \approx 1$, are not reproduced by the hydrodynamic calculations. Hence we currently do not have a consistent picture of the space–time dynamics of reactions at RHIC as revealed by spectra, v_2 and HBT. These inconsistencies prevent us from drawing firm conclusions on properties of the matter such as the equation of state and the presence of a mixed phase.

Critical behavior near the phase boundary can produce nonstatistical fluctuations in observables such as the net-charge distribution and the average transverse momentum. Our search for charge fluctuations has ruled out the most naïve model of charge fluctuations in a QGP, but it is unclear if the charge fluctuation signature can survive hadronization. Our measurement of $\langle p_T \rangle$ fluctuations is consistent with the effect expected of high-p_T jets, and it gives a severe constraint on the fluctuations that were expected for a sharp phase transition.

Many of these observables—for instance, large $dE/d\eta$ and $dN_{\rm ch}/d\eta$, strangeness enhancement, strong radial flow, and elliptic flow—have been observed in heavy ion collisions at lower energies. We have found smooth changes in these observables as a function

of $\sqrt{s_{NN}}$ from AGS energies to SPS energies to RHIC energy. The $dE_T/d\eta$ increases by about 100% and the strength of the elliptic flow increase by about 50% from SPS to RHIC. The strangeness suppression factor γ_s and the radial expansion velocity $\langle\beta_T\rangle$ vary smoothly from AGS to RHIC energies. No sudden change with collision energy has been observed.

The strong suppression of high-p_T particle production at RHIC is a unique phenomenon that has not been previously observed. Measurements of two-hadron azimuthal-angle correlations at high p_T and the x_T scaling in Au + Au collisions confirm the dominant role of hard scattering and subsequent jet fragmentation in the production of high-p_T hadrons. Measurements in deuteron–gold collisions demonstrate that any initial-state modification of nuclear parton distributions causes little or no suppression of hadron production for $p_T > 2$ GeV/c at mid-rapidity. This conclusion is further strengthened by the observed binary scaling of direct photon and open charm yields in Au + Au. Combined together, these observations provide direct evidence that Au + Au collisions at RHIC have produced matter at extreme densities.

Medium-induced energy loss, predominantly via gluon bremsstrahlung emission, is the only currently known physical mechanism that can fully explain the magnitude of the observed high-p_T suppression. The approximately flat suppression factor $R_{AA}(p_T)$ observed in the data, which was predicted by the GLV energy loss model, rules out the simplest energy loss models which predicted a constant energy loss per unit length. However, the model by Wang et al. obtains the same flat $R_{AA}(p_T)$ from apparently different physics. From the GLV model, the initial gluon number density, $dn_g/dy \approx 1000$ and initial energy density, $\varepsilon_0 \approx 15$ GeV/fm^3, have been obtained. These values are consistent with the energy density obtained from our $dE_T/d\eta$ measurement as well as ones from the hydro models.

The large (anti)baryon to pion excess relative to expectations from parton fragmentation functions at intermediate p_T (2–5 GeV/c) is both an unpredicted and one of the most striking experimental observation at RHIC. The data demonstrate that a mechanism other than universal parton fragmentation is the dominant source of (anti)baryons in the intermediate p_T range in heavy ion collisions. Explanations based on the boosting of soft physics to higher transverse momentum have been examined within the context of hydrodynamics and recombination models. While hydrodynamic models can readily explain the baryon to meson ratio as a consequence of strong radial flow, these models have difficulties reproducing the difference in v_2 between protons and mesons above 2 GeV/c. In contrast, recombination models provide a natural explanation for the large baryon to meson ratio as well as the apparent quark-number scaling of the elliptic flow. However, the near-angle correlation between particles is characteristic of jet fragmentation. It is truly remarkable that these baryons have a large v_2 of $\approx 20\%$ typically indicative of strong collective motion and also a large jet-like near-side partner yield. At present, no model provides a complete understanding of hadron formation in the intermediate p_T regime.

The initial operation of RHIC has produced the impressive quantity of significant results described above. These striking findings call for additional efforts to define, clarify and characterize the state of matter formed at RHIC. Further study of the collisions using hard probes such as high-p_T particles, open charm, and J/ψ, and electromagnetic probes such as direct photons, thermal photons, thermal dileptons, and low-mass lepton pairs are

particularly important. The utilization of these penetrating probes is just beginning, and we expect these crucial measurements based on the very-high-statistics data of the year 2004 run will provide essential results towards understanding of the dense matter created at RHIC.

Advances in the theoretical understanding of relativistic heavy ion collisions is vital for the quantitative study of the dense matter formed at RHIC. While there is rapid and significant progress in this area, a coherent and consistent picture of heavy ion collisions at RHIC, from the initial formation of the dense matter to the thermalization of the system to the hadronization to the freezeout, remains elusive. With such a consistent model, it will become possible to draw definitive conclusions on the nature of the matter and to quantitatively determine its properties. The comprehensive data sets ranging from global variables to penetrating probes provided by PHENIX at present and in the future will prove essential in constructing and constraining a consistent model of heavy ion collisions to determine the precise nature of the matter created at RHIC.

In conclusion, there is compelling experimental evidence that heavy-ion collisions at RHIC produce a state of matter characterized by very high energy densities, density of unscreened color charges ten times that of a nucleon, large cross sections for the interaction between strongly interacting particles, strong collective flow, and early thermalization. Measurements indicate that this matter modifies jet fragmentation and has opacity that is too large to be explained by any known hadronic processes. This state of matter is not describable in terms of ordinary color-neutral hadrons, because there is no known self-consistent theory of matter composed of ordinary hadrons at the measured densities. The most economical description is in terms of the underlying quark and gluon degrees of freedom. Models taking this approach have scored impressive successes in explaining many, but not all, of the striking features measured to date. There is not yet irrefutable evidence that this state of matter is characterized by quark deconfinement or chiral symmetry restoration, which would be a direct indication of quark–gluon plasma formation. The anticipated program of additional incisive experimental measurements combined with continued refinement of the theoretical description is needed to achieve a complete understanding of the state of matter created at RHIC.

(Received 28 September 2004; published 2 March 2005)

The PHENIX experiment has measured midrapidity transverse momentum spectra ($0.4 < p_T < 4.0$ GeV/c) of single electrons as a function of centrality in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Contributions from photon conversions and Dalitz decays of light neutral mesons are measured by introducing a thin (1.7% X_0) converter into the PHENIX acceptance and are statistically removed. The subtracted nonphotonic electron spectra are primarily due to the semileptonic decays of hadrons containing heavy quarks, mainly charm at lower p_T. For all centralities, the charm production cross section is found to scale with the nuclear overlap function, T_{AA}. For minimum-bias collisions the charm cross section per binary collision is $N_{c\bar{c}}/T_{AA} = 622 \pm 57(\text{stat}) \pm 160(\text{syst})$ μb.

DOI: 10.1103/PhysRevLett.94.082301 PACS numbers: 25.75.Dw

In central Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV neutral pions and charged hadrons are strongly suppressed at high transverse momentum (p_T) [1–3]. In contrast, a modest high-p_T enhancement is observed in d + Au collisions at the same energy [4,5]. Taken together, these observations indicate that the suppression in Au + Au collisions is caused by final-state effects (e.g., parton energy loss in a dense medium produced in the reaction).

Heavy quarks (charm and bottom) are complementary probes of the hot and dense matter produced in high energy heavy ion collisions. Because of their large masses, charm and bottom cross sections are calculable via perturbative quantum chromodynamics (pQCD) and their yield is sensitive to the initial gluon density [6]. It has been predicted that heavy quarks suffer less energy loss than light quarks while traversing partonic matter due to the ''dead cone'' effect [7–9]. This can be studied through systematic measurements of the p_T spectra of open heavy flavor. In addition, the open-charm yield is an important baseline for understanding J/ψ production which has been predicted to be either suppressed [10] or enhanced [11] in deconfined partonic matter.

The PHENIX experiment observed that inclusive single electrons in central and minimum-bias Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV were produced in excess of purely ''photonic'' contributions (primarily due to π^0 Dalitz decays and conversion of π^0 photons in the detector material) [12]. This excess is consistent with the expected charm production, assuming that it scales with the number of binary nucleon-nucleon collisions ($N_{\rm coll}$) or, equivalently, with the nuclear overlap function, T_{AA}. In this Letter, we present results on the single electron measurement in $\sqrt{s_{NN}} = 200$ GeV Au + Au collisions. Our measurement is in a p_T range sensitive only to charm production. The new data have higher statistics and smaller systematic errors than the 130 GeV data, allowing us to measure charm production as a function of collision centrality.

The data used in this analysis were collected by the PHENIX detector [13] during the 2001 run period of the Relativistic Heavy Ion Collider. A coincidence of the beam-beam counters (BBC), a pair of detector arrays covering 2π in azimuth and $\eta = \pm(3.0$–$3.9)$, and the zero degree calorimeters (ZDC) provides the minimum-bias trigger ($92.2^{+2.5}_{-3.0}\%$ of the 6.8 ± 0.5 barn Au + Au inelastic cross section). The centrality is determined by the correlation between the multiplicity measured by the BBC and the energy of spectator neutrons measured by the ZDC. The BBC also measures the collision vertex, z, with resolution $\sigma = 0.7$ cm. We require $|z| < 20$ cm to eliminate electrons originating from the central magnet.

Charged particles are measured by the PHENIX east-arm spectrometer ($|\eta| < 0.35$, $\Delta\phi = \pi/2$) with resolution $\sigma_p/p \simeq 0.7\% \oplus 1.0\% p({\rm GeV}/c)$. Tracks are reconstructed with the drift chamber and the first layer of pad chambers and confirmed by requiring an electromagnetic calorimeter (EMCal) matching hit within 2σ in position. Electron candidates are required to have at least three associated hits in the ring imaging Čerenkov detector (RICH) that pass a ring shape cut, and are required to pass a timing cut in either the EMCal or the time-of-flight detector. After these cuts, a clear electron signal is observed as a narrow peak at $E/p = 1$. By requiring $-2\sigma < (E - p)/p < 3\sigma$, background from hadrons, which deposit only a fraction of their energy in the EMCal, and nonvertex electrons, which have misreconstructed momenta, is further reduced. Remaining background in the electron sample, due to accidental coincidences between RICH hits and hadron tracks, is estimated ($\approx 10\%$) and subtracted by an event-mixing method.

Inclusive electrons contain two components: (i) ''nonphotonic''—primarily semileptonic decays of mesons containing heavy quarks, and (ii) photonic—Dalitz decays of light neutral mesons (π^0, η, η', ρ, ω, and ϕ) and photon conversions in the detector material. To separate these two components, a photon converter (a thin brass tube of 1.7% radiation length surrounding the beam pipe at $r = 29$ cm) was installed.

We analyzed 2.2 M (2.5 M) events with the converter in (out). The corresponding raw electron p_T spectra for minimum-bias collisions are shown in Fig. 1(a). The photon converter multiplies the photonic contribution to the electron yield by a factor R_γ:

$$N_e^{\text{Conv-out}} = N_e^{\gamma} + N_e^{\text{non-}\gamma}, \tag{1}$$

$$N_e^{\text{Conv-in}} = R_\gamma N_e^{\gamma} + (1 - \epsilon) N_e^{\text{non-}\gamma}. \tag{2}$$

Here $N_e^{\text{Conv-in}}$ ($N_e^{\text{Conv-out}}$) is the measured electron yield with (without) the converter; N_e^{γ} ($N_e^{\text{non-}\gamma}$) is the electron yield due to the photonic (nonphotonic) component; and $\epsilon(\approx 2.1\%)$ represents a small loss of electrons due to the converter. We next define R_{CN} as the ratio of the raw electron yield with and without the converter. Dividing Eq. (2) by Eq. (1) and defining $R_{NP} \equiv N_e^{\text{non-}\gamma}/N_e^{\gamma}$, one has

$$R_{CN} \equiv \frac{N_e^{\text{Conv-in}}}{N_e^{\text{Conv-out}}} = \frac{R_\gamma + (1 - \epsilon) R_{NP}}{1 + R_{NP}}. \tag{3}$$

If there were no contribution from the nonphotonic component ($R_{NP} = 0$), then $R_{CN} = R_\gamma$.

The photonic electron yield per photon is approximately given by $Y \propto \delta + \frac{7}{9} t$, where δ is the Dalitz branching ratio per γ relative to 2γ (for π^0, η, and η') or 1γ (for ρ, ω, and ϕ) decay, and t is the thickness of the conversion material in radiation length (X_0). The factor $\frac{7}{9}$ is the approximate probability for a γ to convert in one X_0. Plugging in $\delta^{\pi^0} = 0.6\%$, $t \approx 1.1\%$ ($t \approx 2.8\%$) for converter out (in) we find $R_\gamma^{\pi^0} = Y^{\text{Conv-in}}/Y^{\text{Conv-out}} \approx 1.9$. There is some p_T depen-

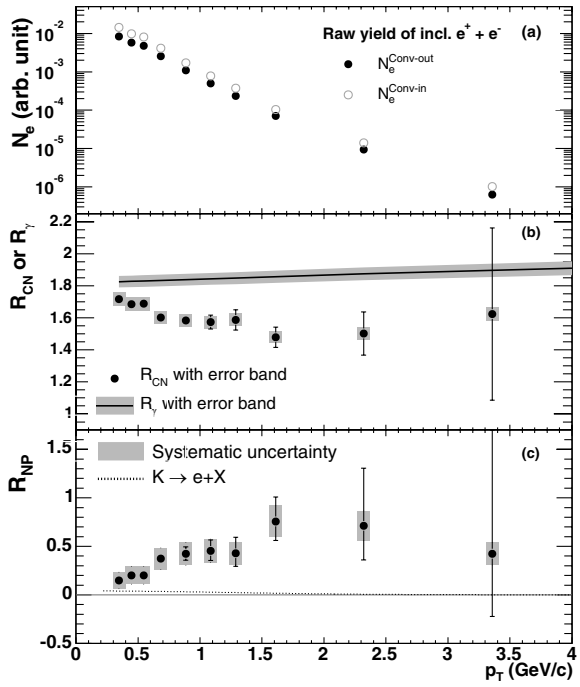

FIG. 1. Shown vs p_T (a) raw $e^{\pm}$ spectra measured with the converter in (open circles) and out (closed circles). (b) Ratio of the converter in/out $e^{\pm}$ yields (R_{CN}, points) and ratio of photonic $e^{\pm}$ yield with/without the converter (R_γ, line and shaded band). (c) Ratio of nonphotonic to photonic $e^{\pm}$ yields (R_{NP}, points) and contribution from kaon decays (dashed line).

dence in the complete formula for Y and the value of δ is species dependent ($\delta^\eta \approx 0.8\%$), so we perform a full GEANT [14] simulation with and without the converter to calculate R_γ. We determine R_γ for π^0 and η separately. We use the π^0 spectrum measured by PHENIX [1] as the input for the π^0 simulation and assume m_T scaling ($p_T \rightarrow \sqrt{p_T^2 + M_\eta^2 - M_\pi^2}$, normalized at high p_T to $\eta/\pi^0 = 0.45 \pm 0.1$) to obtain the input for the η simulation. Contributions from other mesons which undergo Dalitz decay (η', ρ, ω, ϕ) are small (6% at $p_T = 3$ GeV/c, and smaller at lower p_T). Since they have $\delta \approx \delta^\eta$, we assign them $R_\gamma = R_\gamma^\eta$. When calculating the combined R_γ, we use the particle ratios at high p_T ($\eta'/\pi^0 = 0.25 \pm 0.13$, $\rho/\pi^0 = \omega/\pi^0 = 1 \pm 0.5$, $\phi/\pi^0 = 0.4 \pm 0.2$). The ϕ/π^0 ratio used here is consistent with our π^0 and ϕ measurement [15]. The uncertainties in the particle ratios are included in the systematic uncertainties of R_γ. For this method it is essential that the amount of material is accurately modeled in the simulation. We compared the yield of identified photon conversion pairs in the data and in the simulation and conclude that the simulation reproduces R_γ within $\pm 2.0\%$. This uncertainty is included in the overall systematic uncertainty.

Figure 1(b) shows that R_{CN} gradually decreases with increasing p_T, while R_γ slightly increases with p_T. The difference between R_{CN} and R_γ indicates the existence of nonphotonic electrons. Figure 1(c) shows R_{NP} obtained from R_γ and R_{CN} using Eq. (3). R_{NP} increases with p_T and is more than 30% for $p_T > 0.6$ GeV/c. The small amount of conversion material in the PHENIX detector allows a sensitive measurement of R_{CN}.

Background from kaon decays ($K \rightarrow \pi e \nu$) and dielectron decays of ρ, ω, and ϕ remain in the nonphotonic electron yield. The background from kaon decays is estimated with a GEANT simulation using the kaon p_T spectrum measured by PHENIX [16] as input. The contribution of kaon decays to the nonphotonic yield, shown in Fig. 1(c), is 18% at $p_T = 0.4$ GeV/c and decreases rapidly to less than 6% for $p_T > 1$ GeV/c. To calculate background from the e^+e^- decays of ρ, ω, and ϕ, we first generate spectra by applying m_T scaling to the PHENIX π^0 spectrum, as described above. The contribution of these decays to the nonphotonic electrons is $<3\%$ for all p_T. Background from $J/\psi \rightarrow e^+e^-$ decays and from Drell-Yan pairs is negligible. Possible enhancement of low mass dileptons through $\pi + \pi \rightarrow \rho \rightarrow e^+e^-$, as reported in Pb + Pb collisions at the Super Proton Synchrotron [17], would contribute to the nonphotonic electrons. However, this is neglected since the estimated ρ contribution in the absence of enhancement is only $\approx 0.6\%$ over all p_T.

After these backgrounds are subtracted the only other significant source of nonphotonic electrons is the semileptonic decay of heavy flavor, overwhelmingly charm. We denote the remaining electrons as charm electrons. The raw spectrum of charm electrons is corrected for geometrical acceptance ($\epsilon_{\rm geo}$), track reconstruction efficiency ($\epsilon_{\rm rec}$), and electron identification efficiency ($\epsilon_{e\rm ID}$) determined by GEANT simulation. The efficiency $\epsilon_{\rm geo} \times \epsilon_{\rm rec}$ is about 11% of dN_e/dy, and $\epsilon_{e\rm ID}$ is about 65% as confirmed with electrons identified through photon conversion. Correction of multiplicity dependent efficiency losses, estimated by embedding simulated electron tracks into real events, is p_T independent and increases from 5% to 26% from peripheral to central collisions. The 1σ systematic uncertainty of these corrections is 11.8%. Fully corrected charm electron spectra are shown in Fig. 2 for minimum-bias collisions and for five centrality bins. We determined photonic electron spectra and found them to be in good agreement with the background calculated from the measured π^0 spectra using the method described in [12].

We also measured the charm electron spectrum in $p + p$ collisions at $\sqrt{s_{NN}} = 200$ GeV [18]. The lines in Fig. 2 show the best fit curve of this spectrum, scaled by T_{AA} for each Au + Au centrality bin. Here, T_{AA} is the nuclear overlap function calculated by a Glauber model [1] (Table I). The Au + Au data points are in reasonable agreement with the $p + p$ fit in all centrality bins.

To quantify the centrality dependence of charm production, we calculated the integrated yield dN_e/dy ($0.8 < p_T < 4.0$ GeV/c) and fit it to $AN_{\rm coll}^\alpha$, where A is constant. In the absence of medium effects $\alpha = 1$ is the expectation

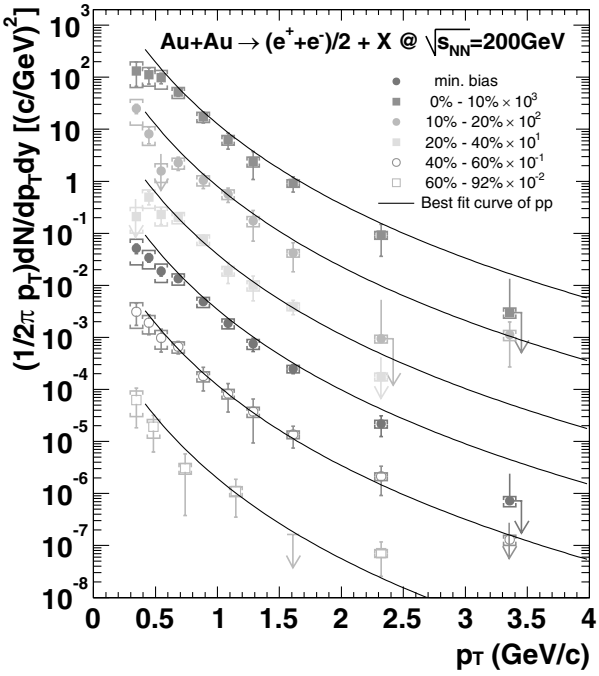

FIG. 2. Fully corrected charm electron p_T spectra for different Au + Au centralities scaled by successive factors of 10 for clarity. Error bars (brackets) correspond to statistical (systematic) uncertainties. Curves are described in the text.

in the absence of medium effects. In this comparison, most of the systematic effects will cancel. Figure 3 shows $dN_e/dy(0.8 < p_T < 4.0)/N_{\rm coll}$ vs $N_{\rm coll}$ for minimum bias and five centrality bins in Au + Au collisions and $p + p$ collisions. We find $\alpha = 0.938 \pm 0.075(\text{stat}) \pm 0.018(\text{syst})$. If $p + p$ data are included, $\alpha = 0.958 \pm 0.035(\text{stat})$. This shows that the total yield of charm electrons for all centralities is consistent with $N_{\rm coll}$ scaling.

For each centrality bin we scale the charm electron spectrum ($p_T > 0.8$ GeV/c) by T_{AA} and fit it with a PYTHIA calculation of the electron spectrum resulting from leading order charm and bottom production. We used PYTHIA 6.205 with a modified set of parameters (described in [12]) and CTEQ5L parton distribution functions [19]. Based on experimental input [20,21] we modified the PYTHIA default charm ratios, using instead $D^+/D^0 = 0.45 \pm 0.1$, $D_s/D^0 = 0.25 \pm 0.1$, and $\Lambda_c/D^0 = 0.1 \pm 0.05$.

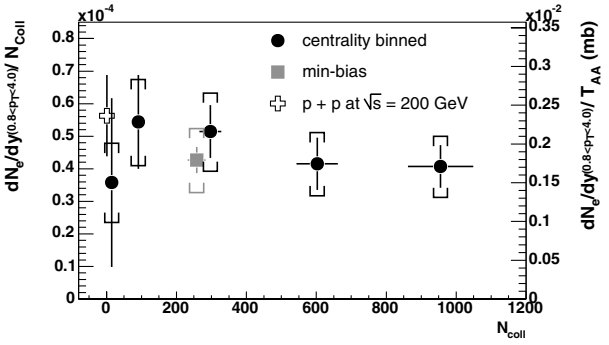

FIG. 3. Charm electron yield ($0.8 < p_T < 4.0$ GeV/c) measured in Au + Au collisions at 200 GeV scaled by $N_{\rm coll}$ as a function of $N_{\rm coll}$ (left-hand scale). Normalizing instead by the nuclear overlap function we obtain charm electron cross section per $N + N$ collision (right-hand scale).

This gives a $c \to e$ total branching ratio of $9.5 \pm 0.4\%$. Charmed hadron ratios from the statistical model [22] gives a similar branching ratio (9.3%). The scaled charm and bottom cross sections are treated as fit parameters, although our data are restricted to p_T values which are sensitive only to charm production. We evaluated the systematic error due to background subtraction ($\approx 21\%$) by refitting to the electron spectrum at the minimum and maximum of its 1σ systematic error band. The change of the p_T range for fitting the charm electron spectrum gives 3% systematic error for minimum-bias collisions. The systematic error due to the PYTHIA spectral shape ($\approx 11\%$) is dominated by the uncertainty in $\langle k_T \rangle = 1.5 \pm 0.5\,\text{GeV}/c$. Different parton distribution functions yield a systematic error of 6.2% for the rapidity-integrated cross section. These systematic errors are added in quadrature to give the overall systematic error on the charm cross section. For minimum-bias collisions we obtain $\frac{1}{T_{AA}} \frac{dN_{c\bar{c}}}{dy}|_{y=0} = 143 \pm 13(\text{stat}) \pm 36(\text{syst})\,\mu\text{b}$ and $N_{c\bar{c}}/T_{AA} = 622 \pm 57(\text{stat}) \pm 160(\text{syst})\,\mu\text{b}$. Results for all centrality bins are shown in Table I. The STAR collaboration reports a somewhat larger charm cross section ($\sigma_{c\bar{c}}^{NN} = 1.3 \pm 0.2 \pm 0.4 mb$) in $p + p$ and d + Au collision at $\sqrt{s_{NN}} = 200$ GeV [23]. Next-to leading order pQCD calculations of the charm production cross section have large associated uncertainties, with typical values between 300 and 450 μb [24].

TABLE I. Centrality bin, number of NN collisions, nuclear overlap function, charm cross section per NN collision, and total charm multiplicity per NN collision, in $\sqrt{s_{NN}} = 200$ GeV Au + Au reactions.

Centrality (%)	N_{coll}	T_{AA} (mb^{-1})	$\frac{1}{T_{AA}} \frac{dN_{c\bar{c}}}{dy}|_{y=0}$ (μb)	$N_{c\bar{c}}/T_{AA}$ (μb)
Minimum bias	258 ± 25	6.14 ± 0.45	143 ± 13 ± 36	622 ± 57 ± 160
0–10	955 ± 94	22.8 ± 1.6	137 ± 21 ± 35	597 ± 93 ± 156
10–20	603 ± 59	14.4 ± 1.0	137 ± 26 ± 35	596 ± 115 ± 158
20–40	297 ± 31	7.07 ± 0.58	168 ± 27 ± 45	731 ± 117 ± 199
40–60	91 ± 12	2.16 ± 0.26	193 ± 47 ± 52	841 ± 205 ± 232
60–92	14.5 ± 4.0	0.35 ± 0.10	116 ± 87 ± 43	504 ± 378 ± 190

We note that final-state effects influence only the momentum distribution of charm; they have little or no effect on the total open-charm yield. Therefore, our results indicate $N_{\rm coll}$ scaling of the initial charm production, as expected for pointlike pQCD processes. pQCD calculations without charm quark energy loss and hydrodynamic calculations assuming complete thermalization of charm quarks predict very similar charm electron spectra for $p_T < 2$ GeV/c [25]. Differentiating between these opposite physical pictures is possible only for $p_T > 2.5$ GeV/c, where statistics of the current analysis are limited.

In conclusion, we have measured single electrons from charm decays in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. We observe that the centrality dependence of charm quark production is consistent with $N_{\rm coll}$ scaling, as expected for hard processes. The much larger Au + Au data set collected by PHENIX in the 2003-04 run will allow us more detailed exploration of medium effects on charm production, both through deviations of the charm electron spectrum from $N_{\rm coll}$ scaling, and also through a measurement of charm quark flow.

(Received 20 September 2004; published 25 March 2005; corrected 6 April 2005)

The PHENIX experiment at the relativistic heavy ion collider (RHIC) has measured transverse energy and charged particle multiplicity at midrapidity in Au + Au collisions at center-of-mass energies $\sqrt{s_{NN}} = 19.6$, 130, and 200 GeV as a function of centrality. The presented results are compared to measurements from other RHIC experiments and experiments at lower energies. The $\sqrt{s_{NN}}$ dependence of $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ per pair of participants is consistent with logarithmic scaling for the most central events. The centrality dependence of $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ is similar at all measured incident energies. At RHIC energies, the ratio of transverse energy per charged particle was found to be independent of centrality and growing slowly with $\sqrt{s_{NN}}$. A survey of comparisons between the data and available theoretical models is also presented.

I. INTRODUCTION

The PHENIX experiment at the relativistic heavy ion collider (RHIC) at Brookhaven National Laboratory was designed to measure the properties of matter at extremely high temperatures and densities. Under such conditions, the possibility exists of producing states of matter that have not been observed and studied in the laboratory. Perhaps the best known of these is the quark-gluon plasma (QGP), a matter in which the quarks are not confined within individual baryons but exist as some form of plasma of individual quarks and gluons. It should be emphasized that the exact properties of this matter are not known and that the characterization of the deconfined state, if such a state is produced, will form an essential part of the RHIC program.

One fundamental element of the study of ultrarelativistic collisions is the characterization of the interaction in terms of variables such as the energy produced transverse to the beam direction or the number of charged particles. These variables are closely related to the collision geometry and are important in understanding global properties of the system during the collision.

This paper describes the PHENIX experiment's systematic study of $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ at midrapidity at center-of-mass energies $\sqrt{s_{NN}} = 19.6$, 130, and 200 GeV. The centrality dependence of $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ is characterized by the number of participants, determined with a Glauber model, and is studied as a function of the incident energy. $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ results for all four RHIC experiments are included in this study. The data taken at 19.6 GeV are particularly interesting because they can be compared with data taken at lower energies by the CERN super proton synchroton (SPS) program. Comparisons are also made with results of previous experiments conducted at the Brookhaven alternating-gradient synchroton (AGS) and the CERN SPS for c.m. energies of 4.8, 8.7, and 17.2 GeV. Finally, an extensive set of collision models describing the E_T and $N_{\rm ch}$ distributions are compared with existing data. Appendix A describes the recalculation of non-PHENIX data to make comparison possible. Appendix B contains the PHENIX measurement data.

II. PHENIX DETECTOR

PHENIX is one of four experiments located at RHIC [1]. The PHENIX detector consists of two central spectrometer arms, designated east and west for their location relative to the interaction region, and two muon spectrometers, similarly called north and south. Each central spectrometer arm covers a rapidity range of $|\eta| < 0.35$ and subtends 90° in azimuth. The muon spectrometers both have full azimuthal coverage with a rapidity range of $-2.2 < \eta < -1.2$ (south) and $1.2 < \eta < 2.4$ (north). Additional global detectors are used as input to the trigger and for global event characterization such as vertex, time of event, and centrality determination. A detailed description of the PHENIX detector can be found in [2]. The PHENIX detector subsystems relevant to the physics analysis presented in this paper are listed below.

Charged particle multiplicity was measured with two multiwire proportional chamber (MWPC) layers of the pad chambers (PCs) [3] called PC1 and PC3. These are located in both central arms at the radii of 2.5 and 5.0 m from the beam axis. The PCs cover the full central arm acceptance and have an efficiency greater than 99.5% for minimum ionizing particles. The position resolution of PC1 was measured to be 1.7 by 3 mm; it was twice that for PC3. PC1 and PC3 can distinguish between two particle tracks if they strike the detector with a separation greater than 4 and 8 cm, respectively.

For the transverse energy measurements, a PbSc sampling calorimeter (EMCal) [4] from the PHENIX central spectrometers was used. The front face of EMCal is located 5.1 m from the beam axis. Scintillation light produced in the PbSc EMCal towers is read out through wavelength shifting fibers that penetrate the module. The depth of the PbSc calorimeter is 18 radiation lengths (X_0) which corresponds to 0.85 nuclear interaction lengths. The PbSc calorimeter has an energy resolution of $8.1\%/\sqrt{E\,(\mathrm{GeV})} \oplus 2.1\%$ for test beam electrons, with a measured response proportional to the incident electron energy that is within $\pm 2\%$ over the range $0.3 \leqslant E_e \leqslant 40.0$ GeV [4].

Two identical beam-beam counters (BBCs) [5] each consisting of 64 individual Cherenkov counters with 3-cm quartz glass radiators cover the full azimuthal angle in the pseudorapidity range $3.0 < |\eta| < 3.9$. These detectors provide a minimum biased (MB) event trigger and timing and are also used for event vertex determination. The vertex position resolution for central Au + Au events was 6 mm along the beam axis.

The zero degree calorimeters (ZDCs) [6] are hadronic calorimeters located on both sides of the PHENIX detector. They cover a rapidity region of $|\eta| > 6$ and measure the energy of the spectator neutrons with approximately 20% energy resolution. The BBC and ZDC were used for the centrality determination.

III. DATA ANALYSIS

The analysis procedures for the $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ measured at $\sqrt{s_{NN}} = 130$ GeV are described in [7] and [8], respectively. In this paper the analysis was improved in the following ways:

- Inflow and outflow corrections were done based on the identified particle data, as opposed to HIJING.
- Corrected trigger efficiency was $92.2^{+2.5}_{-3.0}\%$ instead of $92.0 \pm 2 \pm 1\%$.
- Definition of E_T was modified as discussed below.

The results presented here for $\sqrt{s_{NN}} = 130$ GeV are consistent with results previously published.

The same data samples with zero magnetic field were used for both E_T and $N_{\rm ch}$ measurements at each beam energy. The analyzed numbers of events are approximately 40×10^3, 160×10^3, and 270×10^3 for $\sqrt{s_{NN}} = 19.6$, 130, and 200 GeV, respectively.

The main steps of the analysis procedure are discussed below in connection with the systematic errors associated with them. Some additional details can be found in [9–12].

A. E_T analysis

The transverse energy E_T is defined as

$$E_T = \sum_i E_i \sin\theta_i, \quad (1)$$

where θ_i is the polar angle. The sum is taken over all particles emitted into a fixed solid angle in an event. By convention, E_i is taken to be $E_i^{\rm tot} - m_N$ for baryons, $E_i^{\rm tot} + m_N$ for antibaryons, and $E_i^{\rm tot}$ for all other particles, where $E_i^{\rm tot}$ is the total energy of the particle and m_N is the nucleon mass.[1]

The E_T measurement presented in this paper was performed using the PHENIX PbSc EMCal. The EMCal absolute energy scale was set using the π^0 mass peak reconstructed from pairs of EMCal clusters. The value was checked against a measurement of the minimum ionizing peak for charged particles penetrating along the tower axis and the energy/momentum (E/p) peak of identified electrons and positrons. The uncertainty in the absolute energy scale is 3% in the $\sqrt{s_{NN}} =$ 19.6-GeV data and 1.5% in the 130- and 200-GeV data.

The EMCal acts as a thin but effective hadronic calorimeter at midrapidity at a collider [7]. The mean hadron momenta in the EMCal acceptance are approximately 0.4, 0.55, and 0.9 GeV/c for pion, kaons, and (anti)protons, respectively [13]. Most hadrons stop in the EMCal, depositing all their kinetic energy (at p_T less than 0.35 GeV/c for pions, 0.64 for kaons, and 0.94 for protons).

The average EMCal response to the different particle species was obtained with a GEANT-based [14] Monte Carlo (MC) simulation of the PHENIX detector using the HIJING [15] event generator. The HIJING particle composition and p_T spectra were tuned to the identified charged particle spectra and yields in Au + Au collisions measured by PHENIX [13,16] at $\sqrt{s_{NN}} = 200$ and 130 GeV. The NA49 results [17–19] were used for EMCal response studies for 19.6-GeV data. The "deposited" $E_{T_{\rm EMC}}$ was about 75% of the total E_T "striking" the EMCal. This value varied in the $\pm 1.5\%$ range for different centralities and beam energies.

The uncertainty in the EMCal response to hadrons gave a 3% error to the total E_T. This uncertainty was estimated using a comparison between the simulated energy deposited by hadrons with different momenta and from the test beam data [4]. An additional error of 1.3% at $\sqrt{s_{NN}} = 19.6$ and 200 GeV and 1% at 130 GeV comes from the systematic uncertainties in the particle composition and momentum distribution.

E_T was computed for each event [Eq. (1)] using clusters with energy greater than 30 MeV composed of adjacent towers with deposited energy of more than 10 MeV.[2] The energy losses at the EMCal edges and those due to energy thresholds, 6% each, were estimated with the absolute uncertainty 1.5%.

The first main issue for the E_T measurement is the correction for losses for particles originating within the aperture but whose decay products miss the EMCal ($\sim$10%). The second issue is the inflow contribution ($\sim$24%), which is principally of two types: (1) albedo from the magnet poles and (2) particles originating outside the aperture of the calorimeter but whose decay products hit the calorimeter. The inflow component was checked by comparing the MC simulation and the measurements for events with a vertex just at and inside a pole face of the axial central-spectrometer magnet, for which the calorimeter aperture was partly shadowed. The estimated contribution of the inflow uncertainty to the E_T uncertainty is 3% [7].

Since E_T measurements are based on the sum of all cluster energies in the EMCal, random noise even in a small portion of the total number of EMCal towers ($\sim$15,000 in PbSc) may affect the total energy in the EMCal, particularly in peripheral collisions. This effect was estimated by measuring the total energy in the EMCal in very peripheral events with the collision vertex inside the magnet poles. In this case, the EMCal is fully shadowed and no energy deposit from beam collisions is expected. The estimated contribution was consistent with zero. The uncertainty from this effect contributes 3.5% systematic error to the E_T measurement in the most peripheral bin of 45–50% at $\sqrt{s_{NN}} = 19.6$ GeV, 10% to the most peripheral bin of 65–70% at 130 GeV, and 6% to the bin of 65–70% at 200 GeV. The contribution to the systematic error for central events is negligible.

B. $N_{\rm ch}$ analysis

In the absence of a magnetic field, the particle tracks are straight lines. The number of tracks in the event was determined by combining all hits in PC3 with all hits in PC1. The resulting straight lines were projected onto a plane containing the beam line and perpendicular to the symmetry axis of the PCs. All tracks intersecting the plane at a radius less than 25 cm from the event vertex were accepted. $95\pm1\%$ of all real tracks in the event pointed back within this radius. The complete set of tracks thus formed contained both real tracks and tracks from a combinatorial background. The latter were determined using a mixed event technique in which each sector in PC1 was exchanged with its neighbor and the resulting combinatorial background measured. The average combinatorial background from the mixed event analysis was subtracted from the data obtained from the real events. Several corrections were subsequently applied.

A correction of 15.3% accounted for nonsensitive mechanical gaps between the PC sectors, inactive electronic readout cards, and dead pads in the PC1 and PC3 detectors. The data were also corrected for the PC efficiency for an isolated hit, measured to be 99.5% using cosmic rays [3]. The combined systematic error from these corrections was estimated to be 2.5% for a single east arm and 2.3% for both east and west arms.

Track losses from the finite double hit resolution of the PCs depend on the event multiplicity. Losses can occur in both the direct counting of tracks and in the combinatorial background subtraction. These two effects were studied in great detail using

[1]The definition of E_i in our earlier publication [7] is different for the antibaryon contribution: $E_i^{\rm tot}$ was used instead of $E_i^{\rm tot} + m_N$. The current definition increases the value of E_T by about 4%, independent of centrality.

[2]In [7] thresholds of 20 and 3 MeV were applied for the cluster and for the tower, respectively. Energy losses due to thresholds were properly accounted for in both analyses.

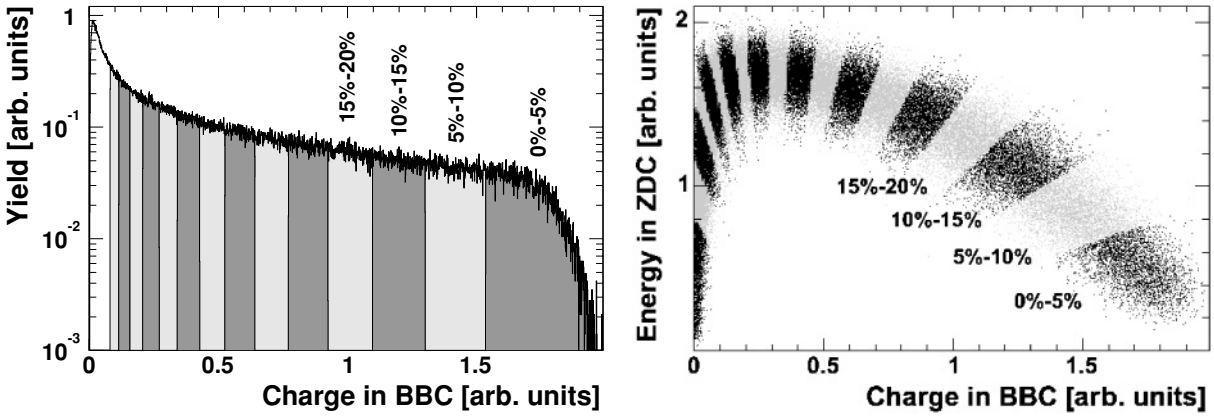

FIG. 1. Different centrality classes based on the BBC (left) and ZDC vs. BBC (right) distributions.

Monte Carlo techniques. To account for the track losses in the real event sample, a correction of 15%, 13%, and 6% for the 5% most central events was applied at $\sqrt{s_{NN}} = 200$, 130, and 19.6 GeV, respectively.

Track losses due to the finite double hit resolution reduce the combinatorial background in the real events more than in the mixed events. The number of tracks in the mixed events must be decreased by 3.6% to account for this. The uncertainty in the correction related to the finite double hit resolution of the PCs was estimated to be 3.5% of the number of reconstructed tracks in the most central events at $\sqrt{s_{NN}} = 200$ GeV. This number was deduced from the simulation and cross-checked with an artificial 50% increase of the double hit resolution of PC1 and PC3.

An additional correction is related to the decay of charged particles and feed-down from the decay of neutral particles. This correction is discussed in [8], where it was determined using the HIJING event generator. In this paper the measured composition of the produced particles at different centralities is used at $\sqrt{s_{NN}} = 200$ and 130 GeV [13,16]. The correction related to particle decay varies about $\pm 1\%$ over the full range of measured centralities. In midcentral events it is $-1 \pm 2.9\%$ and $+1 \pm 2.5\%$ at 200 and 130 GeV, respectively. At the lowest RHIC energy the correction is based on NA49 [17–19] measurements at close energy 17.2 GeV and is about $11 \pm 5.7\%$ independent of centrality. The difference between 19.6 and 130 GeV arises from the decrease of the particle momenta and the width of the η distribution at lower energy which affects the number of tracks from the decay of particles coming from adjacent rapidities. The uncertainty is also larger because the correction was based on non-PHENIX data. More details on the analysis can be found in [8,11,12].

C. Determination of trigger efficiency and N_p

The distribution of the number of participants (N_p) in Au + Au collisions was determined using a Monte Carlo simulation based on the Glauber model. The inelastic cross section of $p + p$ collisions used in the Glauber model was taken to be 31, 41, and 42 mb at $\sqrt{s_{NN}} = 19.6$, 130, and 200 GeV, respectively [20], and was varied within ± 3 mb in order to get the systematic errors. The nuclear density profile $\rho(r)$ was taken as the Woods-Saxon parametrization,

$$\rho(r) = 1/(1 + e^{(r-r_n)/d}), \tag{2}$$

where r_n is the nucleus radius and d is a diffuseness parameter. Based on the measurements of electron scattering from Au nuclei [21], r_n was set to (6.38 ± 0.27) fm and d to (0.54 ± 0.01) fm.

The BBC detectors are located in a region where the number of produced particles is proportional to N_p at $\sqrt{s_{NN}} =$ 130 and 200 GeV [22]. By comparing measured BBC spectra to simulations, the MB trigger efficiency was estimated to be $92.2^{+2.5}_{-3.0}\%$ at both 200 and 130 GeV, with less than 1% uncertainty in the difference between these two energies.

One can also use the BBC (or ZDC vs. BBC) response to define centrality for a given event as a percentage of the total geometrical cross section. The BBC amplitude distribution and ZDC vs. BBC signals divided into centrality classes are shown in Fig. 1.

By matching the detector response simulation to the data, N_p can be assigned to each centrality class. The results for N_p vary by less than 0.5% depending on the shape of the cut in the ZDC/BBC space and whether the BBC alone was used as a centrality measure. The larger error in N_p comes from model uncertainties and can be parametrized as $\Delta N_p/N_p = 0.02 + 3.0/N_p$.

At $\sqrt{s_{NN}} = 19.6$ GeV, the BBC acceptance partially covers the Au nuclei fragmentation region where the relation between the particle production and N_p is not well known for peripheral events. This makes the MB trigger efficiency model dependent. To avoid this problem, an approach based on the Glauber model and the negative binomial distribution (NBD) was applied to the data from the PHENIX central arm. For the centrality associations, the BBC signal can still be used after applying the following correction.

The NBD, written as

$$P(n, \mu, k) = \Gamma(n + k)/(\Gamma(k)n!) \cdot (\mu/k)^n/(1 + \mu/k)^{n+k}, \tag{3}$$

represents the number of independent trials n that are required to get a number of predetermined successes if the average number of successes per trial is μ. The parameter k is related

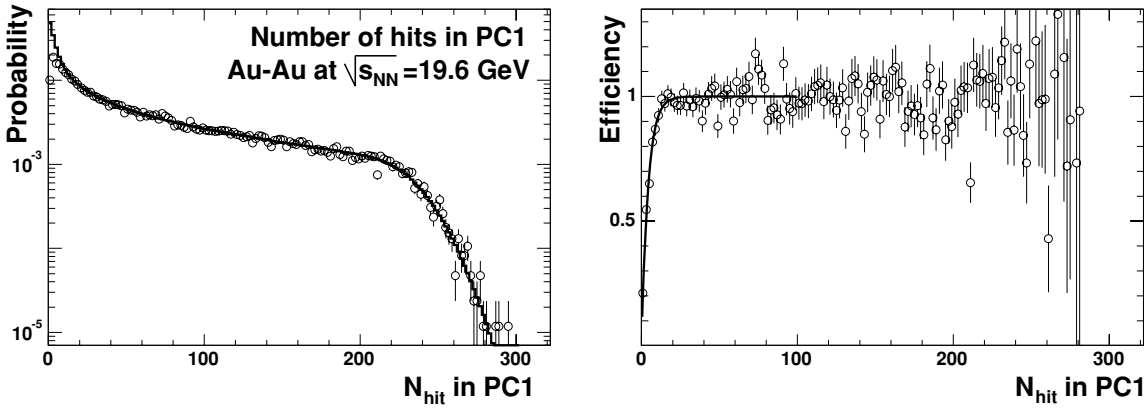

FIG. 2. Left panel: Glauber/NBD fit (line) to the distribution of the number of hits in the PC1 detector at $\sqrt{s_{NN}} = 19.6$ GeV (circles). Right panel: MB trigger efficiency as a function of the number of hits. The parametrization is to guide the eye.

to the variance of the distribution by the equation $(\sigma/\mu)^2 = 1/k + 1/\mu$. By associating n with the number of particles produced in the event such that $n = f(N_p)$, the NBD describes the distribution of hits in a detector [23,24] produced by a given number of N_p. In the simplest case when $n \propto N_p$, $\langle N_{\rm hit}\rangle = \mu\langle N_p\rangle$. Using probability weights for N_p from the Glauber model, one can construct a distribution of the number of hits in a detector. The coefficients μ and k can be obtained by fitting the constructed distribution to the experimentally measured distribution.

The number of hits in the PC1 detector shown in the left panel of Fig. 2 was used to determine the trigger efficiency. $N_{\rm hit} \propto dN_{\rm ch}/d\eta$ can be parametrized as scaling with the number of participants N_p^{α}, where α is between 1.0 and 1.1 as measured by WA98 at the CERN SPS [25]. The Glauber/NBD fit to the distribution of the number of hits in PC1 is shown as the solid line. The fitting range is constrained above some number of hits, where the trigger efficiency is equal to 1. The efficiency as a function of the number of hits in the detector can be found by taking the ratio of measured and reconstructed distributions. This is shown in the right panel of Fig. 2. Intergated over all $N_{\rm hits}$ the MB trigger efficiency was found to be $81.5 \pm 3\%$ at $\sqrt{s_{NN}} = 19.6$ GeV. The 1% uncertainty due to variation of α from 1.0 to 1.1 was included in the systematic error. An uncertainty in the difference between 19.6 and 200 GeV was 1.5%.

A fraction of events missing in the trigger at all energies belongs to the peripheral centrality classes outside the centrality range discussed in this paper.

As a cross-check, the same procedure was applied to the BBC response at 200 GeV. It was found that the MB trigger efficiency in Au + Au and d + Au collisions agrees with the procedure based on a full simulation within one standard deviation of the systematic error. In Au + Au the N_p in the centrality bins determined using the Glauber/NBD method agree better than 0.5% with the values used in this paper. In d + Au for a single nucleon-nucleon collision the MB trigger efficiency was found to be 57%, consistent with the $52 \pm 7\%$ measured for PHENIX $p + p$ trigger efficiency at the same energy using a different method [26]. Finally, the fraction of expected p + Au collisions in the d + Au sample agrees with the fraction of events in which the corresponding ZDC detects the spectator neutron from the deuteron within better than 1.5%.

As stated above, the BBC detector at $\sqrt{s_{NN}} = 19.6$ GeV covers a part of the Au nuclei fragmentation region, and its response is not linear with N_p [22]. Also, the number of hits in BBC has a strong vertex dependence mainly because the BBC samples different parts of the $dN_{\rm ch}/d\eta$ distribution at different vertices; see Fig. 3. The asymmetry of north and south BBC amplitudes in the same event was studied to correct for these two effects. Around vertex $z = 0$ the asymmetry between the number of hits in north BBC $N(z)$ and south BBC $S(z)$ is $(N(z) - S(z))/(S(z) + N(z)) \propto (d^2N_{\rm ch}/d\eta^2)/(dN_{\rm ch}/d\eta)$ reflects the slope of the η distribution at BBC rapidity. To use the BBC signal for the N_p determination, the observed signals were scaled such that the asymmetry between north and south was the same as in the most central events where the influence of the fragmentation region was negligible. The data were also corrected for vertex dependence. The results of the correction are shown in Fig. 3.

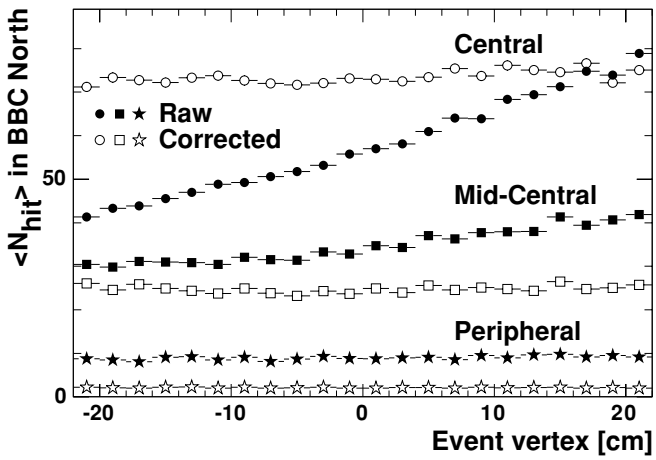

FIG. 3. Average number of hits in BBC north vs. event vertex at different centralities before correction (solid symbols) and after correction (open symbols).

TABLE I. Summary of systematic errors given in percent. When a range is given, the first number corresponds to the most central bin and the second to the most peripheral bin presented in Appendix B, Tables XIII–XV.

	$dE_T/d\eta$			$dN_{\rm ch}/d\eta$		
$\sqrt{s_{NN}}$ (GeV)	19.6	130	200	19.6	130	200
Energy resp.	4.7	3.8	3.9			
Bkg./noise	0.5–3.5	0.4–10	0.2–6	1.0	1.0	1.0
Acceptance	2.0	2.0	2.0	2.3	2.5	2.3
In- & outflow	3.0	3.0	3.0	5.7	2.5	2.9
Occupancy				1.6–0.3	3.1–0.1	3.5–0.1
Centrality	2.0	0.5	0.5		Same	
N_p	2.9–6.7	2.8–15	2.8–15		Same	
Trigger	0.4–8.8	0.3–16	0.3–16		Same	

The corrected BBC response was used for the centrality determination. Based on both data and Monte Carlo simulation, a systematic error of 2% was added to the determination of the centrality classes using the BBC correction procedure.

D. Systematic error summary

Table I summarizes the systematic errors discussed in this section. The "Energy resp." error for the E_T measurements combines the uncertainties in absolute energy scale, hadronic response, and energy losses on the EMCal edges and from energy thresholds. The resulting error for each centrality bin is a quadratic sum of the errors listed in the table.

IV. RESULTS

A. PHENIX results

The distribution of the raw transverse energy $E_{T_{\rm EMC}}$ into the fiducial aperture of two EMCal sectors is shown in the left three panels of Fig. 4 for the three RHIC energies. The lower scale represents the fully corrected E_T normalized to one unit of pseudorapidity and full azimuthal acceptance. The lower axis in the plot is not labeled beyond 200 GeV to avoid confusion between the true shape of the $dE_T/d\eta$ distribution and E_T as measured using the limited acceptance of two EMCal sectors.

For the measurements at $\sqrt{s_{NN}} = 19.6$ and 200 GeV, five EMCal sectors (with azimuthal coverage $\Delta\phi = 112^\circ$) were used, while only two sectors ($\Delta\phi = 45^\circ$) were available during

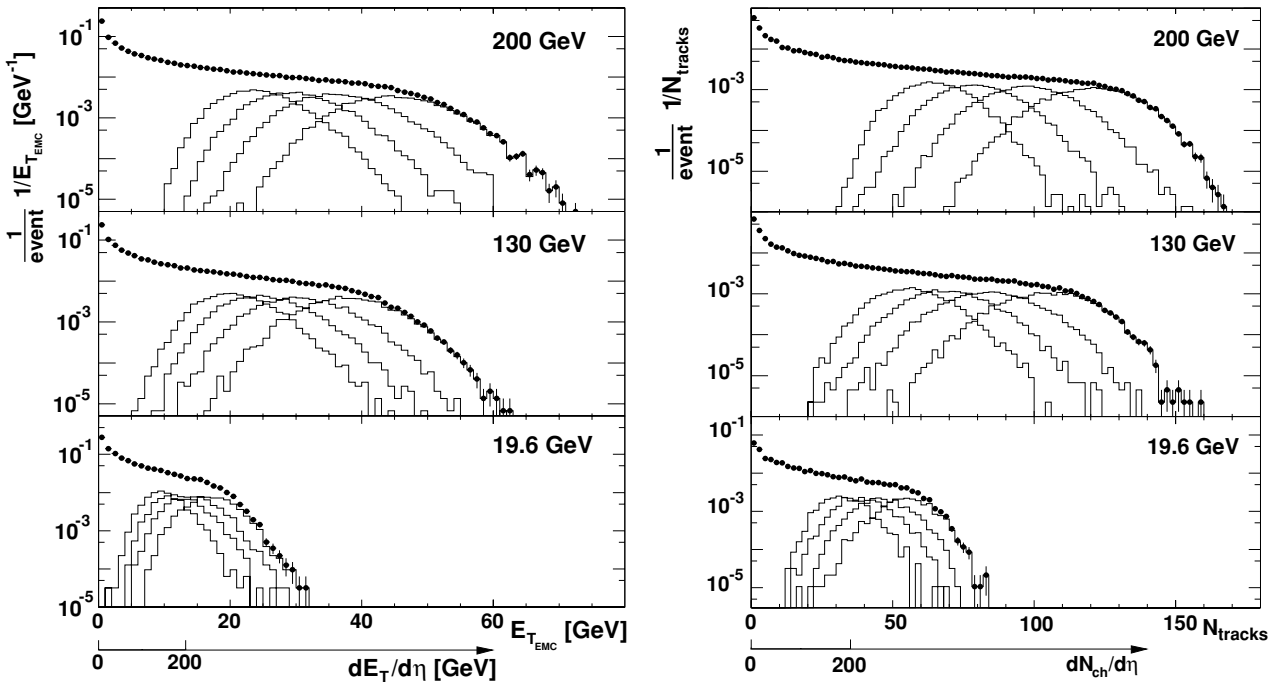

FIG. 4. The distribution of the raw E_T in two EMCal sectors (left) and the number of tracks in the east arm of the PHENIX detector (right) per MB trigger, measured at three energies. The lower axis corresponds to midrapidity values of $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$, respectively. Distributions of the four 5% most central bins are also shown in each plot.

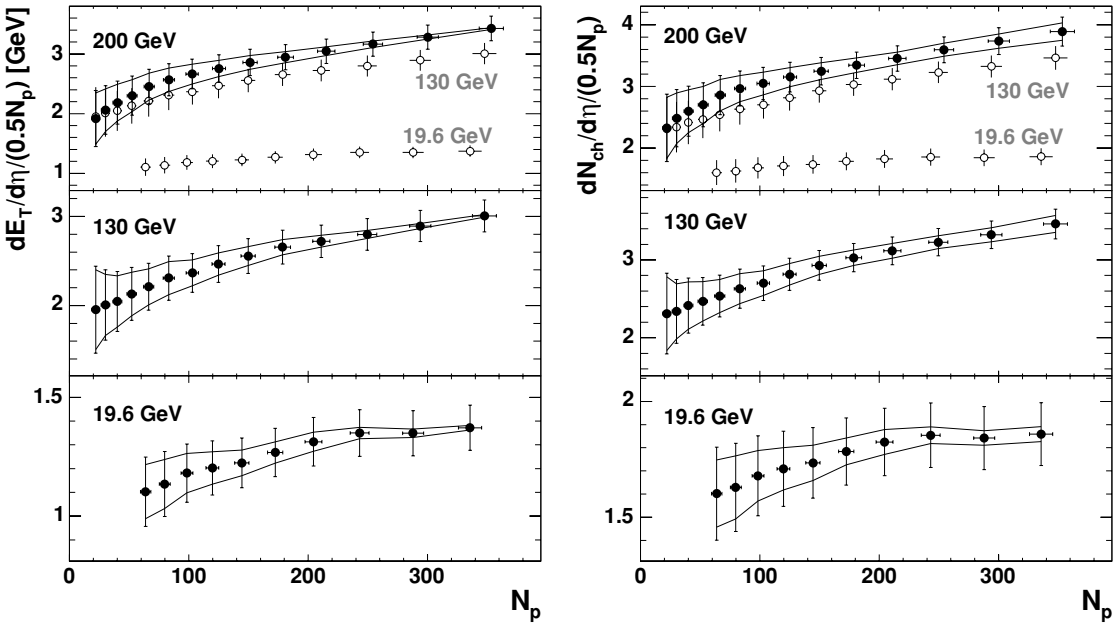

FIG. 5. $dE_T/d\eta$ (left) and $dN_{\rm ch}/d\eta$ (right) divided by the number of participant pairs at three RHIC energies. Errors shown with vertical bars are full systematic errors. Lines show the part of the systematic error that allows bending or inclination of the points. Horizontal errors denote the uncertainty in determination of N_p.

the PHENIX run at 130 GeV. Results obtained with different number of sectors at the same energy were consistent within 1.5%.

The right three panels in Fig. 4 show the number of tracks reconstructed in the east arm of the PHENIX detector after background subtraction and all corrections. The lower axis corresponds to measured distributions normalized to one unit of pseudorapidity and full azimuthal acceptance. For a similar reason as for the E_T measurement, the lower axis is not labeled above 200 GeV in $dN_{\rm ch}/d\eta$.

For the $N_{\rm ch}$ measurements at $\sqrt{s_{NN}} = 130\,\text{GeV}$, only the east arm was used; for the other two energies the measurements were made using both PHENIX central arms. The results obtained with two arms at 200 and 19.6 GeV are consistent with each other within 1.5%.

The distributions shown in Fig. 4 have a characteristic shape with a sharp peak that corresponds to the most peripheral events. Missing events caused by the finite MB trigger efficiency in peripheral events would make this peak even sharper than measured. The plateau in all distributions corresponds to midcentral events, and the falloff to the most central Au + Au events. The shape of the curves in Fig. 4 in the falloff region is a product of the intrinsic fluctuations of the measured quantities and the limited acceptance of the detector.

The distributions for the four most central bins (0–5% to 15–20%) are also shown in each panel. The centroids of these distributions were used to calculate the centrality dependence of $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$.[3] The statistical uncertainties of all mean values (less than or about 1%) determined by the width of the distributions are small because of the large size of the event samples.

The magnitude of $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ at midrapidity divided by the number of participant pairs as a function of N_p is shown in Fig. 5 and tabulated in Appendix B, Tables XIII–XV. The right three panels show the same ratio for $dN_{\rm ch}/d\eta$ at the three RHIC energies.

The horizontal errors correspond to the uncertainty in N_p, determined within the framework of the Monte Carlo–Glauber model. The vertical bars show the full systematic errors of the measurements[4] added quadratically to the errors of N_p. The lines denote the corridor in which the points can be inclined or bent. The statistical errors are smaller than the size of the markers. The upper panel also shows the results of the two lower panels with open markers for comparison.

An important result from Fig. 5 is an evident consistency in the behavior of the centrality curves of E_T shown on the left and $N_{\rm ch}$ shown on the right for all measured energies. Both values demonstrate an increase from peripheral (65–70% bin) to the most central events by 50–70% at RHIC energies 130 and 200 GeV. For the lowest RHIC energy (19.6 GeV) this increase is at the level of systematic uncertainties of the measurement. One can note that results from PHOBOS [27] show that the total charged particle multiplicity is proportional to N_p, while the multiplicity at midrapidity over N_p increases with N_p, indicating that the pseudorapidity distribution gets more narrow for central events.

The ratios of the $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ per participant pair measured at different RHIC energies are shown in

[3]All plotted and quoted numbers correspond to average values in each centrality bin or ratios of those averages.

[4]Here and everywhere errors correspond to one standard deviation.

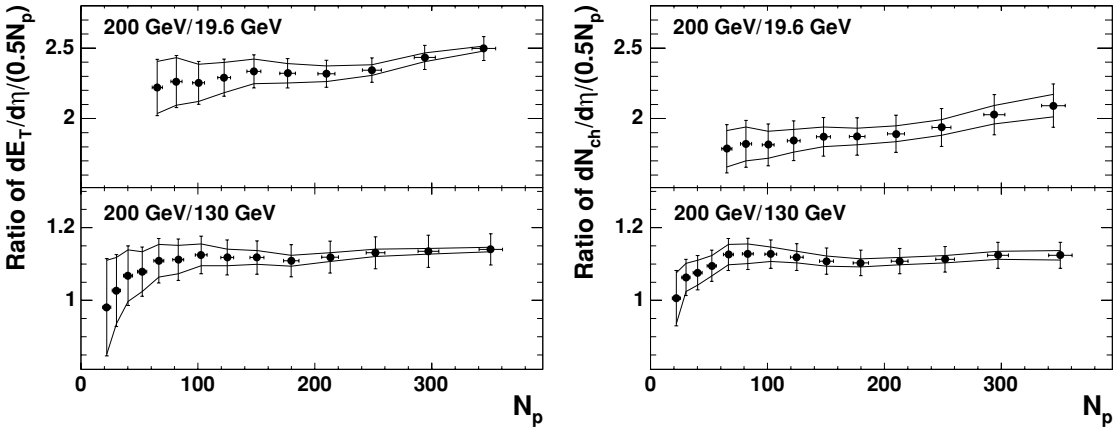

FIG. 6. Same as Fig. 5, but for ratios of $dE_T/d\eta$ (left) and $dN_{\rm ch}/d\eta$ (right) measured at different RHIC energies.

Fig. 6 and tabulated in Table XVI. In these ratios some common systematic errors cancel.

The increase in the E_T production between 19.6 and 200 GeV (with an average factor of 2.3) is larger than for $N_{\rm ch}$ (with average factor of 1.9). This is consistent with an increase in the particle production per participant common to both E_T and $N_{\rm ch}$ and a $\sim$20% increase in $\langle m_T \rangle$ of produced particles contributing to the E_T parameter only. See Appendix A 1 and [16,17].

The ratio of 200/19.6 GeV shows some increase from peripheral to central events; however, the increase is marginally at the level of the systematic errors of the measurement.

The ratio of 200/130 GeV is flat above $N_p \sim 80$ and is equal to 1.140 ± 0.043 for E_T and 1.126 ± 0.036 for $N_{\rm ch}$ in the most central bin. A rather sharp increase between $N_p = 22$ and 83 in the ratios of both quantities is still at the level of systematic uncertainties.

The ratio of the transverse energy and charged particle multiplicity at midrapidity as a function of centrality is shown in Fig. 7 for the three energies. The upper plot also shows the results displayed in the lower panels for comparison.

The ratio $E_T/N_{\rm ch}$,[5] sometimes called the "global barometric observable," triggered considerable discussion [28,29]. It is related to the $\langle m_T \rangle$ of the produced particles and is observed to be almost independent of centrality and incident energy of the collisions within the systematic errors of the previous measurements. The present paper forges a direct link between the highest SPS and lowest RHIC energies, making a more quantitative study of $E_T/N_{\rm ch}$ possible.

The results presented in Fig. 7 and tabulated in Tables XIII–XV show that the centrality dependence of $E_T/N_{\rm ch}$ is weak and lies within the systematic errors plotted with lines. There is a clear increase in $E_T/N_{\rm ch}$ between $\sqrt{s_{NN}} = 19.6$ and 200 GeV. The $\sqrt{s_{NN}}$ dependence of the results is discussed below.

B. Bjorken energy density

The Bjorken energy density [30] can be calculated using

$$\epsilon_{Bj} = \frac{1}{A_\perp \tau} \frac{dE_T}{dy}, \tag{4}$$

where τ is the formation time and $A_\perp$ is the nuclei transverse overlap area.

The transverse overlap area of two colliding nuclei was estimated using a Monte Carlo–Glauber model $A_\perp \sim \sigma_x \sigma_y$, where σ_x and σ_y are the widths of x and y position distributions of the participating nucleons in the transverse plane. The normalization to πR^2, where R is the sum of r_n and d parameters in a Woods-Saxon parametrization [Eq. (2)], was done for the most central collisions at the impact parameter $b = 0$. For the transformation from $dE_T/d\eta|_{\eta=0}$ to $dE_T/dy|_{y=0}$, a scale factor of 1.25 ± 0.05 was used; see Appendix A 1.

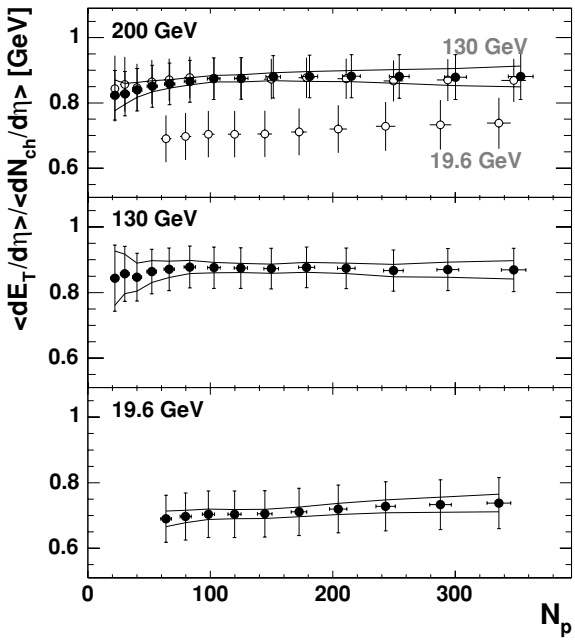

FIG. 7. Same as Fig. 5, but for $E_T/N_{\rm ch}$ vs. N_p at different RHIC energies.

[5] $E_T/N_{\rm ch}$ is used as a shortcut for $\langle dE_T/d\eta \rangle / \langle dN_{\rm ch}/d\eta \rangle$ at $\eta = 0$ in the c.m. system.

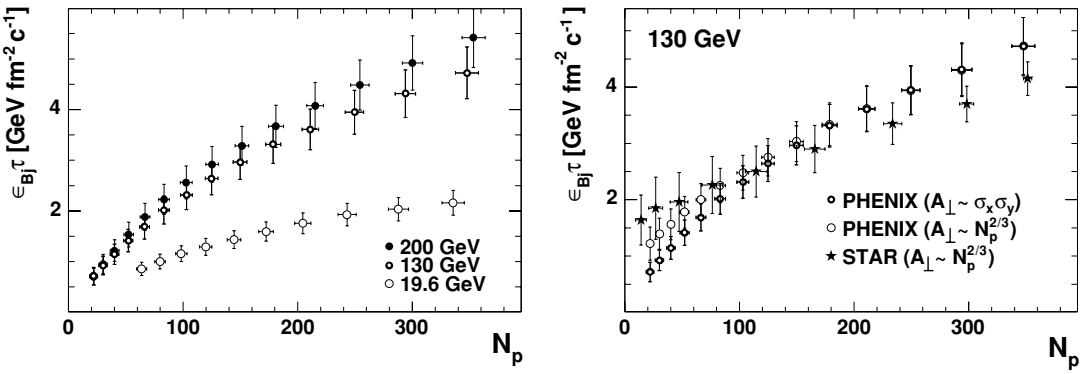

FIG. 8. $\epsilon_{Bj} \cdot \tau$ deduced from the PHENIX data at three RHIC energies (left) and using different estimates of the nuclear transverse overlap at $\sqrt{s_{NN}} = 130$ GeV (right).

The Bjorken energy density for three RHIC energies is plotted in the left panel of Fig. 8 and tabulated in Tables XIII–XV. For the 5% most central collisions, $\epsilon_{Bj} \cdot \tau$ was $2.2 \pm 0.2, 4.7 \pm 0.5$, and 5.4 ± 0.6 GeV fm$^{-2}c^{-1}$ for $\sqrt{s_{NN}} =$ 19.6, 130, and 200 GeV, respectively. These values increase by 2, 4, and 5%, respectively, for the maximal $N_p = 394$, as obtained from extrapolation of PHENIX data points. There is a factor of 2.6 increase between the SPS-like energy (19.6 GeV) and the top RHIC energy (200 GeV). The comparison of the only published $\epsilon_{Bj} = 3.2$ GeV/fm^3 at SPS for head-on collisions [31] and top RHIC energies, assuming the same $\tau = 1$ fm/c, reveals an increase in energy density by a factor of only 1.8, which may come from an overestimation in the SPS measurement, as shown latter in the left panel of Fig. 13 and discussed in Appendix A 3.

Another approach is used by STAR in [32] for the estimate of the transverse overlap area of the two nuclei $A_\perp \sim N_p^{2/3}$ in Eq. (4). This approach accounts for only the common area of colliding nucleons, not nuclei. The results are different only in the peripheral bins as shown in the right panel of Fig. 8. For a comparison, the same panel shows the result obtained by STAR which agrees with PHENIX results within systematic errors, though displaying a smaller increase of the energy density with N_p.

C. Comparison to other measurements

Comparison to the results of other experiments is complicated by several factors. AGS and SPS data were taken in the laboratory (Lab.) system while the RHIC data are in the center-of-mass system (c.m.s.). Since η and E_T are not boost-invariant quantities, the data should be converted into the same coordinate system. Some experiments provide a complete set of identified particle spectra from which information about E_T and $N_{\rm ch}$ can be deduced. For other experiments, additional assumptions are necessary for their published values. Appendix A describes how such recalculation was done in each particular case.

The PHENIX results for $N_{\rm ch}$ are compared to the data available from the other RHIC experiments. This comparison is shown in the left panels of Fig. 9.

There is good agreement between the results of BRAHMS [33,34], PHENIX, PHOBOS [35–37], and STAR [38,39] using N_p based on a Monte Carlo–Glauber model. This agreement is very impressive because all four experiments use different apparatuses and techniques to measure the charged particle production. The systematic errors of all results are uncorrelated, except for those related to the same Glauber model, which are small. That makes it possible to calculate the RHIC average and reduce the systematic uncertainty. The averaged results from all four RHIC experiments are plotted in the right panel of Fig. 9 and tabulated in Table XVII. See Appendix A 2 for the procedure.

Figure 10 compares E_T results from the PHENIX and STAR [40] experiments. The results are consistent for all centralities within systematic errors, though the STAR $dE_T/d\eta$ per participant pair has a smaller slope vs. N_p above $\sim$70 participants, and $E_T/N_{\rm ch}$ shown in the lower panel is consistent for all N_p.

The RHIC run at $\sqrt{s_{NN}} = 19.6$ GeV allows a connection between RHIC and SPS data to be made. The highest SPS energy per projectile nucleon of 158 A GeV corresponds to $\sqrt{s_{NN}} = 17.2$ GeV in the c.m.s., making a direct comparison of RHIC and SPS results possible. This comparison is shown in Fig. 11. See Appendixes A 3–A 6 for the details of the data compilation.

Several comments should be made about this comparison. For both measured parameters the PHENIX results and the SPS results agree. The WA98 results (see Appendix A 4) are systematically higher than the results of other experiments, especially for $dE_T/d\eta$. However, the WA98 data have an additional systematic error common to all points shown for the last bin. For $N_{\rm ch}$ the relative spread of the SPS results is larger than for the RHIC results shown in Fig. 9, though overall the $\sqrt{s_{NN}} = 17.2$ GeV SPS measurements are consistent with the PHENIX result at 19.6 GeV.

Different SPS and AGS experiments made measurements at lower energies. The combined data of AGS, SPS, and RHIC provide a complete picture of the centrality behavior of E_T and $N_{\rm ch}$ as a function of the nucleon-nucleon energy. The centrality dependence of $dN_{\rm ch}/d\eta$ at midrapidity measured at $\sqrt{s_{NN}} =$ 4.8, 8.7, and 17.2 GeV by different experiments is shown in Fig. 12. See Table XVII for the summary of these results and Appendixes A 5–A 7 for the details of the data compilation.

At the highest SPS energy the averaging procedure is the same as for RHIC energies, and weighted experimental errors are

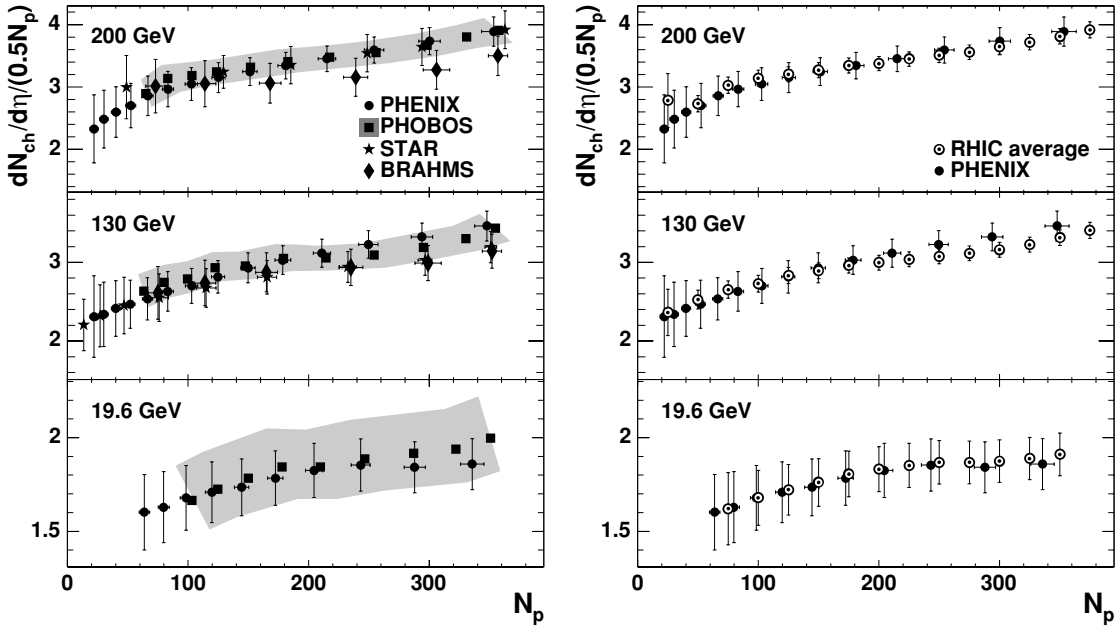

FIG. 9. Left panel: $dN_{\rm ch}/d\eta$ per pair of N_p measured by the four RHIC experiments at different energies. The shaded area is the PHOBOS systematic error. Right panel: RHIC average values (including PHENIX) compared to the PHENIX results.

scaled with the reduced χ^2-like factor S (described in Appendix A 2) reaching the value of 1.5 at some points. For the intermediate SPS energy $\sqrt{s_{NN}} = 8.7$ GeV, two experiments, NA45 [41] and NA50 [42], reported the centrality dependence of $dN_{\rm ch}/d\eta$ at midrapidity. The discrepancy in the measurements is close to three times the quadratic sum of their systematic error. However, the shapes of the two curves are almost the same. NA49 has published results (see Appendix A 3) that give one point in $dN_{\rm ch}/d\eta$ at $N_p = 352$. This point favors the NA45 result.[6]

[6]The NA57 results at both SPS energies are published without systematic errors in [43] They are currently not considered.

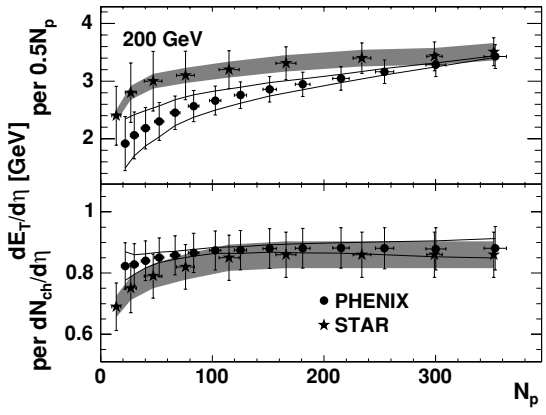

FIG. 10. $dE_T/d\eta$ divided by the number of N_p pairs (top) and $E_T/N_{\rm ch}$ (bottom) measured by the PHENIX and STAR [40] experiments at $\sqrt{s_{NN}} = 200$ GeV. PHENIX systematic errors are explained in the text. The shaded area is the STAR systematic scaling error.

The average centrality curve is produced taking into account the shape of the centrality curves reported by NA45 and NA50 and the single NA49 point. See Appendix A 8 for the averaging procedure at $\sqrt{s_{NN}} = 8.7$ GeV. The errors are scaled with the factor S, which reaches a value of 2.5 at some points. The AGS results are presented with a curve produced from the combined results of the E802/E917 experiments (see Appendix A 7). The averaging procedure in this case is a simple rebinning of the data.

The average SPS centrality dependence at $\sqrt{s_{NN}} = 17.2$ GeV shown in the upper panel in Fig. 12 and the average curve of the two RHIC experiments at 19.6 GeV shown in the lower panel in Fig. 9 are very similar. Less than a 5% increase is expected to result from the difference in the incident energy between the highest SPS and the lowest RHIC energies (see Sec. IV D below). The average values presented in Figs. 9 and 12 are summarized in Table XVII.

D. Dependence on the incident nucleon energy

The data compilation made in the previous section allows for a detailed study of the charged particle production in heavy ion reactions at different incident energies of colliding nuclei. Although the data on transverse energy production are not abundant, a similar comparison can be made [9,10].

1. Central collisions

Figure 13 shows the energy dependence of the $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ production per pair of participants in the most central collisions measured by different experiments. See Appendixes A 5–A 9 for the details of the data compilation.

The results shown in Fig. 13 are consistent with logarithmic scaling as described in [9,11,12]. Use of the logarithmic

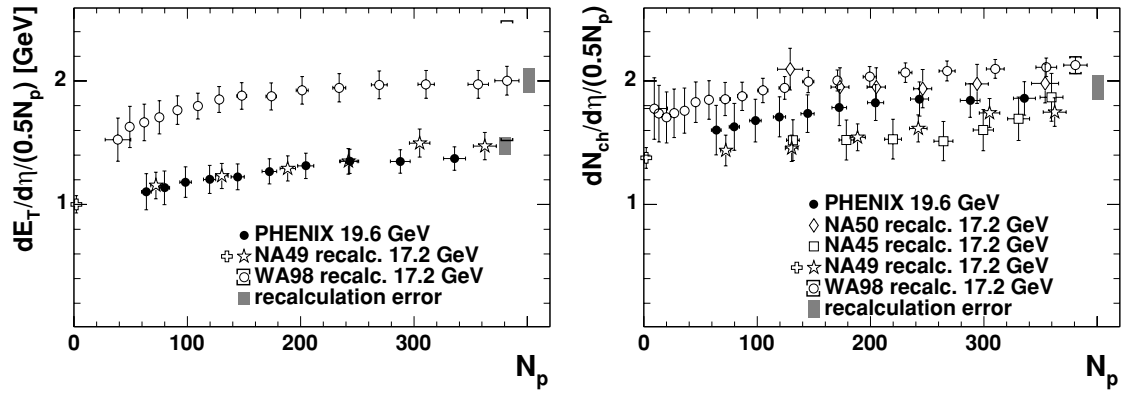

FIG. 11. $dE_T/d\eta$ (left) and $dN_{\rm ch}/d\eta$ (right) divided by the number of N_p pairs measured by PHENIX at $\sqrt{s_{NN}} = 19.6$ GeV (solid markers) and recalculated from the results of the SPS experiments at the highest energy $\sqrt{s_{NN}} = 17.2$ GeV (open markers). The $p + p$ result of NA49 is marked with an open cross.

function is phenomenological and is suggested by the trend of the data in the range of available measurements. The agreement of the fits with the data in both panels is very good, especially in the right panel where the averaged values are used for $N_p = 350$. The single point of NA49 [31] is excluded from the E_T fit (see Appendix A 3). The results of the fit $dX/d\eta = (0.5N_p \cdot A)\ln(\sqrt{s_{NN}}/\sqrt{s^0_{NN}})$ are

for E_T, $\sqrt{s^0_{NN}} = 2.35 \pm 0.2$ GeV and $A = 0.73 \pm 0.03$ GeV,
for $N_{\rm ch}$, $\sqrt{s^0_{NN}} = 1.48 \pm 0.02$ GeV and $A = 0.74 \pm 0.01$.

The parameter $\sqrt{s^0_{NN}} = 2.35$ GeV obtained from the E_T fit is slightly above although within 3σ from the minimum possible value of $\sqrt{s_{NN}} = 2 \times$ amu $= 1.86$ GeV. The measurement closest to it at $\sqrt{s_{NN}} = 2.05$ GeV done by the FOPI experiment

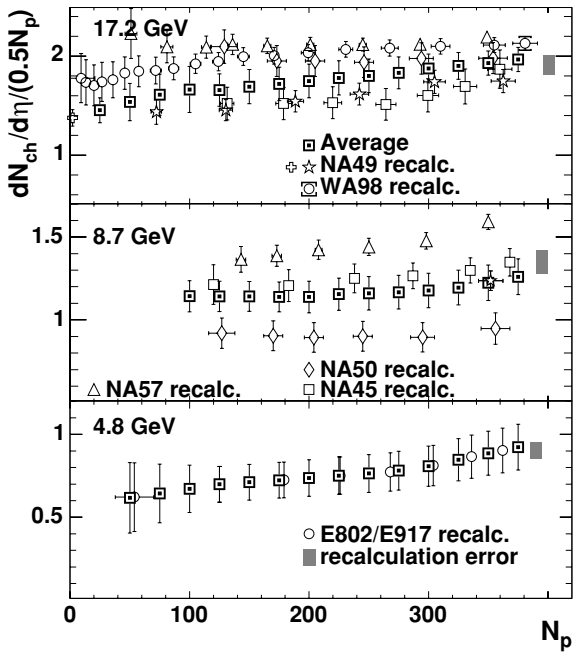

FIG. 12. $dN_{\rm ch}/d\eta$ divided by the number of N_p pairs measured by AGS and SPS experiments and the average taken at different energies recalculated in the c.m.s.

allows one to estimate the amount of $dE_T/d\eta$ produced to be 5.0 GeV in the most central collisions corresponding to $N_p = 359$. Appendix A 9 gives details of the estimate. This does not disagree with the extrapolation of the fit but does indicate that the logarithmic parametrization requires higher order terms to describe how the E_T production starts at very low $\sqrt{s_{NN}}$.

The right panel of Fig. 13 shows the logarithmic fit to the $N_{\rm ch}$ data. It agrees well with all $dN_{\rm ch}/d\eta$ results plotted for $N_p = 350$. Unlike that for E_T, the fit parameter $\sqrt{s^0_{NN}}$ for $N_{\rm ch}$ is 1.48 ± 0.02 GeV which is lower than the minimum allowed $\sqrt{s_{NN}}$. This suggests that above $2 \times$ amu the $N_{\rm ch}$ production as a function of $\sqrt{s_{NN}}$ should undergo threshold-like behavior, unlike the E_T production which must approach zero smoothly because of energy conservation.

The FOPI measurements at $\sqrt{s_{NN}} = 1.94$ and 2.05 GeV agree with the extrapolation of the fit at energy very close to $2 \times$ amu. It is an interesting result that colliding nuclei with kinetic energies of 0.037 and 0.095 GeV per nucleon in the c.m.s. follow the same particle production trend as seen at AGS, SPS, and RHIC energies.

A fit to the charged particle multiplicity shows a factor of 2.2 increase in $dN_{\rm ch}/d\eta$ per participant in the most central events from the highest energy at the AGS ($\sqrt{s_{NN}} = 4.8$ GeV) to the highest energy at the SPS (17.2 GeV) and a factor of 2.0 from the highest SPS energy to the highest RHIC energy (200 GeV). Assuming the same behavior extends to the Large Hadron Collider (LHC) highest energy (5500 GeV) one would expect $dN_{\rm ch}/d\eta = (6.1 \pm 0.13) \cdot (0.5N_p)$ and the increase in particle production from the highest RHIC energy to be $\sim$60% for the most central events. With the greater energy, the rapidity width should increase by $\sim$60%, i.e., the total charged particle multiplicity at LHC would increase by a factor of $\sim$2.6 from the top RHIC energy.

The ratio of $E_T/N_{\rm ch}$ for the most central bin as a function of $\sqrt{s_{NN}}$ is shown in Fig. 14. Note that the line shown in the figure is not the fit to the data points. Rather, it is calculated from the fits shown in Fig. 13. The calculation agrees well with the data. There are two regions in the plot which can be clearly separated. The region from the lowest allowed $\sqrt{s_{NN}}$ to SPS energy is characterized by a steep increase of

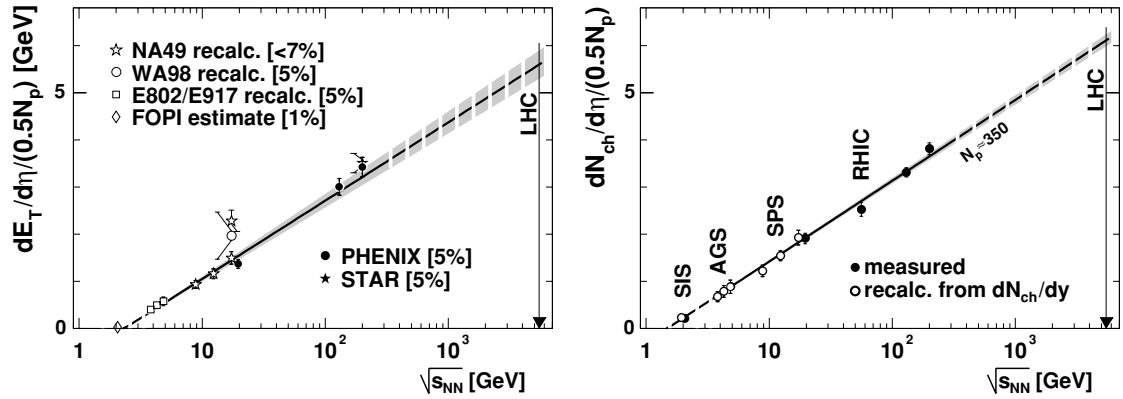

FIG. 13. Left panel: $dE_T/d\eta$ divided by the number of N_p pairs measured in the most central bin (value given in brackets) as a function of incident nucleon energy. The line is a logarithmic fit. The band corresponds to a 1σ statistical deviation of the fit parameters. Right panel: the same for $dN_{\rm ch}/d\eta$. The values of $N_{\rm ch}$ are the average values corresponding to $N_p = 350$. The single point at $\sqrt{s_{NN}} = 56\,{\rm GeV}$ is explained in Appendix A 10.

the $E_T/N_{\rm ch}$ ratio with $\sqrt{s_{NN}}$. In this region the increase in the incident energy causes an increase in the $\langle m_T \rangle$ of the produced particles. The second region starts from the SPS energies and continues above. In this region, the $E_T/N_{\rm ch}$ ratio is very weakly dependent on $\sqrt{s_{NN}}$. The incident energy is converted into particle production at midrapidity rather than into increasing the particle $\langle m_T \rangle$.

The shape of the $E_T/N_{\rm ch}$ curve in the first region is governed by the difference in the $\sqrt{s^0_{NN}}$ parameter between E_T and $N_{\rm ch}$. In the second region it is dominated by the ratio of the A parameters in the fits. This ratio is close to 1 GeV. Extrapolating to LHC energies one gets a $E_T/N_{\rm ch}$ value of (0.92 ± 0.06) GeV.

2. *Centrality shape*

Another interesting question is how the shapes of the centrality curves of E_T and $N_{\rm ch}$ change with $\sqrt{s_{NN}}$.

One approach previously used in a number of papers is to describe the shape of the centrality dependence as a sum of "soft" and "hard" contributions such that the soft component is proportional to N_p and the hard component to the the number of binary collisions N_c, that is, $A \times N_p + B \times N_c$. A disadvantage of this approach is that the contributions called soft and hard do not necessarily correspond to the physical processes associated with these notations. Another approach is to assume that the production of E_T or $N_{\rm ch}$ is proportional to N_p^α, although the parameter α has no physical meaning.

The results of B/A and α obtained from the fits to the data at different $\sqrt{s_{NN}}$ are summarized in Table II. Although the numbers tend to increase with beam energy, the values presented in Table II are consistent with each other within the systematic errors.

The availability of higher quality data would make it possible to derive a more conclusive statement about the shape of the curves plotted in Figs. 9 and 12. With the present set of data usually limited to N_p above 50, a large part of the

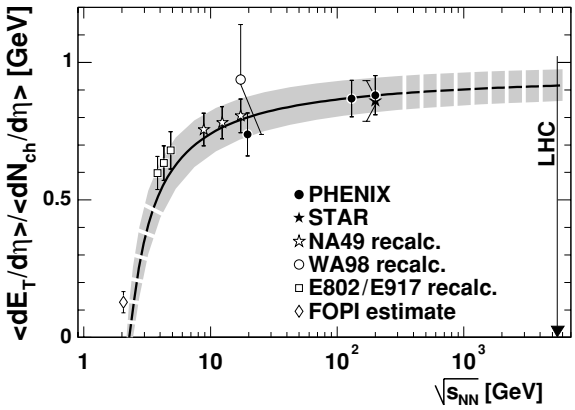

FIG. 14. Ratio of E_T over $N_{\rm ch}$ for the most central events as a function of $\sqrt{s_{NN}}$ recalculated into c.m.s. The line is the ratio of two fits shown in Fig. 13. The band corresponds to one standard deviation of the combined error.

TABLE II. B/A ratio and parameter α from the fit to the data. Errors are calculated assuming a change in the slope of the centrality curves within the limits of the bending errors for PHENIX and full errors for the averaged data (Table XVII).

$\sqrt{s_{NN}}$ (GeV)	$dE_T/d\eta$ PHENIX	$dN_{\rm ch}/d\eta$ PHENIX B/A	$dN_{\rm ch}/d\eta$ Average
200	$0.49^{+.69}_{-.22}$	$0.41^{+.57}_{-.21}$	$0.28^{+.18}_{-.15}$
130	$0.41^{+.52}_{-.23}$	$0.41^{+.45}_{-.23}$	$0.26^{+.18}_{-.11}$
19.6	$0.37^{+.48}_{-.22}$	$0.21^{+.30}_{-.15}$	$0.23^{+.73}_{-.23}$
17.2			$0.31^{+.46}_{-.24}$
8.7			$0.12^{+.64}_{-.20}$
	Parameter α		
200	1.20 ± 0.07	1.18 ± 0.08	1.16 ± 0.06
130	1.14 ± 0.08	1.17 ± 0.08	1.14 ± 0.05
19.6	1.13 ± 0.07	1.09 ± 0.06	1.10 ± 0.11
17.2			1.11 ± 0.08
8.7			1.06 ± 0.13
4.8			1.20 ± 0.24

centrality curve is missing or smeared by systematic errors. To avoid this, one can compare Au + Au collisions to $p + p$ ($N_p = 2$) at the same energy.

Figure 15 shows $dN_{\rm ch}/d\eta/(0.5N_p)$ divided by the parametrization plotted in the right panel of Fig. 13. The top panel shows the most central events with $N_p = 350$. All points are consistent with 1, demonstrating an agreement of the fit to the data. The points are connected with a line for visibility. The middle panel shows results for midcentral events, with $N_p = 100$ connected with a solid line. The dotted line is the same line as in the top panel for $N_p = 350$. The points for $N_p = 100$ are lower than for $N_p = 350$ by a factor of 0.8–0.9, over the plotted range of incident energies. The lower panel shows $p + p$ data corresponding to $N_p = 2$ measured by several experiments. The dotted lines are the same as appear in the upper two panels for $N_p = 350$ and 100, and the $p + p$ parametrizations are taken from [44,45]. In the range of RHIC energies these points are lower by a factor of 0.65–0.75 than the most central events.

These results indicate that the centrality curves normalized to the most central collisions have a similar shape for all RHIC energies within the errors of available measurements.

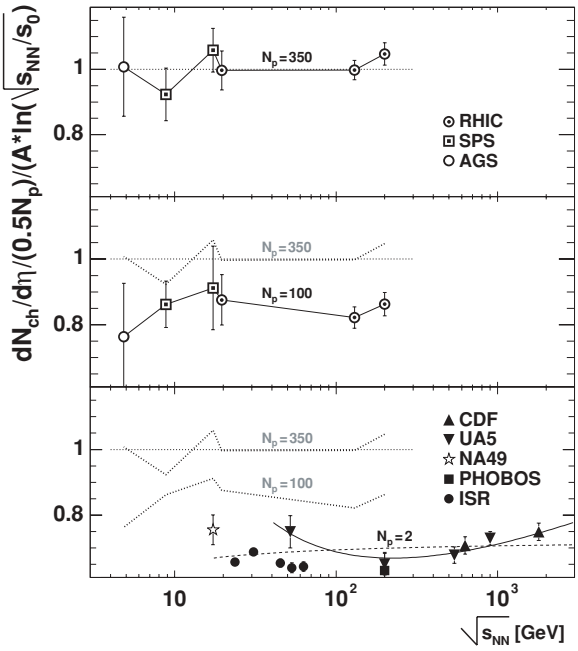

FIG. 15. The three panels show $dN_{\rm ch}/d\eta/(0.5N_p)$ divided by the logarithmic parametrization from Fig. 13. The panels correspond to $N_p = 350$, 100, and 2 ($p + p$) from top to bottom. Au + Au points are connected with lines also shown in lower panels for comparison. The Au + Au data are tabulated in Table XVII. $p + p$ data and parametrizations $dN/d\eta = 2.5 - 0.25\ln(s_{NN}) + 0.023\ln(s_{NN})^2$ (solid line) and $dN/d\eta = 0.27\ln(s_{NN}) - 0.32$ (dashed line) are taken from [44,45].

E. Comparison to models

A variety of models attempting to describe the behavior of E_T and $N_{\rm ch}$ as a function of centrality at different $\sqrt{s_{NN}}$ are available. An updated set of model results were collected from several theoretical groups to make a comparison as comprehensive as possible. Figures 16–18 show the comparison

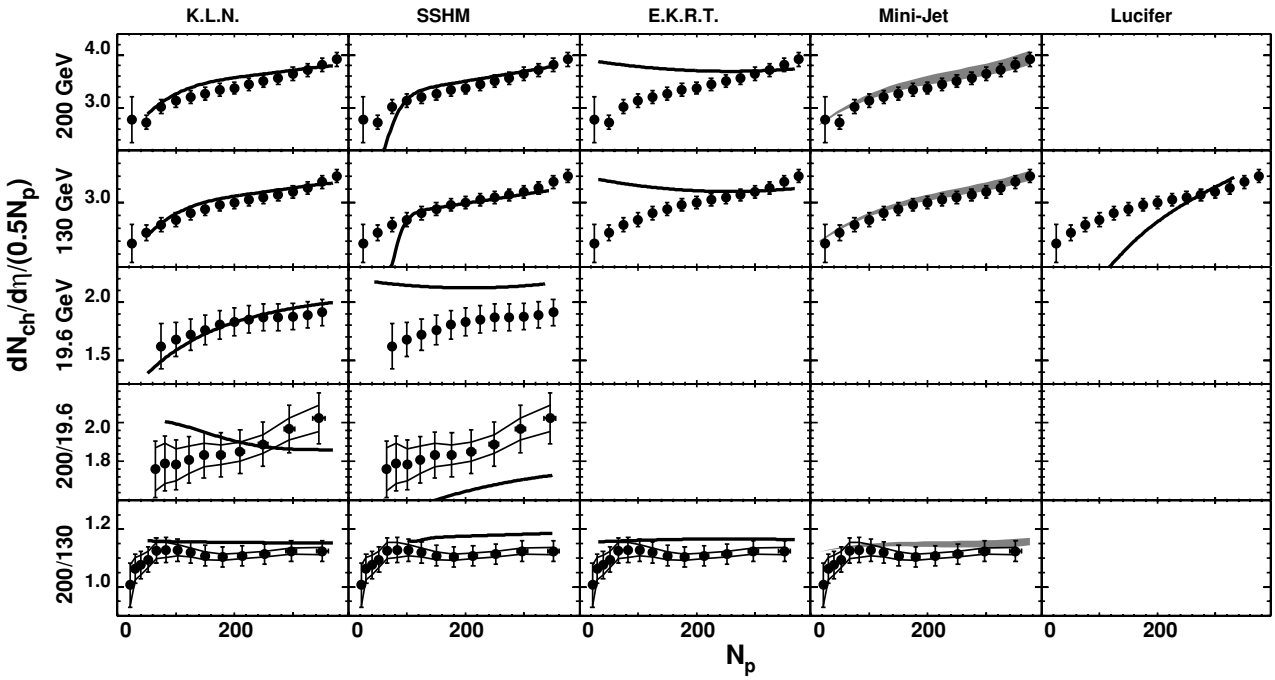

FIG. 16. $dN_{\rm ch}/d\eta$ per pair of participants compared to theoretical models. KLN [49], SSHM [52], EKRT [48], Minijet [50] and LUCIFER [56]. The band shows the range of prediction for the Minijet model.

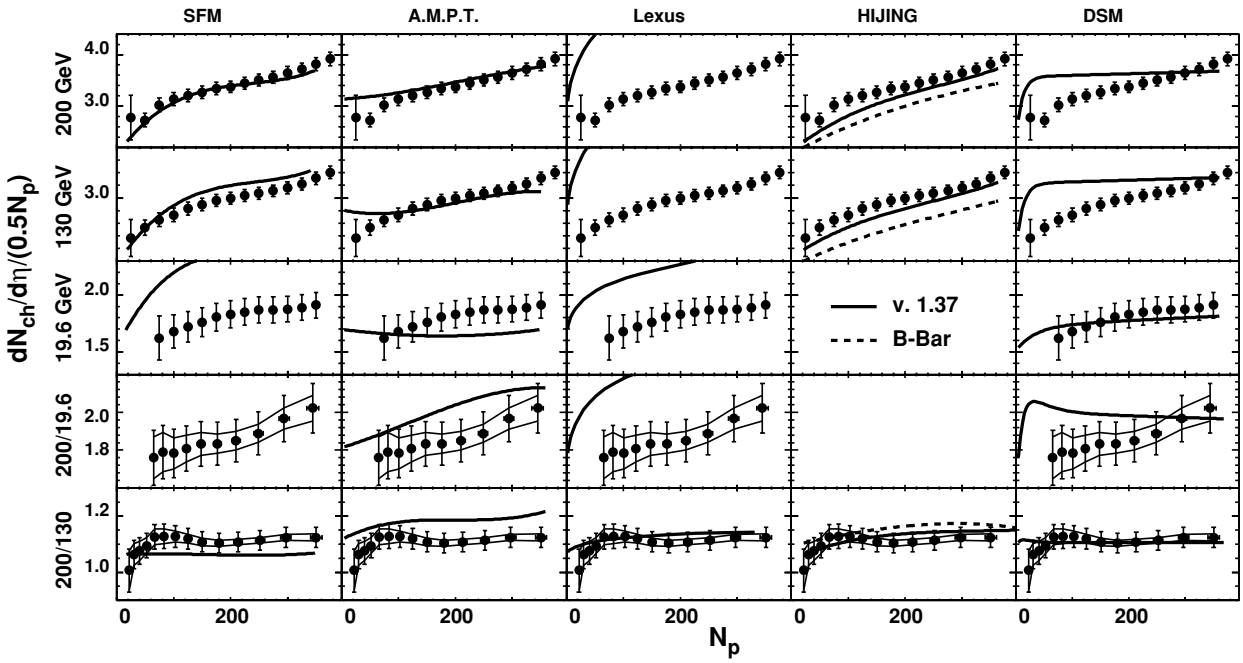

FIG. 17. Theoretical models compared to $dN_{\rm ch}/d\eta$ per pair of participants: SFM [55], AMPT [51], LEXUS [57], HIJING [15,46], and DSM [53].

between the existing theoretical models[7] and the data for 19.6, 130, and 200 GeV. Brief descriptions of the models and their main characteristics are given next.

One of the more commonly used Monte Carlo event generators is HIJING [15,46]. This model, like several others, uses pQCD for initial minijet production and the Lund string model [47] for jet fragmentation and hadronization. HIJING also includes jet quenching and nuclear shadowing. This type of model typically has two components, a soft part proportional to N_p and a hard part proportional to N_e, which partly motivated the discussion in Sec. IV D 2. There are also the so-called saturation models, which also rely on pQCD and predict that at some fixed scale the gluon and quark phase-space density saturates, thus limiting the number of produced quarks and gluons. An example of this type of model is EKRT [48], which is referred to as a final state saturation model. In this paper, comparisons are also made to another parton saturation type model, KLN [49], which is an initial state saturation model, and to models related to HIJING, namely, Minijet [50] and AMPT [51]. AMPT is a multiphase transport model and extends HIJING by including explicit interactions between initial minijet partons and final state hadronic interactions. Minijet follows the same two-component model as HIJING but also incorporates an energy-dependent cutoff scale, similar to the saturation models.

The other models are listed briefly below. SSHM and SFM do not have a designated short identifier, so they were named somewhat arbitrarily here, based on the physics the models incorporate. SSHM (saturation for semi-hard minijet) [52] is also a two-component model: it is pQCD-based for semihard partonic interactions, while for the soft particle production it uses the wounded nucleon model. DSM [53], the dual string model, is basically the dual parton model [54], with the inclusion of strings. SFM (string fusion model) [55] is a string model that includes hard collisions, collectivity in the initial state (string fusion), and rescattering of the produced secondaries. Finally, there are the hadronic models, LUCIFER [56], a cascade model with input fixed from lower energy data, and LEXUS [57], a linear extrapolation of ultrarelativistic nucleon-nucleon scattering data to nucleus-nucleus collisions.

The available model results range from predicting (or postdicting) $dN_{\rm ch}/d\eta$ at one energy to predicting both $dN_{\rm ch}/d\eta$ and $dE_T/d\eta$ at 19.6, 130 and 200 GeV. The models have varying success in reproducing the data.

In Fig. 16, KLN is among the most successful at describing the $dN_{\rm ch}/d\eta$ centrality dependence for all three energies. However, at $\sqrt{s_{NN}} = 19.6$ GeV, the theoretical curve is steeper than the data. This results in a reversed centrality dependence relative to the data for the 200 to 19.6 GeV ratio. SSHM describes the 130 and 200 GeV data well, for centralities above $N_p \sim 100$, which is the approximate limit of applicability for this and other saturation models. For the less central events, the model values are lower than the data. At 19.6 GeV, the model values are significantly higher than the data. The saturation model EKRT describes the central points at both energies but overshoots the more peripheral data points and thus does not reproduce the general centrality dependence of the data. For the nonsaturation models included in this figure, Minijet reproduces both the overall scale and the centrality and energy dependence of the data rather well, while the cascade model

[7]Models are presented as the best fit by the polynomial of the lowest degree which is closer than 1% to any theoretical point provided by the authors of the models. The polynomial is plotted in the range where points are provided.

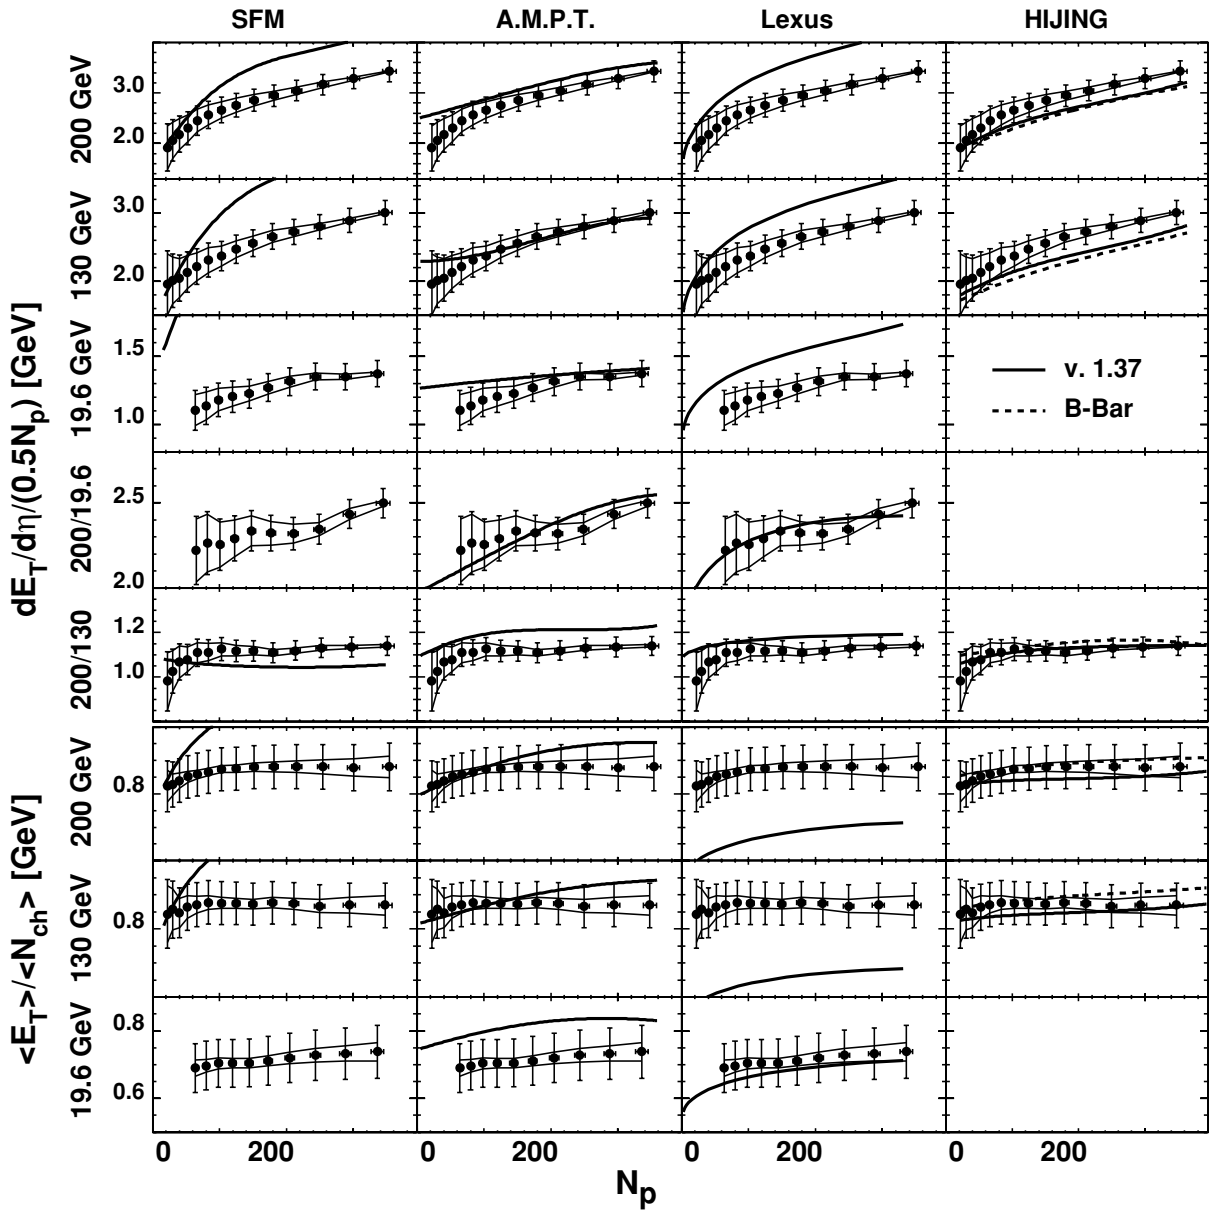

FIG. 18. Theoretical models compared to $dE_T/d\eta$ per pair of participants (upper panels) and per produced charged particle (lower panels): SFM [55], AMPT [51], LEXUS [57], and HIJING [15,46].

LUCIFER describes the central points at 130 GeV well but undershoots the less central values at this energy.

Most of the models included in Fig. 17 provided values for all three energies: 19.6, 130, and 200 GeV. SFM is in reasonable agreement with the 130 and 200 GeV data, but gives much larger values than the data at 19.6 GeV. AMPT is in overall good agreement with the data for the two higher energies, except for the increasing trend in $dN_{\rm ch}/d\eta$ at the most peripheral events, which is not seen in the experimental data. At the lower energy, the $N_{\rm ch}$ centrality behavior is underestimated. LEXUS rather severely overshoots the data for all energies, indicating that nucleus-nucleus effects are not accounted for. The HIJING models (version 1.37 and a new version with implemented baryon junctions, HIJING B-$\bar{\rm B}$) only provide points at 130 and 200 GeV and are in reasonable agreement with the data at those energies, but generally give somewhat lower values. The curves shown include quenching and shadowing implemented in HIJING. DSM describes 19.6 GeV reasonably well for all centralities and the more central bins for 130 and 200 GeV, but it overpredicts the values for semicentral and peripheral events.

Figure 18 shows the results for the models that provide data for both $dN_{\rm ch}/d\eta$ and $dE_T/d\eta$. For $dE_T/d\eta$, LEXUS and SFM consistently overshoot the data for all energies. In the ratio $E_T/N_{\rm ch}$, LEXUS gives values that are too low except at the lowest energy, 19.6 GeV. That might indicate that the hadronization mechanism allows too little energy per particle. The SFM gives values that are too large, except for the most peripheral bin, which suggests that the particles are assigned transverse masses that are too large. The HIJING versions and

the related AMPT model are in reasonable agreement with the data for both $dE_T/d\eta$ and $E_T/N_{\rm ch}$.[8]

Also shown in Fig. 18 are the ratios of results at 200 to 19.6 GeV, and 200 to 130 GeV, for $dE_T/d\eta$. These results, especially the comparison of the 200 to 19.6 GeV data, are intended to make a more precise check of the $\sqrt{s_{NN}}$ dependence of the models. SFM fails to describe the 19.6 GeV data and thus cannot describe the energy dependence probed by these ratios, unlike LEXUS which, however, does not agree well with the individual data curves for 19.6, 130, and 200 GeV. AMPT and the HIJING versions reproduce the values of the ratios well, as expected since they are in reasonable agreement with the individual curves. AMPT and HIJING are also successful in describing the $E_T/N_{\rm ch}$ ratio, as illustrated in the lower panels of Fig. 18.

To summarize, most models reproduce at least some of the data fairly well, but most fail in describing all the data. Since the model results typically are given without systematic errors, it is not entirely straightforward to quantify the level of agreement or disagreement with the data. Qualitatively, the models that are most successful in describing both $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ in terms of the overall trends, regarding both centrality dependence and energy dependence, are AMPT and the HIJING versions. KLN and Minijet unfortunately do not give information on $dE_T/d\eta$ but are successful in describing the $dN_{\rm ch}/d\eta$ results. The $dN_{\rm ch}/d\eta$ results thus can either be described by the initial state saturation scenario (KLN) or by the minijet models that need an energy-dependent minijet cutoff scale as described in [46,50] to reproduce the data.

V. SUMMARY

This paper presents a systematic study of the energy and centrality dependence of the charged particle multiplicity and transverse energy at midrapidity at $\sqrt{s_{NN}} = 19.6$, 130, and 200 GeV.

The yields, divided by the number of participant nucleons, show a consistent centrality dependence (increase from peripheral to central) between $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ for all energies. Furthermore, the increase in the ratio $E_T/N_{\rm ch}$ from 19.6 to 200 GeV is consistent with a 20% increase in $\langle m_T \rangle$ with increasing $\sqrt{s_{NN}}$. The ratio $E_T/N_{\rm ch}$ shows only a weak centrality dependence at RHIC energies.

For the $\sqrt{s_{NN}}$ dependence, comparisons were made not only among RHIC results but also with data from lower energy fixed-target experiments at SPS, AGS, and Schwer-Ionen-Synchrotron (SIS). A phenomenological fit, scaling logarithmically with $\sqrt{s_{NN}}$, describes well both $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ for the most central collisions for all energies.

Using the fit results, one can delineate two regions with different particle production mechanisms. The region below SPS energy is characterized by a steep increase in $E_T/N_{\rm ch} \sim \langle m_T \rangle$ with $\sqrt{s_{NN}}$, whereas for the energies above SPS, $E_T/N_{\rm ch}$ is weakly dependent on $\sqrt{s_{NN}}$.

Within the systematic errors of the measurements, the shape of the centrality curves of $dN_{\rm ch}/d\eta/(0.5N_p)$ vs. N_p were found to be the same in the range of RHIC energies and to scale with $\ln(\sqrt{s_{NN}})$. The same must be true for E_T because $E_T/N_{\rm ch}$ has a very weak centrality dependence.

Based on the $dE_T/d\eta$ measurements, the Bjorken energy density estimates were performed and $\epsilon_{Bj} \cdot \tau$ was determined to be 5.4 ± 0.6 GeV fm$^{-2}\,c^{-1}$ at $\sqrt{s_{NN}} = 200$ GeV for the most central bin. This is in excess of what is believed to be sufficient for a phase transition to the new state of matter. The energy density increases by about a factor of 2.6 from the top SPS energy to the top RHIC energy.

Finally, a comparison between the RHIC $dN_{\rm ch}/d\eta$ and $dE_T/d\eta$ data and a collection of models was performed. A few models, notably HIJING and AMPT, reproduce both $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ rather well for several energies.

ACKNOWLEDGMENTS

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions. We are grateful for information provided by the model authors. In particular, we thank A. Accardi, S. Barshay, S. Jeon, S. Kahana, D. Kharzeev, Z. Lin, N. Armesto Perez, R. Ugoccioni, V. T. Pop, and X. N. Wang for helpful correspondence. APPENDIX A: RECALCULATION OF THE NON-PHENIX EXPERIMENTAL DATA

Comparisons of $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ between different experiments can be made only if the results are presented

[8]Note that the HIJING versions available at the time the data were collected and used for predictions were in worse agreement with the data [10]. This was before energy loss and minijet separation/cutoff scale parameters were updated.

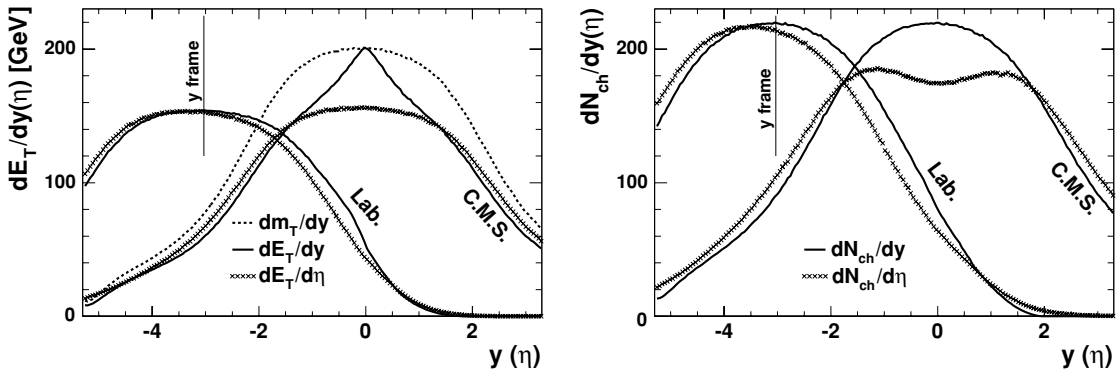

FIG. 19. Simulated E_T (left) and $N_{\rm ch}$ (right) distributions in rapidity and pseudorapidity units in c.m.s. and Lab. systems.

in the same coordinate system since these values are not boost invariants. In some cases a full set of identified particles measured by one experiment can be recalculated into E_T and $N_{\rm ch}$. Each case that involves handling non-PHENIX published data is separately explained in this Appendix.

1. General

Figure 19 shows simulated rapidity distributions for E_T and $N_{\rm ch}$ in the c.m.s. and Lab. frames. Plots presented here are for illustrative purposes only. The invariant distributions which do not change their shape under transition from Lab. to c.m.s. are dm_T/dy and $dN_{\rm ch}/dy$, while all others do.

In the c.m.s. system, the transition from η to y at midrapidity requires a scaling factor between 1.2 and 1.3. An accurate determination of this coefficient from the published data of other experiments is not always possible; therefore for the SPS and AGS energies a coefficient of 1.25 was used. Because of the definition of E_T used in this paper, $dE_T/dy \approx dm_T/dy$, around midrapidity, where m_T is a quadratic sum of the particle mass and transverse momentum: $m_T = \sqrt{m^2 + p_T^2}$.

In the Lab. system $dN_{\rm ch}/dy \approx dN_{\rm ch}/d\eta$ and $dE_T/dy \approx dE_T/d\eta$ at maximum rapidity. A 1.04 conversion factor was assigned to the transition from η to y in the Lab. system.

An error of 5% was assigned to any converted value. This error also absorbs uncertainties on various assumptions used in the calculations. For example, the contribution of neutral particles to the total E_T is assumed to be

$$E_T^{\pi^0} = \left(E_T^{\pi^+} + E_T^{\pi^-}\right)/2,$$
$$E_T^{K^0} = E_T^{K^+} + E_T^{K^-},$$
$$E_T^{n} + E_T^{\bar{n}} = E_T^{p} + E_T^{\bar{p}}. \qquad \text{(A1)}$$

2. Averaging procedure

Average values were calculated for $N_p = 25, 50, \ldots, 375$. The centrality bin corresponding to a given N_p can be different in different experiments. $dN_{\rm ch}/d\eta$ per participant and the associated error were deduced by a weighted average interpolation from the two nearest values of each experiment. The closest value was required to be within a proximity of 25 participants from the N_p value. The error bars are multiplied by the S factor, where $S = \sqrt{\chi^2/\text{n.d.f.}}$ if $\chi^2/\text{n.d.f.} > 1$ or $S = 1$ otherwise. See the Particle Data Group reference [20] for details.

3. NA49

Table III lists the identified particle yields in the most central events at midrapidity at $\sqrt{s_{NN}} = 17.2$ GeV, as shown in Fig. 6 in Ref. [17]. The total yields per participant and number of participants in Table IV are taken from Fig. 10 in Ref. [17]. Using shapes of the dN/dy distributions shown in Fig. 7 of Ref. [17] for different centrality bins, the quantities tabulated in Tables III and IV can be converted into $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$ per participant pair at midrapidity. Systematic errors on particle yields are given in Table 1 in the same reference. The systematic errors for this value are not mentioned in the paper, therefore they were taken from [19]. The results used in this paper are also given in Table IV.

For the same and lower $\sqrt{s_{NN}}$, the identified particle yields and $\langle m_T \rangle$ were reconstructed using formula (1) and Fig. 1 in Ref. [18] and Table II and formulas (1) and (2) in Ref. [19]. The data obtained from the tables and the fits are summarized in Table V. Using dN/dy and $\langle m_T \rangle$, the values of $dE_T/d\eta$ and $dN_{\rm ch}/d\eta$, were recalculated in the c.m.s. frame. The accuracy of the procedure was verified by the consistency of results presented in Tables V and VI.

The single E_T point in Fig. 13 is taken from [31] as 405 GeV and scaled up by 10%, then divided by pairs of $N_p = 390$ as explained in the text. This point does not agree with the value of E_T deduced from [17–19].

4. WA98

The centrality dependencies of E_T, $N_{\rm ch}$, and $E_T/N_{\rm ch}$ were read from the plots in Figs. 7 and 14 in Ref. [25] and converted to the c.m.s. frame. Results are summarized in Table VII.

5. NA45

The NA45/CERES collaboration did not publish results for $dN_{ch}/d\eta$ as a function of centrality at $\sqrt{s_{NN}} = 17.2$ GeV. The data were taken from Fig. 6.5 in Ref. [58], and a 10% error was assigned based on the analysis procedure. The number of participants was taken from the corresponding cross-section bin reported by the NA50 results [42]. At the lower energy, the results were originally published in [59] and then N_p was subsequently corrected (see [41], for example). The results presented in Fig. 4 of Ref. [41] for charged hadrons h^- and $(h^+ - h^-)$ were added together to get $dh/d\eta$ and then converted to $dN_{ch}/d\eta$ in the c.m.s. frame. The published and recalculated results are summarized in Table VIII.

6. NA50

Results on N_p are taken from Tables 1 and 2 in Ref. [42] and on multiplicity from Figs. 2 and 4 tabulated in captions in Ref. [42]. The systematic errors are mentioned in the text. There is some discrepancy in the results of NA50 and NA45 as shown in Fig. 12. In this respect the comparison made in Table 3 of Ref. [42] is unclear. The results were converted to the c.m.s. frame. Recalculated values are given in Table IX.

7. E802/E917

The centrality dependence of π^+, K^+ yields and $\langle m_T \rangle$ were recalculated from Tables V and VI in Ref. [60]. Number of participants are taken from Table II in the same publication. The results are presented in Table X.

TABLE VIII. Published (P) NA45 results at $\sqrt{s_{NN}} = 17.2$ GeV taken from Fig. 6.5 in Ref. [58] and at $\sqrt{s_{NN}} = 8.7$ GeV from Fig. 4 in Ref. [41], and recalculated (R) results plotted in Figs. 11 and 12.

Error	0.10	0.09	0.09	0.09	0.09	0.09

K^-/K^+ ratio was assigned a value of 0.17 for all centralities based on Tables II and III in Ref. [61]. This is consistent with results reported in Fig. 6 in Ref. [62] and Fig. 11 in [63]. The proton production reported in Table IV in Ref. [60] was compared to measurements reported in Fig. 2 in [64] and Fig. 10 in [63] for different centrality bins. The results are consistent. $\bar{p}/p$ ratio was assigned a value of 0.0003 based on Fig. 11 in Ref. [63]. A 25% enhancement in π^-/π^+ ratio for low m_T reported in [65] for the most central bin is not clearly seen in Fig. 11 in [63] for all centralities. Such an enhancement would contribute an additional 8–9% to the total particle and transverse energy production. This is less than the systematic error on the result and the recalculation error, and thus this effect is not considered. The resulting values shown in Table X were recalculated to midrapidity in the c.m.s. frame.

For the lower $\sqrt{s_{NN}}$ the information about particle yields and $\langle m_T \rangle$ was extracted for π^+ and K^+ from Tables II and I in Ref. [66], respectively; for K^- from Table I in [67]; and for p from Fig. 2 in [64]. The same assumptions as above were made to recalculate values plotted in Figs. 13 and 14. The numbers are given in Table XI.

8. Averaging procedure at $\sqrt{s_{NN}} = 8.7$ GeV

The averaging procedure is slightly different for this curve. First the average results of NA45 and NA50 are produced.

TABLE X. Centrality dependence of the identified particles measured by E802/E866/E917 collaborations. Number of participant pairs is published (P) in Table II in Ref. [60]. π^+ and K^+ values are obtained by extrapolation (E) from E802 measurement very close to midrapidity. Data were taken from Tables V and VI in Ref. [60]. Proton data are a compilation of the results taken from Table IV in [60] and Fig. 2 in [64]. Recalculated values (R) are plotted in Figs. 11 and 12.

TABLE XI. Recalculated values from E802/E917 experiments plotted in Figs. 13 and 14.

$\sqrt{s_{NN}}$ (GeV)	4.84	4.27	3.81
$dE_T/d\eta/(0.5N_p)$ (GeV)	0.579 ± 0.087	0.498 ± 0.075	0.405 ± 0.061
$dN_{\rm ch}/d\eta/(0.5N_p)$	0.851 ± 0.128	0.787 ± 0.118	0.678 ± 0.102
$E_T/N_{\rm ch}$ (GeV)	0.680 ± 0.068	0.634 ± 0.063	0.598 ± 0.060

TABLE XII. Particle yields measured by FOPI experiment at midrapidity extracted from Fig. 21 in Ref. [68].

Z	1	2	3	4	5–6
$dM/d(\cos\theta)$	43	12	2	0.5	0.25
Error	4.3	1.2	0.2	0.05	0.025

Then at $N_p = 350$, this result is combined with the NA49 measurement using the weighted error method. A scaling coefficient before and after NA49 averaging is calculated. The NA45/NA50 combined result is scaled by this factor for all values of N_p.

9. FOPI

The FOPI results for $N_{\rm ch}$ were calculated for 400 A MeV based on the data plotted in Fig. 21 of Ref. [68]. The points were read at the angle corresponding to the midrapidity angle ($\theta = 55^\circ$) and then converted to $dN_{\rm ch}/d\eta$ resulting in 39 ± 4 at $\sqrt{s_{NN}} = 2.053$ GeV.

The corresponding number of participants for a 42-mb event sample is 359 based on Fig. 8 in Ref. [69]. Data for 150 A MeV were compiled based on the comparison between Figs. 13 and 14 in [68] and the used definition of rapidity y, resulting in $dN_{\rm ch}/d\eta = 40 \pm 5$ at $\sqrt{s_{NN}} = 1.937$ GeV.

The estimate of the E_T production at 400 A MeV is made based on a comparison of the total yields of the particles with $Z = 1$ in [68] and yields of protons and deuterons published in [70]. That allowed us to determine the number of all pions at midrapidity to be 20.6 and the number of all hadrons with $Z = 1$ to be 15.2. Assuming that the particle temperatures are equal to $T = 40$ MeV (exact numbers are published in [69,70]), one can estimate that the contribution to E_T from pions is $m_\pi + 3/2T$ and from baryons is $3/2T$, according to the definition of E_T used in this paper. The resulting number of 5.0 GeV is a lower limit estimate because the contribution of heavier particles is not considered. A conservative error of 30% is assigned to this number.

10. PHOBOS measurement at $\sqrt{s_{NN}} = 56$ GeV

The PHOBOS experiment published $dN_{\rm ch}/d\eta = 408 \pm 12(\text{stat}) \pm 30(\text{syst})$ at $\sqrt{s_{NN}} = 56$ GeV measured for $N_p = 330 \pm 4(\text{stat})^{+10}_{-15}(\text{syst})$ in [35]. In the same paper, $dN_{\rm ch}/d\eta$ per participant between 130 and 56 GeV was measured to increase by $1.31 \pm 0.04(\text{stat}) \pm 0.05(\text{syst})$. That allows the use of the averaged value at $\sqrt{s_{NN}} = 130$ GeV consistent with the PHOBOS result published in [36] to recalculate $dN_{\rm ch}/d\eta$ at $\sqrt{s_{NN}} = 56$ GeV with smaller systematic error. This value is plotted in Fig. 13.

APPENDIX B: OUTPUT TABLES

(Received 7 August 2004; published 27 May 2005)

Two particle correlations between identified meson and baryon trigger particles with $2.5 < p_T < 4.0$ GeV/c and lower p_T charged hadrons have been measured at midrapidity by the PHENIX experiment at RHIC in p+p, d+Au, and Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV. In noncentral Au+Au collisions, the probability of finding a hadron near in azimuthal angle to the trigger particles is almost identical for mesons and baryons and significantly higher than in p+p collisions. The *associated* yields for trigger baryons decrease in the most central collisions, consistent with some baryon production by thermal recombination in addition to hard scattering.

DOI: 10.1103/PhysRevC.71.051902 PACS number(s): 25.75.Dw

A remarkable feature of relativistic heavy ion collisions is greatly enhanced production of baryons and antibaryons relative to mesons. This enhancement over elementary $p+p$ collisions occurs at transverse momenta (p_T) of 2–5 GeV/c [1–3]. In this range, particle production shifts from soft processes (nonperturbative, low momentum transfer scattering) to hard (high momentum transfer parton-parton scattering). Hard scattering is followed by fragmentation of the scattered partons to jets of hadrons. Baryon and antibaryon production is suppressed in fragmentation in vacuum. Phenomenologically, this can be thought of as a large penalty for creating a diquark/antidiquark pair for baryons vs. a quark/antiquark pair for meson formation.

Since there is no sharp separation of scales between hard and soft processes, it is natural to ask which causes the baryon excess in Au+Au collisions. Hadron formation by coalescence of quarks from the expanding thermal fireball can explain single particle yields [4–7] but causes no jetlike correlations. The yield of baryons in this momentum range scales approximately with the number of binary nucleon-nucleon collisions [2], which is typical of hard processes. However, if hard scattering is at the root of the baryon excess, additional mechanisms absent in elementary $p+p$ collisions are required, such as alteration of the jet fragmentation function in the dense medium formed in Au+Au collisions, or recombination of hard scattered quarks with accidental comoving quarks from the medium. Models include hard parton fragmentation but recombination of thermal quarks only [5], thermal quark recombination with jet fragments [6,8], and recombination of quarks from hard scattering with a modified fireball distribution [7]. Hadron production via recombination between jet fragments and thermal quarks [6–8] could preserve jetlike correlations among the final hadrons, presuming that each hadron contains at least one quark arising from a fragmenting hard scattered parton.

To determine the role of jets in production of intermediate p_T protons, the PHENIX experiment at RHIC has measured energetic hadronic partners near the baryons. These are the additional fragmentation products from the same jet as the baryon. We present first results on two particle correlations where the *trigger* particle is an identified meson (π, K) or baryon (p, $\bar{p}$) at $2.5 < p_T < 4.0$ GeV/c. *Associated* particles, i.e., lower p_T charged hadrons near the trigger particle in azimuthal angle are counted. A Monte Carlo study shows that for these trigger particle momenta, resonance decays do not contribute associated particles at $p_T > 1.2$ GeV/c; at lower p_T, there is a small contribution, but it is less than the statistical uncertainty. The centrality and collision system dependence of the associated particle yield per trigger is measured. Trigger particles from recombination of boosted thermal quarks only should not have correlated partners beyond effects of elliptic flow, as a thermal source is by definition uncorrelated. However, trigger particles from hard scattered partons should have jetlike partners with a probability depending upon the medium effect on fragmentation. We use $p+p$ collisions without trigger identification to provide a comparison baseline.

Collisions at $\sqrt{s_{NN}} = 200$ GeV of Au+Au (24 million events), d+Au (42 million events), and $p+p$ (23 million events) are analyzed. Charged particles are reconstructed in the central arms of PHENIX using drift chambers, each with azimuthal coverage of $\pi/2$, and two layers of multiwire proportional chambers with pad readout (PC1, PC3) [9]. Pattern recognition is based on a combinatorial Hough transform in the track bend plane, with the polar angle determined by PC1 and the collision vertex along the beam direction [1]. Particle momenta are measured with a resolution $\delta p/p = 0.7\% \oplus 1.0(1.1)\% p(\mathrm{GeV}/c)$ in Au+Au (d+Au, $p+p$). The portion of the east arm spectrometer containing the high resolution time-of-flight (TOF) detector, which covers pseudorapidity $|\eta| < 0.35$ and $\phi = \pi/4$ in azimuthal angle, is used for trigger particle identification. Beam counters (BBC) [9] provide the global start; stop signals are from TOF scintillators at a radial distance of 5.06 m. The timing resolution is $\sigma = 120$ ps, which allows a 4σ separation of mesons/baryons up to $p_T \approx 4$ GeV/c. The Au+Au centrality determination is described in Ref. [10].

Distributions of azimuthal angular difference $\Delta\phi$ are constructed for trigger-partner pairs. The combinatorial background is determined by constructing mixed events in two steps: the number of trigger and partner particles per event is determined by sampling the measured particle multiplicity distributions in the relevant momentum and centrality ranges. The measured trigger and partner particle momentum distributions are then sampled to yield three-momenta of particles in each mixed event. To correct for the limited acceptance of PHENIX, the real event $\Delta\phi$ distributions are divided by $\Delta\phi$ distributions from mixed events, with the integral fixed to correspond to perfect acceptance as a function of $\Delta\phi$. The shape of this distribution corrects for the $\Delta\phi$ dependence of the PHENIX azimuthal acceptance, but has no true correlations. The $\Delta\phi$ distributions are shown in Fig. 1; mixed events are indicated by solid lines. The partner yield is corrected for the reconstruction efficiency, detector aperture, and (for Au+Au only) detector occupancy [11]. No extrapolation is made to $|\eta| > 0.35$. No correction for the PHENIX $\Delta\eta$ acceptance is needed in Figs. 1 and 2, as the same acceptance is used for both trigger type and the different collision systems. Since d+Au and Au+Au collisions contain uncorrelated combinatorial background from other particles in the underlying event, the mixed event partner yield per trigger, after the same efficiency correction, is subtracted. The absolute normalization of the background is obtained independently by a convolution of the trigger and partner single particle rates.

In real events, collisions from the more central edge of the bin contribute more pairs than those from the less central edge. Mixed events are constructed by randomly sampling single particle multiplicity distributions within a 5% centrality bin. As the particle multiplicity is not flat with centrality, mixed events underweight the upper edge of the bin compared to real events. The mixed event background is corrected for this effect. The spread of trigger and partner number within a bin is determined from the measured centrality dependence of particle multiplicity in the relevant momentum region and particle species [10–13]. The correction modifies the background level by $\approx$0.2% in the most central and $\approx$25% in the most peripheral Au+Au collisions.

Elliptic flow causes an angular correlation in Au+Au unrelated to jet fragmentation, and is a background to this

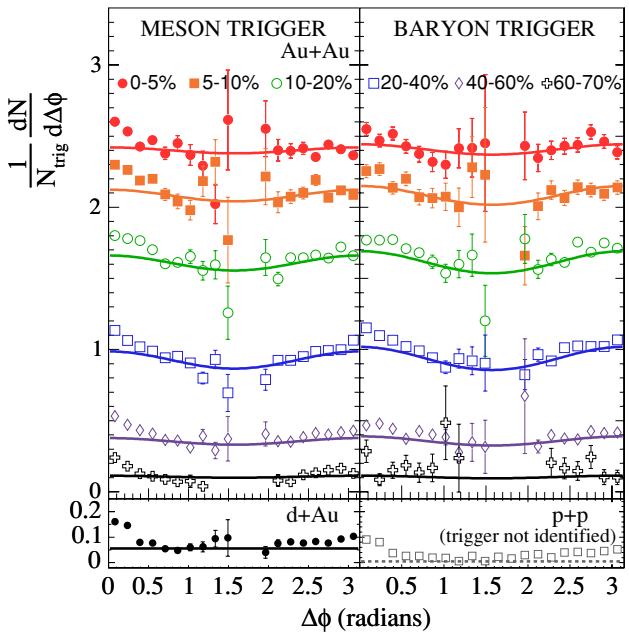

FIG. 1. (Color online) Top panels show $\Delta\phi$ distributions for meson (left) and baryon (right) triggers with $2.5 < p_T < 4.0$ GeV/c and associated charged hadrons with $1.7 < p_T < 2.5$ GeV/c in Au+Au collisions. Bottom panels show the same quantity for meson triggers in d+Au collisions (left) and unidentified triggers in p+p collisions (right). Lines indicate the calculated combinatorial background in the event modulated by the measured elliptic flow (Au+Au only).

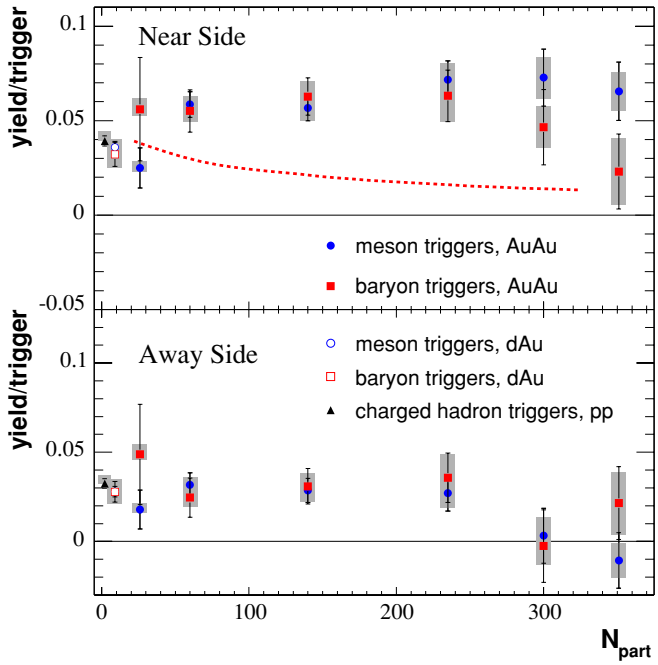

FIG. 2. (Color online) Yield per trigger for associated charged hadrons between $1.7 < p_T < 2.5$ GeV/c for the near- (top) and away- (bottom) side jets. The error bars are statistical errors, and the gray boxes are centrality-dependent systematic errors There is an additional 12% error on the overall normalization, which moves all points together. The dashed line (top) represents an upper limit of the centrality dependence of the near-side partner yield from thermal recombination (see text).

measurement. The elliptic flow correlation is removed by modulating the azimuthally uniform combinatorial background by $1 + 2v_2^{\text{assoc}} v_2^{\text{trig}} \cos(\Delta\phi)$, where v_2^{assoc} and v_2^{trig} are the v_2 values measured for the partner and trigger p_T ranges, respectively [14]. The reaction plane is measured by the BBC at $3 < |\eta| < 4$ in order to minimize the influence of jets in the v_2 values. Because the centrality binning in this analysis is finer than in [14], the p_T integrated centrality dependence is used to interpolate v_2 for collisions more central than 20%. The modulation of the mixed event $\Delta\phi$ distributions is visible in Fig. 1.

Systematic uncertainties in Au+Au and d+Au partner yields arise from uncertainties in the corrections for centrality bin width, systematic and statistical errors on v_2 [14] (Au+Au only), uncertainty in the background subtraction due to the event mixing technique, and uncertainty in the detector occupancy correction. Cross-contamination of mesons and protons is less than 5%. The error on the occupancy correction reaches a maximum of 5% in the most central Au+Au collisions. For most Au+Au bins, the dominant systematic uncertainty on the partner yields is the uncertainty in v_2. This produces a systematic error of approximately 0.01 partners per trigger baryon in semicentral and central collisions; for trigger mesons, the corresponding error is 60% of this. The event mixing uncertainty is nearly comparable. In peripheral Au+Au collisions, the dominant systematic error is from uncertainty on centrality bias corrections and v_2. In d+Au collisions, there is no v_2, and the partner yield uncertainty is driven by the correction for centrality bias. In p+p collisions, the systematic error is taken to be the same size as the combinatorial background, which is subtracted. The total systematic errors are shown in Fig. 2.

The background shown in Fig. 1 is subtracted from the data points, which in most cases lie systematically above the line. The number of associated partners per trigger is integrated to determine the conditional yield of partners. The near- (far-) side yield is the integral over $0 < \Delta\phi < 0.94$ radians ($2.2 < \Delta\phi < \pi$ radians). This range maximizes the partner acceptance while omitting the region around $\Delta\phi = \pi/2$, where the TOF coverage creates an acceptance hole. Nonbackground associated partners are observed in the angular range characteristic of jet fragmentation in p+p, which was measured by PHENIX to be $\approx$0.25 radians in a similar p_T range [15].

Figure 2 shows the conditional yield per trigger of partner particles in p+p, d+Au, and Au+Au collisions, as a function of the number of participant nucleons. Small relative angle yields, from the same jet as the trigger hadron, are in the top panel. The partners increase for both trigger baryons and mesons by almost a factor of two from d+Au to peripheral and midcentral Au+Au. There is an indication that jetlike correlations for baryons relative to mesons decrease in the most central collisions, as expected for production of a fraction of the baryons by recombination of thermal quarks. It is notable, however, that the baryon excess

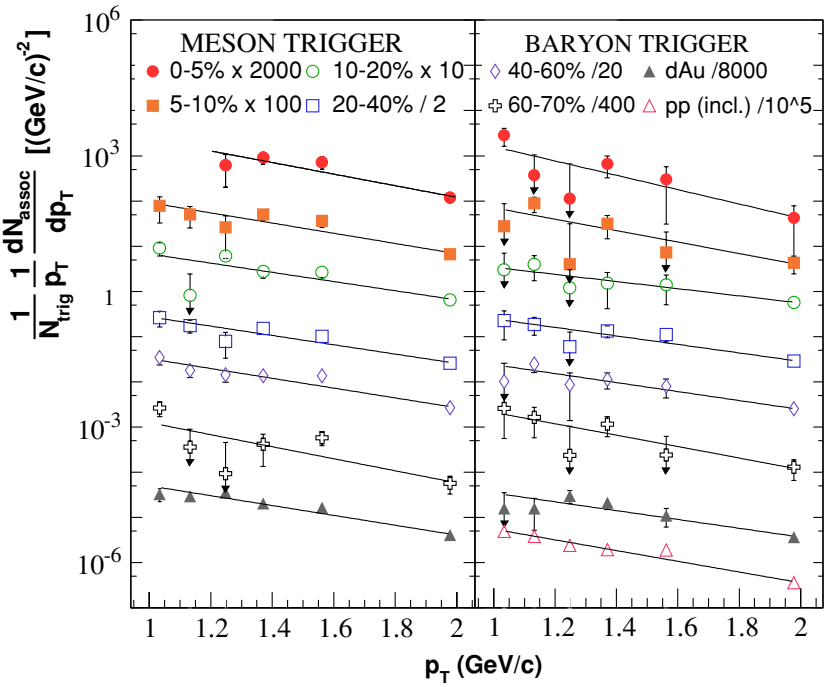

FIG. 3. (Color online) p_T spectra of the near-side associated charged hadrons corrected to the full jet yield for meson (left) and baryon (right) triggers at $2.5 < p_T < 4.0$ GeV/c and $|\eta| < 0.35$. Errors are statistical only. The curves are exponential fits.

observed via p/π ratios [1–3] is already large in midcentral collisions. In d+Au collisions, the near-side yields per trigger are the same for meson and baryon triggers, and they agree with results from p+p collisions generated with PYTHIA [16].

The dashed line in Fig. 2 shows the expected centrality dependence of partners per baryon if all the "extra" baryons [10], that increase p/π over that in p+p collisions, were to arise solely from soft processes; such baryons dilute the per-trigger conditional yield. Because this simple estimate omits meson production by recombination, which must also occur along with baryon production, it represents an upper limit to the centrality dependence of the jet partner yield from thermal recombination. The data clearly disagree with both the centrality dependence and the absolute yields of this estimate, indicating that hard processes must also contribute to the baryon excess. The bottom panel of Fig. 2 shows the conditional yield of partners on the away side. The partner yield in $2.2 < \Delta\phi < \pi$ radians drops equally for both trigger baryons and mesons from p+p and d+Au to central Au+Au, in agreement with the observed disappearance [17] and/or broadening [15] of the away-side jet. It further supports the conclusion that the baryons originate from the same jetlike mechanism as mesons.

Figure 3 shows the p_T spectra of associated particles [18] on the near side with trigger mesons and baryons. The measured transverse momentum of jet hadrons with respect to the initial parton direction $\langle j_T \rangle$ is constant as a function of collision energy and p_T [15,19]. Thus, the angular size of jets increases as the partner p_T decreases. We use the PHENIX measurement of $\langle |j_{Ty}| \rangle = 0.359 \pm 0.011$ GeV/c [15] to correct the near-side conditional yield measured in $\Delta\phi < 0.94$ radians, and the PHENIX η acceptance to the full jet yield, assuming that jets are symmetric gaussians in both ϕ and η. The conditional yields in Fig. 2 do not have this additional correction as they are measured in a single p_T bin. The partner spectra in Fig. 3 are fitted with exponentials, and the inverse slopes are given in Fig. 4. The systematic uncertainty on the associated

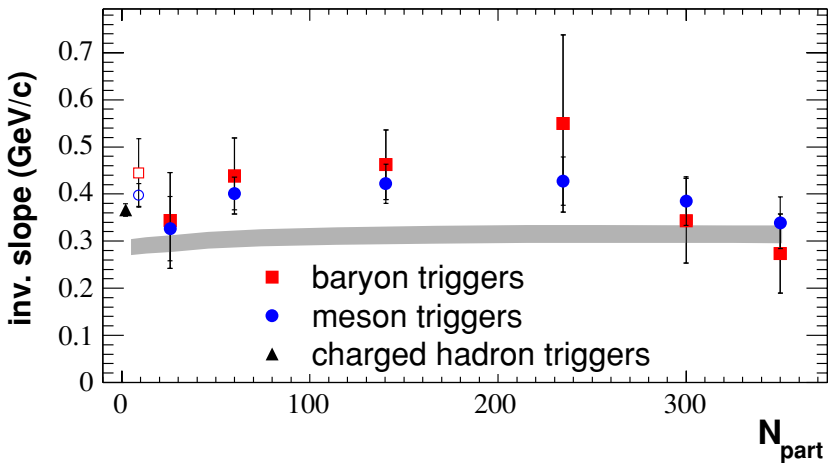

FIG. 4. (Color online) Inverse slopes from the fits in Fig. 3. Solid (open) squares and circles are Au+Au (d+Au), collisions and the triangle is p+p collisons. The solid band indicates the slopes of inclusive particle spectra in Au+Au collisions [11]. Errors are statistical only.

particle slope in central collisions is approximately 20%, based on a conservative estimate of 50% uncertainty on the correction to the full jet yield. We note that this is comparable to the statistical error for leading mesons and smaller than the statistical error for leading baryons. Within the available statistics, the inverse slopes of the associated particles are similar for trigger mesons and baryons in $p+p$, $d+$Au, peripheral, and midcentral Au+Au. The spectra are harder than inclusive hadron spectra, as expected from jet fragmentation. In the most central Au+Au collisions, the partner and inclusive hadron spectra are in better agreement.

We have presented the first study of the jet structure of baryons $(p, \overline{p})$ and mesons (π, K) in the momentum region where baryon production is greatly enhanced in central Au+Au collisions at RHIC. Three observations indicate that mesons and baryons arise from hard processes in all but the most central Au+Au collisions. First, baryons and mesons both have jetlike partner particles. Second, within the limited statistics available, the inverse slopes of the associated particles are similar for both baryons and mesons; these are larger than for inclusive hadrons. Finally, on the away side, the jet partner yield into a 0.94 radian opening angle has the same centrality dependence for trigger baryons and mesons, consistent with attenuation in central collisions. The increase in jetlike partners between $p+p$ and Au+Au is strong evidence for medium modification of the fragmentation process. Recombination of thermal quarks with jet fragments [6,8] and a "wake effect" from comoving radiated gluons [7] are two examples of how the medium might modify jet fragmentation. The decrease with centrality of partner yields for trigger baryons suggests a growing contribution of baryons from thermal recombination.

Abstract. The azimuthal distributions of photons and charged particles with respect to the event plane are investigated as a function of centrality in ^{208}Pb + ^{208}Pb collisions at 158 $\cdot A$ GeV/c in the WA98 experiment at the CERN SPS. The anisotropy of the azimuthal distributions is characterized using a Fourier analysis. For both the photon and charged particle distributions the first two Fourier coefficients are observed to decrease with increasing centrality. The observed anisotropies of the photon distributions compare well with the expectations from the charged particle measurements for all centralities.

PACS. 25.75.Dw

1 Introduction

Non-isotropic emission of particles with respect to the reaction plane, as first observed at the Bevalac [1], provides evidence for collective flow in high energy heavy ion collisions. Flow, or anisotropic particle emission, has been observed for a large variety of interacting systems from incident energies of a few A GeV/c at the Bevalac (SIS) and AGS to much greater energies at the SPS and RHIC [2–13].

Anisotropic flow manifests itself as asymmetries in the azimuthal distribution of particles and can be reproduced in theoretical models with different underlying assumptions. One scenario is incorporated in transport models where the particles have a mean free path comparable to the system size [14–16]. The models can describe the observed flow up to AGS energies. The other scenario applies when the mean free path is much smaller than the system size which allows the description of the equilibrated system in terms of macroscopic quantities [17,18]. Hydrodynamic models are able to describe the qualitative features of the observed flow [19] for p_T below about 3 GeV/c.

The initial asymmetry in the overlap zone of the colliding nuclei translates into unequal pressure gradients in different directions that leads to an elliptic final state momentum distribution of the particles [17], causing an elliptic pattern of flow. The elliptic flow is therefore expected to be sensitive to the system evolution at the time of maximum compression [20] and is shown to be sensitive to the equation of state of the compressed nuclear matter. The variation of asymmetry with centrality enables to relate the observed flow to the geometry of the overlap region [21,16]. One would then expect a scaling of the data from AGS to SPS and RHIC provided the physics of elliptic flow remains the same [22]. In the case that there is a phase transition from hadronic matter to a quark gluon plasma, it is expected that the reflection of this transition in the equation of state of the dense nuclear matter would result in changes in the pressure gradients which would then be reflected in changes in the particle flow pattern.

The first evidence of azimuthal anisotropy at SPS energies was observed in the distribution of photons from S+Au collisions at 200 $\cdot A$ GeV measured in the preshower photon multiplicity detector of the WA93 experiment at CERN [8]. Since almost 90% of photons produced in ultra-relativistic nuclear collisions originate from the decay of π^0's, the anisotropy of the observed photon distributions should reflect the anisotropy of the π^0 production followed by the effects of decay of the π^0's. Methods have been proposed to estimate the anisotropy of the neutral pion emission by measuring the anisotropy of photons [23]. The decay introduces non-flow correlations between the photon pairs due to four-momentum conservation and may dilute the correlations between the π^0's and the event plane. Determination of the effect of decay enables the deduction of the anisotropy of the neutral pions. The photon anisotropy measurement thus complements the study of the anisotropy of charged particle distributions.

In the present work we report results from the WA98 experiment on the centrality dependence of the anisotropy coefficients extracted from measurement of the azimuthal distributions with respect to the event plane of photons and charged particles in the same pseudorapidity interval. Preliminary results on the anisotropy of photon emission in Pb+Pb collisions have been reported earlier [24,25]. The paper is organized in the following manner: Sect. 2 describes the experimental setup and data selection. The analysis technique is discussed in Sect. 3. The results on the centrality dependence of the azimuthal anisotropy of charged particles and photons are discussed in Sect. 4 and Sect. 5 summarises our investigations.

2 WA98 experiment and data selection

The WA98 experiment at CERN [26] placed emphasis on simultaneous detection of hadrons and photons. The experimental setup consisted of large acceptance hadron and photon spectrometers, detectors for photon and charged particle multiplicity measurements, and calorimeters for transverse and forward energy measurements. The experiment recorded data with 158$\cdot A$ GeV Pb beams from the CERN SPS in 1994, 1995, and 1996. The results presented here are from a portion of the Pb run in 1996 during which the magnet (GOLIATH) was turned off. The analysis presented here used data recorded with the photon multiplicity detector (PMD) and the silicon pad multiplicity detector (SPMD). The data from the mid-rapidity calorimeter (MIRAC) was used to characterize events on the basis of centrality of the collision.

The circular Silicon Pad Multiplicity Detector (SPMD), used for measurement of the charged particle multiplicity, was located 32.8 cm from the target. It had full azimuthal coverage in the region $2.35 \leq \eta \leq 3.75$ (beam rapidity $y_{\rm beam} = 5.81$). The detector had four overlapping quadrants, each fabricated from a single 300 μm thick silicon wafer. The active area of each quadrant was divided into 1012 pads forming 46 azimuthal wedges and 22 radial bins with pad size increasing with radius to provide a uniform pseudo-rapidity coverage. The intrinsic efficiency of the detector was better than 99%. During the datataking, 95% of the pads worked properly. The SPMD was nearly transparent to high energy photons since only about 0.2% are expected to interact in the silicon. Multiple hits of charged particles on a single pad were treated as a single hit for the present analysis, and are counted as $N_{\rm hits}$. The detector is sensitive to all charged particles. The energy cutoff appears as a low noise threshold. Details of the characteristics of the SPMD can be found in [27,28].

The photon multiplicity was measured using the preshower photon multiplicity detector (PMD) located at a distance of 21.5 meters from the target. The detector consisted of 3 radiation length (X_0) thick lead converter plates placed in front of an array of square scintillator pads of four different sizes that varied from 15 mm×15 mm to 25 mm×25 mm, placed in 28 box modules. Each box module had a matrix of 38×50 pads which were read

out using one image intensifier + CCD camera. Details of the design and characteristics of the PMD may be found in [29,30].

The clusters of hit pads with a signal above a hadron rejection threshold were identified as photon-like. The present analysis has been performed with the photon-like clusters, which are referred to as photons for brevity. Detailed simulations showed that the photon counting efficiencies for the central to peripheral cases varied from 68% to 73%. The purity of the photon sample in the two cases varied from 65% to 54%. Most of the contaminants of the photon sample are charged particles which deposit enough energy to fall above the hadron rejection threshold. The hadron rejection threshold is taken as three times the energy deposited by a minimum ionizing particle. For photons this leads to a low p_T threshold of 30 MeV/c.

The transverse energy was measured with the MIRAC calorimeter [31] located at 24.7 meters downstream from the target. The MIRAC was used to measure the total transverse energy by measurement of both the transverse electromagnetic ($E_{\rm T}^{\rm em}$) and hadronic ($E_{\rm T}^{\rm had}$) energies in the pseudorapidity interval $3.5 \leq \eta \leq 5.5$. The measured total transverse energy, $E_{\rm T}$, provides a measure of the centrality of the reaction. Events with large $E_{\rm T}$ correspond to very central reactions with small impact parameter, and vice versa.

The minimum bias $E_{\rm T}$ distribution has been divided into different fractions of the minimum bias cross section corresponding to different centrality bins [30]. The most central selection corresponds to that 5% of the minimum bias cross section σ_{MB} with largest measured $E_{\rm T}$. A total of about 0.25 Million events have been analysed. The minimum number of events in any centrality selection is 15K and the maximum is 70K. Table 1 shows the percentage cross section and the corresponding number of participants for each centrality bin. The results presented here use only the data for the pseudorapidity region of common coverage of the PMD and SPMD ($3.25 \leq \eta \leq 3.75$) where both detectors have full azimuthal coverage. The average measured photon and charged particle multiplicities for this region of acceptance are also quoted for each centrality in Table 1.

3 Analysis

The anisotropy of the azimuthal distribution of particle emission with respect to the reaction plane (or event plane) is characterized by the coefficients of the Fourier expansion of the azimuthal distribution [32]. The first and the second coefficients are measures of the directed and elliptic flow when the expansion is made about the reaction plane, the plane defined by the beam direction and the impact parameter. This may be written as

$$\frac{2\pi dN}{d(\phi-\psi_R)} = 1 + 2v_1\cos(\phi-\psi_R) + 2v_2\cos 2(\phi-\psi_R) \quad (1)$$

where ϕ is the azimuthal angle of the measured particle and ψ_R denotes the azimuthal orientation of the reaction plane. The reaction plane can be most accurately determined in an experiment that measures the (transverse) momenta of the target or projectile fragments. Both v_1 and v_2 can take positive or negative values. By convention, positive (negative) values of v_1 in (1) denote flow (anti-flow) in the direction of the deflected projectile fragment, and positive (negative) values of v_2 indicate in-plane (out-of-plane) flow.

Though the most accurate determination of the reaction plane requires the measurement of target (or projectile) fragments, most experiments *assume* that the measurement of any particle type, in any kinematic window enables a determination of the reaction plane. We wish to distinguish between the plane determined by projectile or target fragments and the plane determined by any other particle type, and throughout this article refer to the latter as the *event plane*. Obtaining the values of coefficients after projecting azimuthal angles on the event plane determined from the same set (after removing auto correlations) maximises the values of anisotropy coefficients, and may include non-flow correlations. The values obtained are necessarily positive, and have been shown as such in the present work. The coefficients determined by projecting on an event plane from any other set of particles are expected to be smaller, and can also have negative values. The difference in the values determined using different sets of event planes have been included in systematic error by various experiments [10,11,13].

3.1 Method

In the present analysis, the azimuthal distributions of particles for any particle species in any pseudorapidity window is expanded as a Fourier series where the coefficients of expansion determine the shape of the event. Retaining terms up to second order coefficient in the expansion, the shape can be characterized by an ellipse for small values of

the coefficients. The direction of the centroid and the major axis of the ellipse are determined from the azimuthal distributions of the particles. These directions, along with the beam direction, define the first order and the second order event plane respectively, and are obtained as [32]

$$\psi'_m = \frac{1}{m}\left(\tan^{-1}\frac{\Sigma w_i \sin m\phi_i}{\Sigma w_i \cos m\phi_i}\right) \quad (2)$$

where $m = 1$ or 2 for the first and the second order, respectively. The ϕ_i are the azimuthal angles of the emitted particles with respect to a fixed laboratory direction and the w_i are the weight factors. For the azimuthal distribution of the particle yield, as in (1), the weight factors are set equal to one. In reality, due to finite particle multiplicities ψ'_1 and ψ'_2 fluctuate about the *actual* event planes that represent the direction of the centroid and the direction of the major axis of the elliptic shape. To the extent that initial state nuclear densities are spherically symmetric and the density fluctuations are negligible, the initial nucleon density in the overlap region is symmetric about the impact parameter or reaction plane and so it is expected that the two event plane angles are either the same or perpendicular to the reaction plane.

The anisotropy, or Fourier coefficients of order n, can be determined from the azimuthal distribution of the particles with respect to the event plane angle of order m, provided n is an integral multiple of m, by fitting to the following equation [32]

$$\frac{dN}{d(\phi - \psi'_m)} \propto 1 + \textstyle\sum_{n=1}^{\infty} 2v'_{nm}\cos nm(\phi - \psi'_m) \quad (3)$$

v'_{nm} is a measure of the offset of the centroid of the distribution when $n \cdot m = 1$ and is a measure of the difference between the major and the minor axes of the ellipse when $n \cdot m = 2$. The actual coefficients are obtained from the observed coefficients v'_{nm} as described later.

Since the event planes do not depend on the geometrical setup of the experiment, the distribution of the event plane angles determined for a large number of events is expected to be uniformly distributed in laboratory angle. Any non-uniformity in the acceptance of the detectors over the full azimuth will be reflected in a non-uniform distribution of event plane angles. Any non-uniformity that is identifiable within a large subset of events can be corrected for by appropriate correction methods. The method employed in the present work is summarized in the following.

3.2 Detector acceptance correction

The corrected event plane angle is obtained by shifting the observed event plane angles ψ'_m by $\Delta\psi'_m$ [32] where the latter is written as

$$\Delta\psi'_m = \sum_{n=1}^{N}\frac{2}{nm}(-\langle\sin(nm\ \psi'_m)\rangle\cos(nm\ \psi'_m) + \langle\cos(nm\ \psi'_m)\rangle\sin(nm\ \psi'_m)) \quad (4)$$

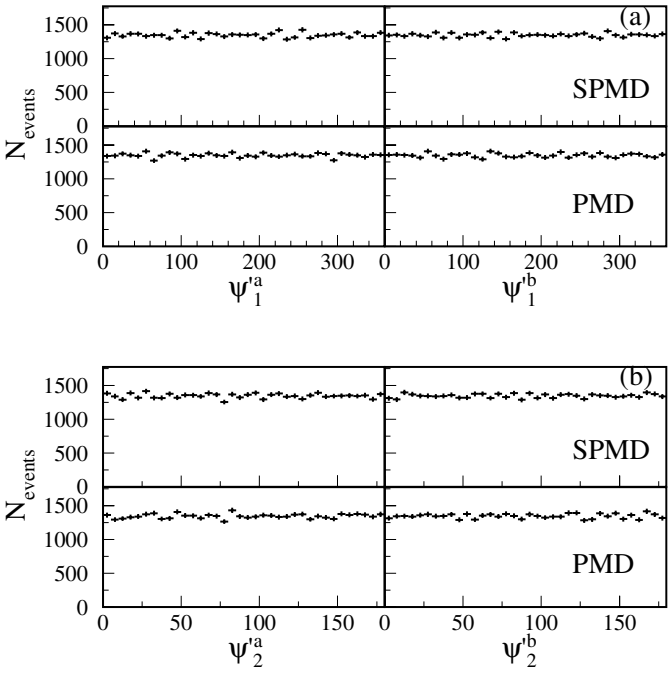

Fig. 1. Acceptance corrected distributions of **a** the first order event plane angle, ψ'_1, of the two subevents for the charged particles hits in the SPMD and the photons in the PMD in the region $3.25 \leq \eta \leq 3.75$ for the centrality class defined by 225.5 $\leq E_T \leq$ 298.6. **b** The same for second order event plane angle, ψ'_2

where $N = 4/m$ is sufficient to flatten the raw ψ distribution. The angular brackets denote an average over all events and are obtained from the raw distribution of the m^{th} order event plane distribution.

The distribution of the first and the second order event plane angles, corrected for acceptance, is shown in Fig. 1 for the charged particle hits in the SPMD and the photon hits in the PMD.

3.3 Event plane resolution correction

The average deviation of the estimated event plane from the true event plane due to multiplicity fluctuations can be determined experimentally and is termed as the resolution correction factor (RCF). Experimentally, RCF is obtained using the subevent method described in [32]. The particles in each event are sorted in ascending order of pseudorapidity. Each event is divided into two equal multiplicity subevents separated by a pseudorapidity interval. The two subevents are separated by one pad for the SPMD and by $\Delta\eta = 0.05$ for the PMD. The actual location of the pad in SPMD and the $\Delta\eta$ interval in PMD is allowed to vary in the region 3.25 to 3.75 to ensure equal multiplicity for the two subevents. The event plane angle ψ'_m is determined for each subevent.[1]

[1] The distribution of the corrected event plane angles for these subevents is observed to be flat, for both orders, for photons and for charged particles.

This enables determination of a parameter χ_m directly from the experimental data using the fraction of events where the correlation of the planes of the subevents is greater than $\pi/2$ [32,33]:

$$\frac{N_{\rm events}(m|\psi'^a_m - \psi'^b_m| > \pi/2)}{N_{\rm total}} = \frac{{\rm e}^{-\frac{\chi^2_m}{4}}}{2} \quad (5)$$

where $N_{\rm total}$ denotes the total number of events, ψ'^a_m, ψ'^b_m are the observed event plane angles of the two subevents (labeled a and b) and the numerator on the left denotes the number of events having the angle between subevents greater than $\pi/2m$. The parameter χ_m so obtained is then used to determine ${\rm RCF}_{nm} = \langle\cos(nm(\psi'_m - \psi^{true}_m))\rangle$, where ψ^{true}_m is the true direction of the event plane, and the average is over all events. The RCF can be determined from χ_m by the following relation from reference [32].

$$\langle\cos(nm(\psi'_m - \psi^{true}_m))\rangle = \frac{\sqrt{\pi}}{2\sqrt{2}}\chi_m \exp(-\chi^2_m/4) \cdot \left[I_{\frac{n-1}{2}}(\chi^2_m/4) + I_{\frac{n+1}{2}}(\chi^2_m/4)\right] \quad (6)$$

where $\rm I_\nu$ are the modified Bessel functions of order ν.

The errors on the RCF values have been obtained by considering that the error on $N_{\rm events}$ is statistical. The new values of χ_m are then calculated for values of $N_{\rm events} \pm \sqrt{N_{\rm events}}$ and used in (6) to calculate new values of RCF. The change in the RCF values gives the statistical error on the RCF determination. In general, the errors determined in this way are asymmetric. Symmetric errors have been quoted using the larger of the two asymmetric errors.

3.4 Anisotropy coefficients

The anisotropy coefficients are obtained by filling up particle azimuthal distributions of one subevent with respect to the event plane of the other subevent where the subevent division is described in the previous section. The anisotropy coefficients have been determined by three methods which differ in detail and provide a consistency check. In this analysis the Fourier coefficients prior to event plane resolution correction v'_{nm} are extracted for the case with event plane order equal to the order of the extracted Fourier coefficient, i.e. $v'_{nm} = v'_{nn}$ which we will denote by v'_n.

In the first method we determine $v'^a_n = \langle\cos n(\phi^a - \psi'^b_n)\rangle$ and $v'^b_n = \langle\cos n(\phi^b - \psi'^a_n)\rangle$ where ϕ^a represent the azimuthal angles of particles in subevent a and ψ'^b_n is the event plane angle determined using particles in subevent b. The averages are computed over all particles over all events. In the absence of non-flow correlations, v_n can be determined using

$$v_n = \sqrt{\frac{v'^a_n \cdot v'^b_n}{\langle\cos n(\psi'^a_n - \psi'^b_n)\rangle}} \quad (7)$$

This determines the magnitude of the coefficients and is necessarily positive.

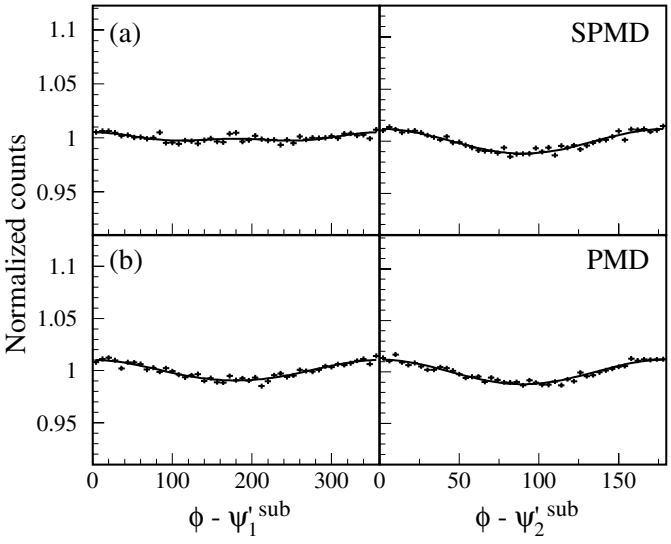

Fig. 2. Distributions of azimuthal angles with respect to the first and second order event plane for the centrality class defined by $225.5 \leq {\rm E}_T \leq 298.6$. **a** for charged particle hits in the SPMD and **b** for photons in the PMD, both in the pseudorapidity region $3.25 \leq \eta \leq 3.75$

The distributions with respect to the event plane are shown in Fig. 2 for both photon and charged particles, for both orders for the centrality selection corresponding to 10–20% of the cross section. In the second method the distributions have been fitted to (3) to determine v'_{11}. The corresponding distributions with respect to the second order event plane are shown in Fig. 2 and have been fitted to (3) to determine v'_{22}. For both orders, the fits have been made keeping terms up to values of $n \cdot m = 2$ in the summation in (3).

The v'_{nm} are the values determined with respect to the estimated event plane and must be corrected for the event plane resolution [32] to obtain the actual anisotropy values

$$v_{nm} = \frac{\sqrt{2} \cdot v'_{nm}}{RCF_{nm}} \quad (8)$$

The factor $\sqrt{2}$ arises because the particle distributions have been obtained with respect to the event plane of a subevent with half of the total event multiplicity. The subevent resolution, $\sqrt{\langle\cos(nm(\psi^a_n - \psi^b_n))\rangle}$, is averaged over all events and is in good agreement with ${\rm RCF}_{nm}/\sqrt{2}$.

In the third method, the values v_{nn} have been obtained directly by the subevent method from χ_m of (5) and the fluctuation in the average multiplicity M of the full events in that centrality bin.

$$v_{nn} = \frac{\chi_n}{\sqrt{2M}} \quad (9)$$

The different methods yield consistent results for both the first order and the second order anisotropy coefficients and the difference in the values is included in the systematic error. The equivalence of the first two methods arises due to the equivalence of the geometric mean (method

1) and the arithmetic mean (method 2) of the resolution uncorrected values v'_n of the two subevents and due to the $1/\sqrt{M}$ dependence of the fluctuation in event plane determination. The latter contributes to the equivalence of the third method with the first two. The three methods may yield different values in the presence of non-flow correlations where the differences will be governed by the nature and strength of these correlations. The most probable values are determined using method 1 above. The following sections discuss the systematic effects that distort the measured anisotropies and the centrality dependence of the anisotropies for charged particles and for photons.

4 Anisotropy in charged particles

The measured anisotropy is expected to be less than the actual anisotropy due to the finite granularity of the detector. The measured values of anisotropy may also be affected by the imprecision in the vertex position due to the finite spread of the beam. These effects are particularly relevant for the charged particle distribution measurement due to the relatively coarse segmentation and close proximity to the target of the SPMD detector. The effects are estimated using simulations.

4.1 Granularity

The finite granularity of the SPMD detector causes a dilution of the anisotropy of the azimuthal distribution primarily due to efficiency losses from multiple hits. The quantitative effect of the finite granularity on the measured anisotropy has been estimated and is briefly discussed in the following. This has been corroborated by simulations and is described in greater detail in [34].

Defining the mean occupancy as the ratio of the number of particles incident on the detector to the number of active cells

$$\mu = \frac{N_{\rm part}}{N_{\rm cell}} \tag{10}$$

one can show that

$$\mu = \ln\left(1 + \frac{N_{\rm occ}}{N_{\rm unocc}}\right) \tag{11}$$

where $N_{\rm occ}$ and $N_{\rm unocc}$ are the number of occupied and unoccupied cells [35]. One can further show that

$$\frac{N_{\rm hit}}{N_{\rm part}} = \frac{1 - {\rm e}^{-\mu}}{\mu} \tag{12}$$

where $N_{\rm hit}$ is the number of ocupied cells.

Since the intrinsic occupancy of cells increases with the increase in the number of incident particles, the occupancy will have the same azimuthal dependence as the incident particles. Substituting this for the occupancy in (12) gives us the azimuthal dependence of the hits. Expressing the resulting equation as a Fourier series and collecting coefficients of $\cos n\phi$ enables a determination of the ratio $v_n^{\rm hits}/v_n$, which to first order can be approximated by

$$\frac{v_n^{\rm hits}}{v_n} = -\frac{1-x}{x} \cdot \ln(1-x) \tag{13}$$

where $x = \frac{N_{\rm hit}}{N_{\rm cell}}$ $(= \frac{N_{\rm occ}}{N_{\rm cell}})$.

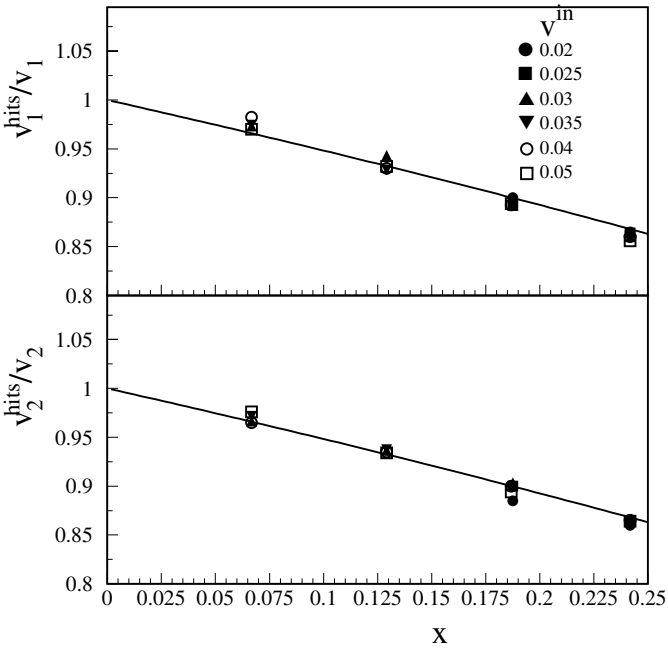

Fig. 3. The ratio $v_n^{\rm hits}/v_n$ for different number of occupied cells. x is the number of occupied cells scaled with the total number of cells. Different symbols correspond to different initial values of v_n. The solid line represents (13)

The anisotropy in the distribution of charged particles can be obtained using the measured value of anisotropy in the distribution of hits.

The azimuthal distributions of the charged particles were generated with different initial anisotropies with multiplicities corresponding to the measured results. The charged particle hits were sorted into the SPMD bins (2° ϕ-bin) assuming a 94% detection efficiency but taking into account hit losses due to multiple hits in a single SPMD pad. The resulting azimuthal distributions were then analyzed to determine the anisotropy coefficients using the method detailed in Sec 3.4 above. Figure 3 shows the results of the simulation for both orders, where the ratio of the estimated anisotropy from the hit distribution to the initial anisotropy is shown for varying hit multiplicities, far beyond the range of measured values in the SPMD. This is done for different values of initial anisotropy. The correction factor as given by (13) is shown as a solid line in the figure. One observes that the simulation results corroborate the results obtained above. The simulation results show that the extracted anisotropy is systematically lower than the initial anisotropy. Part of this loss occurs directly due to efficiency losses from multiple hits, and contributes both to the anisotropy and the event plane resolution.

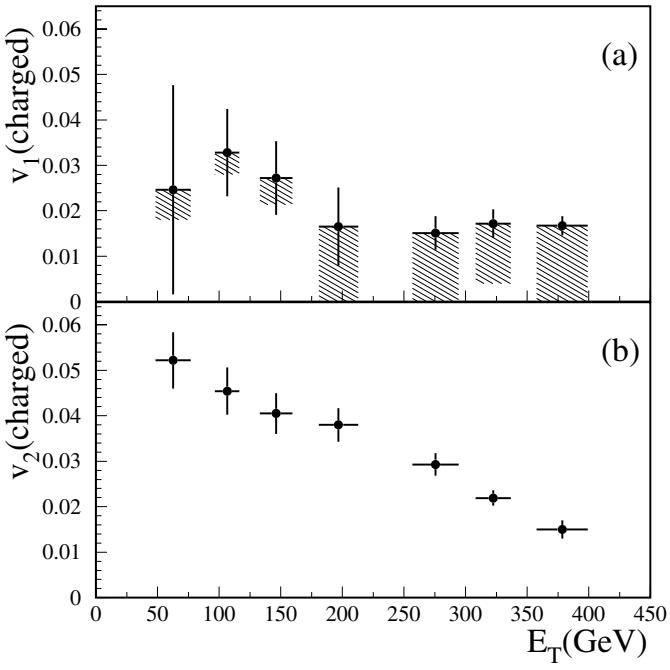

Fig. 4. Anisotropy coefficients of the azimuthal distributions of charged particles in the pseudorapidity region $3.25 \leq \eta \leq 3.75$ for different centralities characterised by the measured transverse energy. **a** First order, v_1, where the shaded region indicates the extent of the total systematic error due to uncertainty in the vertex position. **b** Second order, v_2

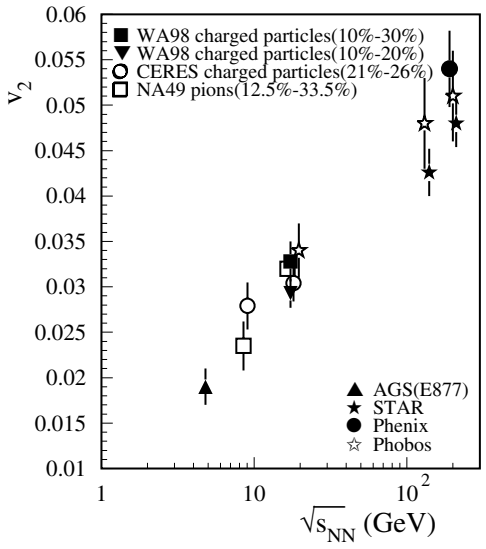

Fig. 5. Second order coefficient for different centre of mass energies. The results of the present work are for charged particles and are shown for two different centrality classes. The ordinates of CERES, NA49, STAR and PHENIX results have been shifted slightly for clarity. The error bars on WA98 points indicate the statistical and systematical errors added in quadrature. E877, STAR, PHENIX and PHOBOS v_2 values are for charged particles. The centrality cuts for all experiments are comparable

4.2 Shift in vertex and beam spread

The finite beam size caused an imprecision in the assumed vertex by up to one mm in the WA98 experiment. A small shift in the vertex position does not affect the azimuthal distribution in the fine granularity PMD, situated at 21.5 meters from the vertex. However, it can produce an apparent anisotropy in the hit distribution in the SPMD situated at 0.328 meters from the target.

The effect of vertex shifts due to the beam spread was also investigated by simulation. The vertex position was generated according to a two dimensional Gaussian with width σ. Particles were simulated to originate from this vertex position with a realistic η and p_T distribution and an azimuthally symmetric ϕ distribution. The particles were projected onto the SPMD plane, and their hit positions recorded according to the granularity and nominal location of the SPMD detector. The recorded positions corresponded to values of η and ϕ which differed from the generated values due to the shifted position of the vertex. The simulated distributions were then analyzed in the same manner as the experimental data. This was repeated for different values of σ and the values of v_n were obtained for each sample generated. The maximum possible shift has been deduced by assuming an azimuthally symmetric distribution for the most central class, and assigning the granularity corrected observed value for first order anisotropy to the shift in vertex. This corresponded to a maximum width of the Gaussian distribution due to beam spread of 0.3 mm.

A shift in the vertex position due to beam spread, or time variation during the 2.5 s SPS spill, produces an azimuthal distribution which has a shifted centroid. If the shift occurs on an event-by-event basis it cannot be corrected for by the acceptance correction methods discussed above, since they can only correct for average effects. To investigate the possibility of systematic shifts correlated with time during the SPS spill, the SPMD charged particle azimuthal distributions were analyzed for different times during the spill. No significant variations with time during the spill were observed.

The second order anisotropy is obtained from the fit to the elliptical shape of the measured hit distribution. A vertex shift does not affect the elliptical shape, as verified by simulations.

4.3 Results

The finite granularity requires a correction which is obtained using the measured values of v_n from the hit distributions and using (13). The corrected results are shown for both orders of anisotropy in Fig. 4. The error bars shown are statistical. The results for the first order anisotropy include contributions from a possible vertex shift. The upper and the lower limit of the boxes shown in Fig 4a show the asymmetric systematic error and correspond to no uncertainty and a maximum uncertainty in the position of the vertex, as discussed above.

Figure 5 shows v_2 as a function of centre of mass energy from various experiments (results mostly taken from com-

pilation of [36]). These have been measured in different experiments in different kinematic ranges using methods that vary in detail. The general behaviour shows a continuous increase in v_2 as a function of centre of mass energy. The results of the present work are shown for two different centrality ranges corresponding to 10–20% of cross section and 10-30% of cross section. For comparison to the present results, values of v_2 from PHOBOS, NA49 and CERES experiments [35–37] at nearly the same centre of mass energy are included. The various measurements are seen to agree well within errors.

5 Anisotropy in photons

The photons incident on the PMD predominantly result from the two photon decay of the neutral pion, and if both photons are detected in the PMD an additional apparent anisotropy will result from the kinematic correlation between the photons. The limited efficiency and purity of the detected photon sample in the PMD affect the measured photon anisotropy values. The quantitative effect is estimated using simulations and is described in the following.

5.1 Decay effect

The decay of neutral pions into two photons introduces correlations that can cause apparent anisotropies in the photon distributions which are greater than the actual anisotropy of the pions. On the other hand, the process of decay smears the photon momenta relative to the initial pion momenta and can thereby dilute the initial correlation present in the neutral pions. The relative importance of these two competing effects has been shown to scale with the experimentally measured quantity χ_m and enables a determination of the neutral pion anisotropy from the measured photon anisotropy [23]. However, the limited efficiency and the contamination of charged particles in the sample preclude a determination of the π^0 anisotropy from the measured γ anisotropy in the present work. Using the anisotropy values of the charged particles folded with the π^0 decay and experimental response allows one to determine the expected values of anisotropy of the photons in the PMD, as discussed below.

5.2 Efficiency and contamination

The PMD records particle hits which include incident photons and a contamination of charged particle hits. These charged particles could be primary, or secondary rescattered particles. As noted above, the photon counting efficiency (e) of the sample varies from 68% to 73% for central and peripheral events and the corresponding purity (p) of the sample varies from 65% to 54%.

The effect of decay, identification efficiency, and contamination on the observed photon anisotropy has been estimated using simulations. The simulations assume that the photon sample contains a contribution from charged particle contamination which directly reflects the measured charged particle anisotropy in addition to a contribution from photons from π^0 decays with a π^0 anisotropy which is also equal to the measured charged particle anisotropy. These simulations use the anisotropy values of the charged particles, π^0 decay kinematics, the PMD acceptance, and the purity of the PMD photon sample to generate simulated data. The simulated sample is analyzed to obtain an estimate of the expected photon anisotropy corresponding to the observed charged particle anisotropy.

The neutral pions were generated using the experimental pseudorapidity distribution of the charged pions [38] with an exponential p_T distribution ($dN/dp_T = p_T \cdot \exp(-6p_T)$). The π^0 multiplicity values were chosen as half of those measured for charged particles with the SPMD for the same centrality selection. The second order anisotropy values of π^0 were chosen to be linearly increasing with p_T before saturating at $p_T \sim 1.5$ GeV/c. For each centrality, the p_T dependence was chosen to reproduce the p_T integrated mean values of v_n of charged particles shown in Fig. 4. The linear dependence and the value of p_T at saturation were both varied to estimate the systematic errors. Neutral pions were generated and decayed and the decay photons were accepted if within the PMD acceptance. Using the measured photon multiplicity for a given centrality class, $p \cdot N_{photons}$ photons were randomly selected from those falling onto the PMD, where p was assigned a value of 0.65 to 0.54 corresponding to the centrality selection being simulated. A background contribution of $(1-p) \cdot N_{photons}$ charged particles was added to the simulated event. This simulated data was then analyzed using the methods detailed in Sect. 3.4.

The systematic errors in the simulated results have been estimated for both orders of anisotropy for each centrality. The contribution to the systematic error on the simulated results are shown for one particular centrality selection (20%–30% of minimum bias cross section) in Table 2.

The relation between the neutral pion anisotropy and photon anisotropy is not linear [23]. v_n^{PMD} has been estimated for a range of pion anisotropy values corresponding to the error measured in this experiment. An increase

Table 2. Contribution to systematic error from various sources for the simulated values of both orders of anisotropy of the $N_{photons}$ distributions for the centrality selection corresponding to 20–30% of minimum bias cross section

Source	First order	Second order
Charged particle anisotropy	+0.005	+0.002
	−0.004	−0.003
Purity of photon sample	±0.002	±0.001
Anisotropy of contaminants	−0.004	−0.007
η and p_T distribution of π^0	± 0.001	± 0.001
Neutral pion multiplicity	± 0.002	± 0.001

(decrease) in the charged particle anisotropy increases (decreases) the anisotropy in the simulated results of $v_n^{\rm PMD}$ for all centralities. The percentage change in $v_n^{\rm PMD}$ corresponding to a 10% change in the purity of photon sample is small and is about the same for all centralities. If 50% of the contaminants are assumed to be isotropic, then the resulting anisotropy decreases for all centralities, and contributes maximumally to the total systematic error. The uncertainty in the neutral pion multiplicity also has a small effect, which is almost independent of centrality.

The systematic error on the measured values of $v_n^{\rm PMD}$ have been obtained by

- increasing and decreasing the region of acceptance for the analysis
- varying the size of the interval $\Delta\eta$ between the two subevents in the range 0.03 to 0.07.
- randomly removing up to 20% of the photons in the PMD.
- obtaining the $v_n^{\rm PMD}$ values by the correlation between the subevents as described in Sect. 3.4 above.

Repeating the analysis by rejecting clusters closer than twice the size of the scintillator pads did not change the $v_n^{\rm PMD}$ values.

5.3 Results

The measured values of $v_n^{\rm PMD}$ are shown in Fig. 6. The errors on $v_n^{\rm PMD}$ are obtained by adding the systematic and the statistical error in quadrature and are also shown. The open triangles show the expected values of $v_n^{\rm PMD}$ from the simulations described above. The statistical and systematic errors are added in quadrature and are shown by the shaded regions. The photon anisotropy coefficients extracted from the simulated PMD data are consistent within errors with the measured PMD result. This demonstrates that the photon anisotropy results measured with the PMD are consistent with the charged particle results presented in Sect. 4. Note, however, that the results shown in Fig. 6 include π^0 decay and charged particle contamination effects, and should not be compared directly with other results. In particular, the use of the PMD photons themselves to determine the event plane gives a strong π^0 decay effect. This is shown by the open circles in Fig. 6 which show the simulation values of $v_n^{\rm PMD}$ for the assumption of isotropic π^0 emission, $v_n(\pi) = 0$. It is seen that the first order photon anisotropy results are dominated by the π^0 decay effect while the second order photon anisotropy results also have a significant decay contribution, which cannot simply be subtracted from the measured $v_2^{\rm PMD}$. Since the relationship between v_γ and v_{π^0} depends in a non-trivial way on the π^0 (p_T dependent) multiplicity and anisotropy [23,39] it is non-trivial to extract the π^0 anisotropy from the photon anisotropy measured with respect to the event plane determined using photons. It should be noted that the WA98 photon v_n results measured with the LEDA photon detector covering the photon rapidity region $2.3 \leq y \leq 2.9$ [39] were obtained with respect to an event plane determined in the target fragmentation region. The $v_n^{\rm PMD}$ measured using the PMD photons and

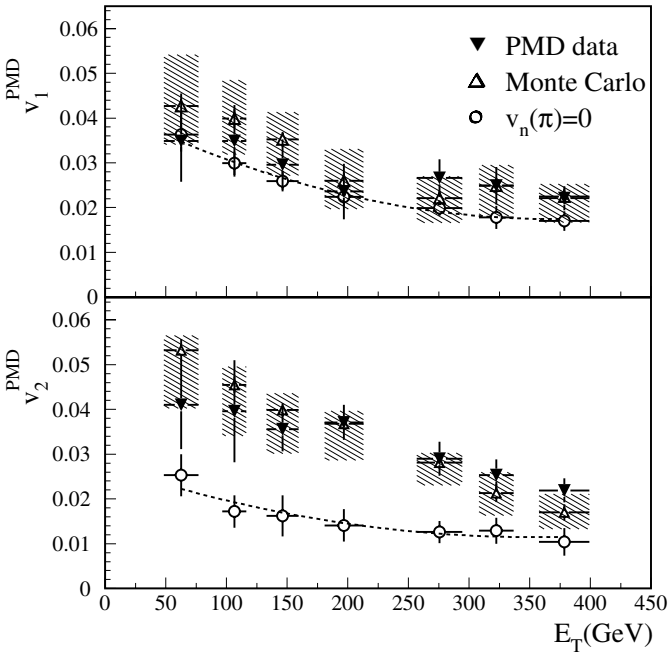

Fig. 6. a First order, $v_1^{\rm PMD}$, and **b** second order, $v_2^{\rm PMD}$, photon anisotropy coefficients in the pseudorapidity region $3.25 \leq \eta \leq 3.75$ for different centralities are shown by filled triangles. Statistical and systematical errors are added in quadrature and shown as bars on the filled triangles. Open triangles are the most probable values of $v_n^{\rm PMD}$ as expected from the simulation. The shaded regions indicate the simulation uncertainties as described in Sect. 5.4. The open circles show the calculated values of $v_n^{\rm PMD}(v_n(\pi) = 0)$ assuming an isotropic distribution of pions with the dashed curve indicating a smooth polynomial fit to the open points. Note, however, that $v_n^{\rm PMD}(v_n(\pi) = 0)$ can not be directly subtracted from the $v_n^{\rm PMD}(v_n(\pi) > 0)$ to obtain the anisotropy flow coefficents v_n, as explained in the text

v_n measured using the LEDA photons will therefore have different sensitivity to the π^0 decay effect. The PMD results include effect of decay correlations, and therefore the current measurement, $v_n^{\rm PMD}$, provides upper limits on the anisotropic flow coefficients v_n.

6 Summary

The azimuthal angle distributions with respect to the event plane have been measured for charged particles and photons with full azimuthal coverage in the pseudorapidity region of $3.25 \leq \eta \leq 3.75$ for ^{208}Pb + ^{208}Pb collisions at 158 $\cdot A$ GeV/c. A total of 0.25 million events, classified in seven centrality selections, have been used in the analysis. The Fourier coefficients of the azimuthal distributions have been extracted in several ways, all giving consistent results for the first order v_1 (directed) and v_2 second order (elliptic) anisotropies for photons and charged particles. The results show the expected trend of decreasing anisotropy with increasing centrality for both v_1 and v_2 for charged particles and photons. Our results agree with the

results reported by other experiments for near similar conditions. [35–37,39]. The observed anisotropies of the photon distributions compare well with those obtained from simulations that include the charged particle contamination and the correlations arising due to the decay of the neutral pions assumed to have the same anisotropies as measured for charged particles.

Acknowledgements. We wish to express our gratitude to the CERN accelerator division for the excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians, and support staff who have participated in the construction of this experiment.

This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR and FRN, the Dutch Stichting FOM, the Polish KBN under Contract No. 621/E-78/SPUB-M/CERN/P-03/DZ211/, the Grant Agency of the Czech Republic under contract No. 202/95/0217, the Department of Atomic Energy, the Department of Science and Technology, the Council of Scientific and Industrial Research and the University Grants Commission of the Government of India, the Indo-FRG Exchange Program, the PPE division of CERN, the Swiss National Fund, the INTAS under Contract INTAS-97-0158, ORISE, Grant-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science and Culture, the University of Tsukuba Special Research Projects, and the JSPS Research Fellowships for Young Scientists. ORNL is managed by UT-Battelle, LLC, for the U.S. Department of Energy under contract DE-AC05-00OR22725. The MIT group has been supported by the US Dept. of Energy under the cooperative agreement DE-FC02-94ER40818.

(Received 1 June 2004; published 1 April 2005)

The production of deuterons and antideuterons in the transverse momentum range $1.1 < p_T < 4.3$ GeV/c at midrapidity in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV has been studied by the PHENIX experiment at RHIC. A coalescence analysis, comparing the deuteron and antideuteron spectra with that of proton and antiproton, has been performed. The coalescence probability is equal for both deuterons and antideuterons and it increases as a function of p_T, which is consistent with an expanding collision zone. Comparing (anti)proton yields, $\overline{p}/p = 0.73 \pm 0.01$, with (anti)deuteron yields, $\overline{d}/d = 0.47 \pm 0.03$, we estimate that $\bar{n}/n = 0.64 \pm 0.04$. The nucleon phase space density is estimated from the coalescence measurement.

Ultrarelativistic heavy-ion collisions are used to study the behavior of nuclear matter at extreme conditions of temperature and density, similar to those that existed in the universe a few microseconds after the Big Bang. Previous measurements indicate that high particle multiplicities [1] and large $\bar{p}/p$ ratios prevail at the Relativistic Heavy-Ion Collider (RHIC), which is expected for a nearly net baryon-free region [2]. As the hot, dense system of particles cools, it expands and the mean-free path increases until the particles cease interacting (''freeze-out''). At this point, light nuclei such as deuterons and antideuterons (d and $\bar{d}$) can be formed, with a probability proportional to the product of the phase space densities of its constituent nucleons [3,4]. Thus, the invariant yield of deuterons, compared to the protons [5,6] from which they coalesce, provides information about the size of the emitting system and its space-time evolution.

PHENIX [7] at RHIC is a versatile detector designed to study the production of leptons, photons, and hadrons over a wide momentum range. In this Letter, results on d and $\bar{d}$ production in Au + Au interactions at $\sqrt{s_{NN}} = 200$ GeV are presented. For the sake of brevity, in the rest of this Letter, our statements will generally apply to both particles and antiparticles.

The east central tracking spectrometer in the PHENIX detector [5,7,8] is used in this analysis. The information from the PHENIX beam-beam counters (BBCs) and zero-degree calorimeters (ZDCs) is used for triggering and event selection. The BBCs are Čerenkov counters surrounding the beam pipe in the pseudorapidity interval $3.0 < |\eta| < 3.9$, and provide the start timing signal. The ZDCs are hadronic calorimeters 18 m downstream of the interaction region and detect spectator neutrons in a narrow forward cone. Particle identification in the central rapidity region is achieved by measuring momentum (by drift chamber) and time of flight (by time-of-flight detector). The drift chamber (DC) and two layers of pad chambers are used for tracking and momentum reconstruction [8]. The time-of-flight (TOF) detector spans the pseudorapidity range $|\eta| < 0.35$ and $\Delta\phi = \pi/4$ azimuthally. The TOF consists of plastic scintillators, with a combined time resolution of ≈115 ps. The TOF thus provides identification of d and $\bar{d}$ in the transverse momentum (p_T) range $1.1 < p_T < 4.3$ GeV/c. For $p_T < 1.1$ GeV/c, the signal-to-background ratio suffers due to multiple scattering and energy loss effects.

The data set for this analysis includes 21.6×10^6 minimum bias events. The minimum bias cross section corresponds to $92.2^{+2.5}_{-3}\%$ of the total inelastic Au + Au cross section (6.9 b) [9]. Using the momentum determined by the DC, which has a resolution of $\delta p/p \approx 0.7\% \oplus 1\% p$ GeV/c, and the time of flight from the event vertex provided by the TOF, the mass of the particle is determined. The d and $\bar{d}$ yields are obtained by fitting the mass squared distributions to the sum of a Gaussian signal and an exponential background. Examples of mass squared distributions with fits for antideuterons in minimum bias collisions are shown in Fig. 1.

The raw yields are corrected for effects of detector acceptance, reconstruction efficiency, and detector occupancy. Corrections are determined by reconstructing single deuterons simulated using GEANT [10] and a detector response model of PHENIX, using the method described in [6]. The track reconstruction efficiency decreases in high multiplicity events because of high detector occupancy. This effect can be slightly larger for slower, heavier particles, due to detector dead times between successive hits. Occupancy effects on reconstruction efficiency (≈83.5% for 0%–20% most central events) are evaluated by embedding simulated single particle Monte Carlo (MC) events in real events. Since the hadronic interactions of nuclei are not treated by GEANT, a correction needs to be applied to account for the hadronic absorption of d and $\bar{d}$ (including annihilation). The d- and the $\bar{d}$-nucleus cross sections are calculated from parametrizations of the nucleon and antinucleon cross sections:

$$\sigma_{d/\bar{d},A} = \left[\sqrt{\sigma_{N/\bar{N},A}} + \Delta_d\right]^2. \quad (1)$$

The limited data available on deuteron induced interactions [11] indicate that the term Δ_d is independent of the nuclear mass number A and that $\Delta_d = 3.51 \pm 0.25$ mb$^{1/2}$. The hadronic absorption varies only slightly over the applicable p_T range and is ≈ 10% for d and ≈ 15% for $\bar{d}$. The background contribution from deuterons knocked out due to the interaction of the produced particles with the beam pipe is estimated using simulations and is found to be negligible in the momentum range of our measurement.

Figure 2 shows the corrected d and $\bar{d}$ invariant yields as a function of transverse mass [m_T in the range $1.1 < p_T < 4.3$ GeV/c, for minimum bias events, and two centrality bins: 0%–20% (most central) and 20%–92% (noncen-

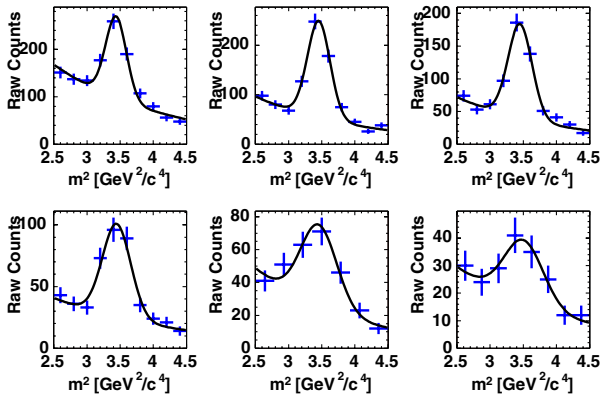

FIG. 1 (color online). Histograms of the mass squared for identified antideuterons in the transverse momentum range $1.1 < p_T < 3.5$ GeV/c (in 400 MeV/c increments), with Gaussian fits including an exponential background.

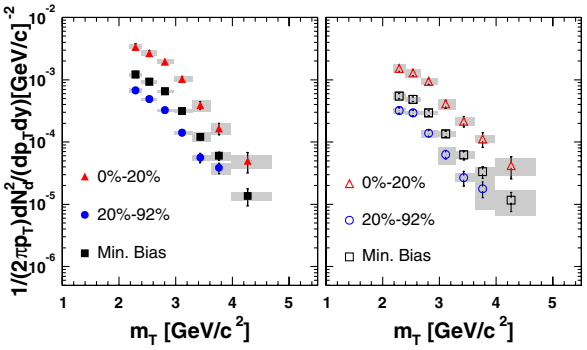

FIG. 2 (color online). Corrected spectra for deuterons (left panel) and antideuterons (right panel) for different centralities are plotted vs m_T. Error bars indicate statistical errors and gray bands the systematic errors. Values are plotted at the "true" mean value of m_T of each bin, the extent of which is indicated by the width of the gray bars along the x axis.

tral)]. The 20%–92% centrality bin is dominated by mid-central events, due to larger track multiplicities relative to peripheral events.

Systematic uncertainties have several sources: errors in particle identification, DC-TOF hit match efficiency, the uncertainty in momentum scale, d and $\bar{d}$ hadronic interaction correction, and uncertainty in occupancy corrections. All the systematic uncertainties are added in quadrature, depicted by the gray bars in Fig. 2.

The p_T spectra Ed^3N/d^3p are fitted in the range $1.1 < p_T < 3.5$ GeV/c to an exponential distribution in $m_T = \sqrt{p_T^2 + m^2}$. The inverse slopes ($T_{\rm eff}$) of the spectra are tabulated in Table I. The deuteron inverse slopes of $T_{\rm eff} =$ 500–520 MeV are considerably higher than the $T_{\rm eff} =$ 300–350 MeV observed for protons [5,6]. The invariant yields and the average transverse momenta ($\langle p_T \rangle$) are obtained by summing the data over p_T and using a Boltzmann distribution, $\frac{d^2N}{2\pi m_T dm_T dy} \propto m_T e^{-m_T/T_{\rm eff}}$, to extrapolate to low m_T regions where we have no data. The extrapolated yields constitute $\approx 42\%$ of our total yields. The rapidity distributions, dN/dy, and the mean transverse momenta, $\langle p_T \rangle$, are compiled in Table I for three different centrality bins. Systematic uncertainties in dN/dy and $\langle p_T \rangle$ are estimated by using an exponential in p_T and a "truncated" Boltzmann distribution (assumed flat for $p_T < 1.1$ GeV/c) for alternative extrapolations.

TABLE I. The inverse slope parameter $T_{\rm eff}$ obtained from a m_T exponential fit to the spectra along with multiplicity dN/dy and mean transverse momentum $\langle p_T \rangle$ obtained from a Boltzmann distribution for different centralities.

$T_{\rm eff}$ [MeV]	Deuterons	Antideuterons
Minimum bias	519 ± 27	512 ± 32
0%–20%	536 ± 32	562 ± 51
20%–92%	475 ± 29	456 ± 35
dN/dy		
Minimum bias	$0.0250 \pm ^{0.0006(\rm stat)}_{0.005(\rm syst)}$	$0.0117 \pm ^{0.0003(\rm stat)}_{0.002(\rm syst)}$
0%–20%	$0.0727 \pm ^{0.0022(\rm stat)}_{0.0141(\rm syst)}$	$0.0336 \pm ^{0.0013(\rm stat)}_{0.0057(\rm syst)}$
20%–92%	$0.0133 \pm ^{0.0004(\rm stat)}_{0.0029(\rm syst)}$	$0.0066 \pm ^{0.0002(\rm stat)}_{0.0015(\rm syst)}$
$\langle p_T \rangle$ [GeV/c]		
Minimum bias	$1.54 \pm ^{0.04(\rm stat)}_{0.13(\rm syst)}$	$1.52 \pm ^{0.05(\rm stat)}_{0.12(\rm syst)}$
0%–20%	$1.58 \pm ^{0.05(\rm stat)}_{0.13(\rm syst)}$	$1.62 \pm ^{0.07(\rm stat)}_{0.1(\rm syst)}$
20%–92%	$1.45 \pm ^{0.05(\rm stat)}_{0.15(\rm syst)}$	$1.41 \pm ^{0.06(\rm stat)}_{0.15(\rm syst)}$

With a binding energy of 2.24 MeV, the deuteron is a very loosely bound state. Thus, the observed deuterons can be formed only at a later stage in the collision. The proton and neutron must be close in space and tightly correlated in velocity to coalesce. As a result, d and $\bar{d}$ yields are a sensitive measure of correlations in phase space at freeze-out and can provide information about the space-time evolution of the system. If deuterons are formed by coalescence of protons and neutrons, the invariant deuteron yield can be related [12] to the primordial nucleon yields by

$$E_d \frac{d^3N_d}{d^3p_d}\Big|_{p_d=2p_p} = B_2 \left(E_p \frac{d^3N_p}{d^3p_p} \right)^2, \qquad (2)$$

where B_2 is the coalescence parameter, with the subscript implying that two nucleons are involved in the coalescence. The above equation includes an implicit assumption that the ratio of neutrons to protons is unity. The proton and antiproton spectra [6] are corrected for feed-down from Λ and $\bar{\Lambda}$ decays by using a MC simulation tuned to reproduce the particle ratios: (Λ/p and $\bar{\Lambda}/\bar{p}$) measured by PHENIX at 130 GeV [13].

Figure 3 displays the coalescence parameter B_2 as a function of p_T for different centralities. Thermodynamic models [4] predict that B_2 scales with the inverse of the effective volume $V_{\rm eff}$ ($B_2 \propto 1/V_{\rm eff}$). The lower B_2 in more central collisions may thus reflect the increase in the participant volume with centrality. We also observe that B_2 increases with p_T. This is consistent with an expanding

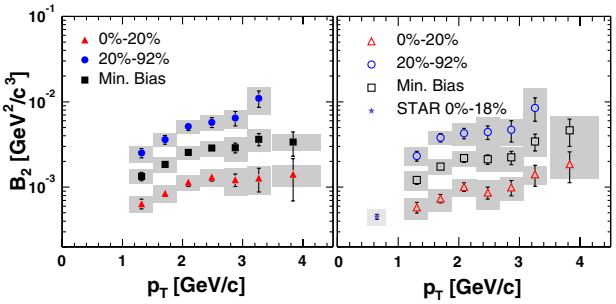

FIG. 3 (color online). Coalescence parameter B_2 vs p_T for deuterons (left panel) and antideuterons (right panel). Gray bands indicate the systematic errors. Values are plotted at the true mean value of p_T of each bin, the extent of which is indicated by the width of the gray bars along the x axis.

source because position-momentum correlations lead to a higher coalescence probability at larger p_T. The p_T dependence of B_2 can provide information about the density profile of the source as well as the expansion velocity distribution. It has been shown [14,15] that a Gaussian source density combined with a linear flow velocity profile leads to a constant B_2 with p_T. This is not supported by our data, which show a rise in B_2 with p_T. An increase of B_2 with p_T can be achieved if the Gaussian source density is replaced with a flat distribution [14,15]. The increase is a consequence of the flat density distribution giving greater weight to the outer parts of the system where the flow is strongest when a linear velocity profile is used.

Figure 4 compares B_2 for most central collisions to results at lower $\sqrt{s}$ [16–21]. Note that B_2 is nearly independent of $\sqrt{s}$, indicating that the source volume does not change appreciably with center-of-mass energy (with the caveat that B_2 varies as a function of p_T, centrality, and rapidity). This observation is consistent with what has been observed in Bose-Einstein correlation Hanbury Brown-Twiss analysis at RHIC [22] for identified particles. The coalescence parameter B_2 for d and $\bar{d}$ is equal within errors, indicating that nucleons and antinucleons have the same temperature, flow, and freeze-out density distributions.

The $\bar{d}/d$ ratio is independent of centrality and p_T within errors. The average value of $\bar{d}/d$ is 0.47 ± 0.03, consistent with the square of the ratio $\bar{p}/p = 0.73 \pm 0.01$ [6] within statistical and systematic uncertainties. This is expected if deuterons are formed by coalescence of comoving nucleons and $\bar{p}/p = \bar{n}/n$. The ratio $\bar{n}/n$ can, however, be estimated from the data based on the thermal chemical model. Assuming thermal and chemical equilibrium, the chemical fugacities are determined from the particle/antiparticle ratios [14]:

$$\frac{E_A(d^3N_A/d^3p_A)}{E_{\bar{A}}(d^3N_{\bar{A}}/d^3p_{\bar{A}})} = \exp\left(\frac{2\mu_A}{T}\right) = \lambda_A^2. \quad (3)$$

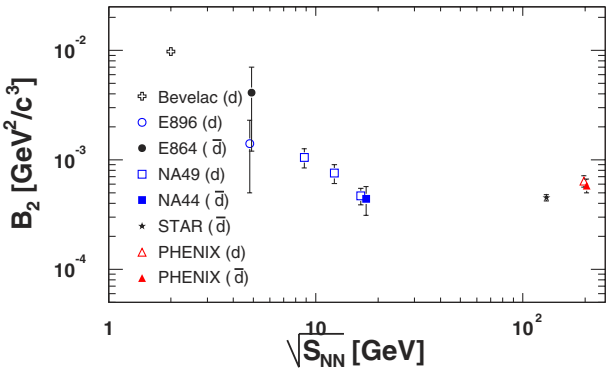

FIG. 4 (color online). Comparison of the coalescence parameter for deuterons and antideuterons ($p_T = 1.3$ GeV/c) with other experiments at different values of $\sqrt{s}$.

Using the ratio $p/\bar{p}$, the extracted proton fugacity is $\lambda_p = \exp(\mu_p/T) = 1.17 \pm 0.01$. Similarly, using the $d/\bar{d}$ ratio, the extracted deuteron fugacity is $\lambda_d = \exp[(\mu_p + \mu_n)/T] = 1.46 \pm 0.05$. From this, the neutron fugacity can be estimated to be $\lambda_n = \exp(\mu_n/T) = 1.25 \pm 0.04$, which results in $\bar{n}/n = 0.64 \pm 0.04$. The extracted $\bar{p}/p$ and $\bar{n}/n$ ratios are in agreement with what one would expect from the initial neutron excess in the Au nucleus if the same number of (anti)neutrons and (anti)protons are produced in the collision. Thermal models predict [23] $\bar{d}/d = 0.52$ and $\bar{n}/n = 0.73$ for $T = 177$ MeV and $\mu_B = 29$ MeV.

Finally, the coalescence requirement allows us to estimate the nucleon phase space distribution, i.e., the average number of nucleons per cell $(d^3pd^3x)/h$ in phase space. We define the phase space distribution averaged over the source volume as

$$\langle f(p)\rangle = \frac{1}{2S+1}\frac{(2\pi\hbar)^3}{V}\frac{d^3N}{dp^3}, \quad (4)$$

where $2S + 1$ is the spin degeneracy factor. From the coalescence equation [15], $f_A(\vec{r}, \vec{p}) = [f(\vec{r}, \vec{p}/A)]^A$, we can thus calculate $\langle f\rangle$ as a function of p_T from the measured invariant yields, if we assume that the protons, neutrons, and deuterons are emitted from the same volume. The results are shown in Fig. 5. The phase space density is well below 1 in the range of our measurement, and much lower than what has been found for pions produced in Au + Au collisions previously [24].

To summarize, the transverse momentum spectra of d and $\bar{d}$ in the range $1.1 < p_T < 4.3$ GeV/c have been measured at midrapidty in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV, and are found to be less steeply falling than proton (and antiproton) spectra. The extracted coalescence parameter B_2 increases with p_T, which is indicative of an expanding source. The results rule out a Gaussian source density distribution combined with a linear flow velocity profile and seem to favor a flat density distribution. The B_2 measured in nucleus-nucleus collisions is independent of $\sqrt{s_{NN}}$ above 12 GeV, consistent with the energy depen-

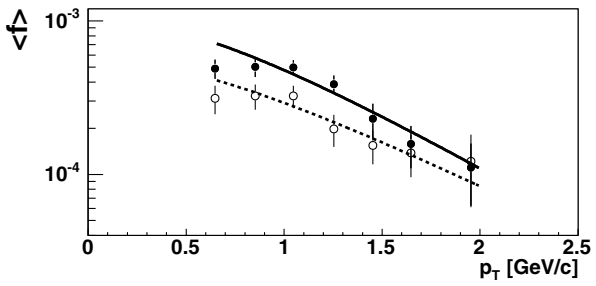

FIG. 5. Average nucleon phase space density as a function of p_T for central collisions. Solid circles correspond to nucleons and open circles correspond to antinucleons. The curves are fits to a Boltzmann function, $C\exp(-m_T/T)$, with $T = 568 \pm 96$ MeV (nucleons) and $T = 670 \pm 182$ MeV (antinucleons).

dence of the source radii extracted from Bose-Einstein correlation measurements. B_2 is equal within errors for both deuterons and antideuterons. From the measurements, it is estimated that $\bar{n}/n = 0.64 \pm 0.04$.

(Received 21 April 2004; published 11 November 2004)

We present a measurement of the double longitudinal spin asymmetry in inclusive π^0 production in polarized proton-proton collisions at $\sqrt{s} = 200$ GeV. The data were taken at the Relativistic Heavy Ion Collider with average beam polarizations of 0.27. The measurements are the first in a program to study the longitudinal spin structure of the proton, using strongly interacting probes, at collider energies. The asymmetry is presented for transverse momenta 1–5 GeV/c at midrapidity, where next-to-leading-order perturbative quantum chromodynamic (NLO pQCD) calculations well describe the unpolarized cross section. The observed asymmetry is small and is compared to a NLO pQCD calculation with a range of polarized gluon distributions.

DOI: 10.1103/PhysRevLett.93.202002 PACS numbers: 13.85.Ni, 13.88.+e, 21.10.Hw, 25.40.Fq

From polarized lepton-nucleon deep inelastic scattering (DIS) experiments over the past 20 years it is known that only ~25% of the proton spin can be attributed to the spins of the quarks and antiquarks [1]. The rest of the proton spin must hence be carried by the gluons and orbital angular momentum. DIS experiments have constrained the possible gluon polarization in the proton through the measurement of scaling violation in inclusive polarized scattering [2], and through semi-inclusive measurements of two hadrons to utilize the photon-gluon fusion process [3]. A fixed target experiment at Fermilab first presented a measurement with strongly interacting probes [4]. The reach of these measurements was limited, due to the low energy available for fixed target experiments. Presently, the gluon contribution to the proton spin is largely unknown.

The polarized proton collisions at the Relativistic Heavy Ion Collider (RHIC) provide a new laboratory to study the proton spin structure with strongly interacting probes. The PHENIX experiment has reported the unpolarized cross section for π^0 production at midrapidity for $p_T = 1$–14 GeV/c, which is described well by next-to-leading-order perturbative QCD (NLO pQCD) calculations over 8 orders of magnitude [5]. In this Letter we report the first results on the double spin asymmetry A_{LL} for inclusive π^0 production at midrapidity in longitudinally polarized proton-proton collisions corresponding to $0.22\ \mathrm{pb}^{-1}$ integrated luminosity with the PHENIX detector.

In perturbative QCD A_{LL} is directly sensitive to the polarized gluon distribution function in the proton through gluon-gluon and gluon-quark subprocesses [6,7].

The double spin asymmetry in π^0 production is given by

$$A_{LL}^{\pi^0} = \frac{\sigma_{++} - \sigma_{+-}}{\sigma_{++} + \sigma_{+-}}, \tag{1}$$

where σ_{++} (σ_{+-}) is the cross section of the reaction when two colliding particles have the same (opposite) helicity. Here we neglect the parity violating difference in cross section between $(++) \leftrightarrow (--)$ and $(+-) \leftrightarrow (-+)$ beam helicity configurations. Since the cross section can be obtained by dividing the experimental yield (N) by the integrated luminosity (L), A_{LL} is expressed as

$$A_{LL} = \frac{1}{|\langle P_B P_Y \rangle|} \frac{N_{++} - R N_{+-}}{N_{++} + R N_{+-}}; \qquad R = \frac{L_{++}}{L_{+-}}, \tag{2}$$

where $P_{Y(B)}$ are the polarizations of the RHIC "yellow" ("blue") beams, and R is the ratio of luminosities of protons colliding with like to unlike helicities.

For the 2002–2003 RHIC run, 55 bunches of polarized protons, typically 5×10^{10} protons per bunch, were loaded into each of the yellow and blue accelerator/storage rings of RHIC and accelerated to 100 GeV. The bunch lengths and separations were ~1 and 213 ns, respectively. The beam polarization sign for each bunch was prepared independently at the source, with the successive bunches in one ring alternating in polarization sign, and with successive pairs of bunches in the other ring alternating in sign. The locations of the bunches were identified relative to a RHIC timing clock. In this way, the experiments collected data from collisions with all four combinations of blue-yellow ring beam polarization signs simultaneously.

The stable direction of the proton spin in RHIC is vertical, but the region around the PHENIX experiment includes sets of magnets (spin rotators) to rotate the spin to the longitudinal direction at the collision point, and then back to vertical after the interaction point, in order to provide collisions with longitudinal polarization, and to maintain the required vertical polarization around RHIC. The RHIC polarimeters measure the transverse beam polarization away from the interaction points, independent of the operation of the spin rotators.

The transverse beam polarization was measured in RHIC independently in each beam using proton-carbon elastic scattering in the Coulomb nuclear interference region [8]. The analyzing power A_N^{pC} was measured for 22 GeV beam energy, $A_N^{pC}(22)$, to ±30% [9]. The energy dependence of the analyzing power over the RHIC energies is expected to be small, <10% [10]. For the results reported here, we have used the same analyzing power at 100 GeV as at 22 GeV, and 10% is added in quadrature to the relative uncertainty for $A_N^{pC}(22)$ to give a ±32% uncertainty for $A_N^{pC}(100)$. With these assumptions, the average polarization in the analyzed data set in this paper was $\sqrt{\langle P_B P_Y \rangle} = 0.27 \pm 1\%(\mathrm{stat}) \pm 10\%(\mathrm{syst}) \pm 32\%(A_N^{pC}\ \mathrm{syst})$.

Local polarimeters, sensitive to the transverse polarization at collision, were used to set up the spin rotators, and to monitor the beam polarization direction at the PHENIX experiment. The local polarimeters utilized a transverse single-spin asymmetry in neutron production in p-p collisions at $\sqrt{s} = 200$ GeV [11]. For vertically polarized beam a left-right asymmetry is observed for neutrons produced at very forward angles, with no asymmetry for production at very backward angles. A fully longitudinally polarized beam produces no asymmetry.

Neutrons with $E_n > 20$ GeV and production angle $0.3 < \theta_n < 2.5$ mrad were observed by two hadronic calorimeters located ±18 m from the interaction point [zero degree calorimeter (ZDC) [12]]. Scintillator hodoscopes at 1.7 interaction length provided the neutron position at the ZDC, and thus the neutron production angle and azimuthal angle $\phi = \arctan(x/y)$ with $\hat{y}$ vertically upward. The $\hat{x}$ axis forms a right-handed coordinate system with the $\hat{z}$ axis defined by the beam direction for forward

production. The single-spin asymmetry ϵ was calculated versus azimuth, from the four rates $N_{\uparrow,\phi}$, $N_{\uparrow,\phi+\pi}$, $N_{\downarrow,\phi}$, $N_{\downarrow,\phi+\pi}$, using the geometric mean [13]. This method largely cancels differences in luminosity between $\uparrow$ and $\downarrow$ polarization collisions and between detector acceptance differences at ϕ and $\phi + \pi$. Figure 1 shows the observed asymmetry, for the spin rotators off and on, for the blue and yellow beams. With the spin rotators off, a left-right asymmetry is observed from the vertically polarized beam. With the spin rotators on, the measured transverse polarization, averaged over the run, was $\langle P_{Bx}\rangle = 0.033 \pm 0.019$, $\langle P_{By}\rangle = 0.008 \pm 0.020$, $\langle P_{Yx}\rangle = -0.020 \pm 0.013$, and $\langle P_{Yy}\rangle = 0.054 \pm 0.017$, out of $\langle P\rangle = 0.27$. The double spin transverse polarization was $\langle P_{Bx}P_{Yx}\rangle = (0.4 \pm 1.1) \times 10^{-3}$ and $\langle P_{By}P_{Yy}\rangle = (-0.2 \pm 0.8) \times 10^{-3}$, compared to $\langle P_B P_Y\rangle = 0.07$. Therefore, with the spin rotators on, the transverse asymmetry is greatly reduced, indicating a high degree of longitudinal polarization: the longitudinal fraction of the beam polarization was 0.99 and 0.98 for the blue and yellow beams, respectively.

A separate run with the spin rotators set to give radial polarization confirmed the direction of the polarization for each beam.

Collisions in PHENIX are defined by the coincidence of signals in two beam-beam counters (BBC) [14] located ± 1.44 m from the nominal interaction point and subtending a pseudorapidity range $\pm(3.0$–$3.9)$ with full azimuthal coverage. The BBCs select about half of the inelastic proton-proton collisions [5]. The vertex was reconstructed from the time difference of the hits in the two BBCs. The collision vertex was required to be within 30 cm of the nominal interaction point. Events satisfying this condition constitute the minimum bias (MB) trigger, which was used for relative luminosity measurements.

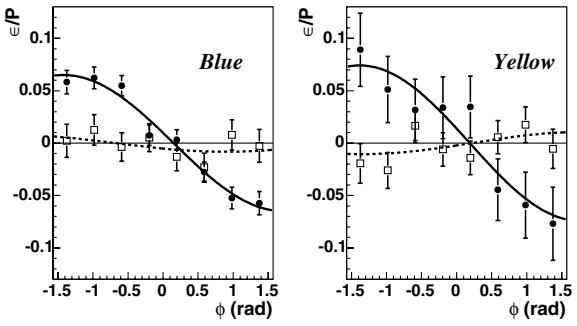

FIG. 1. The raw asymmetry normalized by the beam polarization ϵ/P as a function of azimuthal angle ϕ, for forward neutron production. The solid points and curve correspond to the spin rotators off (transverse polarization) and the open points and dashed curve correspond to the spin rotators on (longitudinal polarization). Curves are sine function fits to the data, representing possible transverse polarization. The data are for special runs used to set up the spin rotators, where the blue (yellow) polarization was 0.24 and 0.33 (0.08 and 0.28), for spin rotators off and on, correspondingly.

A coincidence of the two ZDCs was used to estimate the possible bias in the relative luminosity measurement from the BBCs. This was done by comparing the accumulated number of triggers in the ZDCs and BBCs for each bunch and each fill. The accuracy of relative luminosity measurements δR [Eq. (2)] was estimated to be 2.5×10^{-4}, which for the average beam polarization of 0.27 translated to $\delta A_{LL} = 1.8 \times 10^{-3}$, and, on the same uncertainty level, confirmed no A_{LL} asymmetry of BBC triggers relative to ZDC. The ratio R averaged over the data sample used in the analysis was within 0.5% of unity.

Neutral pions were reconstructed from the $\pi^0 \to \gamma\gamma$ decays using finely granulated ($\Delta\phi \times \Delta\eta \sim 0.01 \times 0.01$) electromagnetic calorimeters (EMCal) [15], which consisted of two subsystems: a lead scintillator (PbSc) and a lead glass (PbGl) calorimeter covering three quarters and one quarter of the EMCal acceptance, respectively. Located at a radial distance of $\sim$5 m from the beam line, the EMCal covered the pseudorapidity range of $|\eta| < 0.35$ and two azimuthal angle intervals of $\Delta\phi \approx 90°$ separated by $\phi \approx 70°$ (nearly back-to-back).

High p_T π^0's were collected using coincidences between a MB trigger and an EMCal-based high p_T photon trigger [5]. The trigger efficiency for π^0's varied from 8% in the 1–2 GeV/c p_T bin to 90% in the 4–5 GeV/c p_T bin.

The π^0 reconstruction and photon identification cuts were optimized to minimize the background contribution under the π^0 peak in the invariant mass distribution while keeping the π^0 efficiency high. For photon identification we used the shower shape and the time of flight measured by the EMCal, and charge veto cuts. The charge veto was set for those EMCal clusters associated with hit(s) in the pad chamber [16], which was located $\sim$20 cm in front of the EMCal surface. In order to avoid the effects of electronic noise and to suppress the very low energy background, only clusters with energy greater than 0.1 GeV in PbSc and 0.2 GeV in PbGl were used in the analysis.

The π^0 yield was extracted by integrating the two photon invariant mass spectrum over a ± 25 MeV/c^2 region around the π^0 mass (signal region). The EMCal resolution was such that the widths of the π^0 mass peaks varied from 12 MeV/c^2 in the 1–2 GeV/c p_T bin to 9.5 MeV/c^2 in the 4–5 GeV/c p_T bin, in both PbSc and PbGl. In the p_T range of 1 to 5 GeV/c, 4×10^6 π^0 candidates were collected. The background contribution (combinatorial + hadronic) under the π^0 peak r varied from 27% in the 1–2 GeV/c bin to 8% in the 4–5 GeV/c bin. The π^0 reconstruction efficiency due to photon identification cuts varied from 84% in the lowest p_T bin to 93% in the highest p_T bin.

The asymmetry of the background in the signal region A_{LL}^{BG} was evaluated using the asymmetry calculated from the data in $\gamma\gamma$ mass regions 50 MeV/c^2 wide on either side of the π^0 peak, centered at masses 75 and

195 MeV/c^2. The measured π^0 asymmetry $A_{LL}^{\rm raw}$ was corrected for the contribution of background using

$$A_{LL}^{\pi^0} = \frac{A_{LL}^{\rm raw} - rA_{LL}^{BG}}{1-r}, \qquad \sigma_{A_{LL}^{\pi^0}} = \frac{\sqrt{\sigma^2_{A_{LL}^{\rm raw}} + r^2\sigma^2_{A_{LL}^{BG}}}}{1-r}. \quad (3)$$

The spin asymmetry for each beam fill [17] $A_{LL}^{\rm fill}$ was calculated using Eq. (2). For the $A_{LL}^{\rm fill}$ error evaluation, we considered only the N_{++} and N_{+-} statistical errors. The resulting A_{LL} was obtained after fitting a constant to all $A_{LL}^{\rm fill}$'s. The fit $\chi^2_{\rm fit}$ and a "bunch shuffling" technique were used to evaluate the uncertainties assigned to A_{LL}. In each bunch shuffling we randomly assigned the helicity sign to every bunch crossing, keeping the balance between the number of bunches with correctly and inversely assigned helicities, so that the average polarization for each shuffled sample was nearly zero, and recalculated A_{LL}. The widths of the distributions of A_{LL} values obtained in all bunch shuffles were consistent with errors assigned to A_{LL} indicating that all noncorrelated bunch-to-bunch and fill-to-fill systematic errors were much smaller than the π^0 yield statistical errors.

A number of systematic checks, including variation of photon identification criteria and mass window range for π^0's and background, were performed to look for possible systematic effects on the measured A_{LL} values. None were found.

The double spin asymmetries between $(++)$ and $(--)$ and between $(+-)$ and $(-+)$ helicity configurations, as well as the single-spin asymmetries for each polarized beam ($A_L = -\frac{\sigma_+ - \sigma_-}{\sigma_+ + \sigma_-}$) were evaluated. These measure parity violating asymmetries, if any. All of these asymmetries were consistent with zero.

The results are presented in Table I and Fig. 2. Systematic uncertainties for the asymmetry measurements are negligible. A total scale uncertainty of $\pm 65\%$, from the correlated polarization analyzing power uncertainty δA_N^{pC} for the two beams and the uncorrelated measurement uncertainties, is not shown.

Two theoretical curves based on NLO pQCD are shown in Fig. 2, representing different assumptions for the gluon polarization, one using the best global fit to inclusive DIS data (GRSV-std), and another one using a gluon polarized distribution equal to the unpolarized distribution at the input scale of $Q^2 = 0.6$ GeV^2 (GRSV-max) [6,18]. The gluon polarization contributes to A_{LL} through gluon-gluon and gluon-quark subprocesses, with the gluon-gluon contribution significantly larger at midrapidity and for the estimated gluon momentum fraction for these results $x \approx 0.03$–0.1 [19]. Thus, the asymmetry A_{LL} is approximately proportional to the square of the gluon polarization and a negative value of A_{LL} is not expected [20]. The results are consistent with zero or small gluon polarization, with a confidence level (C.L.) of 16%–20% for GRSV-std, for the range in polarization uncertainty of the measurement. The results are less consistent with a large gluon polarization, with C.L. = 0.02%–5% for GRSV-max.

We emphasize the following points: (1) The lowest p_T point reported here can have a significant contribution from soft physics, since the agreement of the NLO pQCD calculation with the measured cross section [5] can only be checked to within the uncertainties of the calculation, estimated to be a factor two at this p_T [6,20]. If the soft physics is represented by an exponential falloff in p_T (e^{-6p_T} is typically used [21]), the soft physics contribution to the higher p_T data is small ($< 10\%$ to the 2–3 GeV/c p_T bin if we assume equal soft/hard contributions to the lowest bin). If we consider only the highest three p_T bins, the C.L. = 58%–67% for GRSV-std, and C.L. = 0.4%–29% for GRSV-max. (2) These confidence levels do not include a theoretical uncertainty, from either scales or from choices of parton distribution functions and fragmentation function. The comparisons are made for NLO pQCD, rather than extracting a leading-order estimate of the gluon polarization. (3) The range of theory curves in Fig. 2 reflects the uncertainty on gluon polarization from inclusive DIS measurements [18,22–24].

In summary, we have presented a new technique for determining the polarized gluon distribution using polarized protons acting as strongly interacting probes, at

TABLE I. Double and single-spin asymmetries for four p_T bins with mean $p_T(\pi^0)$ 1.59, 2.39, 3.37, and 4.38 GeV/c.

p_T (GeV/c)	$A_{LL}^{\rm raw}$ (10^{-2})	A_{LL}^{BG} (10^{-2})	$A_{LL}^{\pi^0}$ (10^{-2})	$A_L^{\pi^0}$ (10^{-2})
1–2	-1.5 ± 0.9	1.6 ± 1.4	-2.7 ± 1.3	-0.2 ± 0.3
2–3	-1.5 ± 1.1	-3.0 ± 2.4	-1.3 ± 1.3	-0.1 ± 0.3
3–4	-1.8 ± 2.5	-2.4 ± 6.8	-1.7 ± 2.8	-0.3 ± 0.6
4–5	2.6 ± 5.7	24 ± 17	0.7 ± 6.2	-1.0 ± 1.2

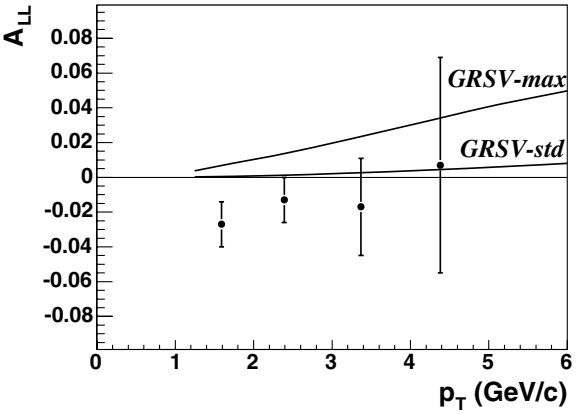

FIG. 2. $A_{LL}^{\pi^0}$ versus mean p_T of π^0's in each bin. A scale uncertainty of $\pm 65\%$ is not included. Two theoretical calculations based on NLO pQCD are also shown for comparison with the data (see text for details).

collider energies. The reported results of the double spin helicity asymmetries for π^0 production begin to probe the proton spin structure in the perturbative QCD regime with a sensitivity comparable to the polarized inclusive deep inelastic scattering data. The observed asymmetry is small and consistent with a small gluon polarization.

We thank the staff of the Collider-Accelerator Department, Magnet Division, and Physics Department at BNL and the RHIC polarimetry group for their vital contributions. We thank W. (Received 5 January 2004; published 8 October 2004)

Bose-Einstein correlations of identically charged pion pairs were measured by the PHENIX experiment at midrapidity in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The Bertsch-Pratt radius parameters were determined as a function of the transverse momentum of the pair and as a function of the centrality of the collision. Using the standard core-halo partial Coulomb fits, and a new parametrization which constrains the Coulomb fraction as determined from the unlike-sign pion correlation, the ratio $R_{\mathrm{out}}/R_{\mathrm{side}}$ is within 0.8–1.1 for $0.25 < \langle k_{\mathrm{T}} \rangle < 1.2$ GeV/c. The centrality dependence of all radii is well described by a linear scaling in $N_{\mathrm{part}}^{1/3}$, and $R_{\mathrm{out}}/R_{\mathrm{side}}$ for $\langle k_{\mathrm{T}} \rangle \sim 0.45$ GeV/c is approximately constant at unity as a function of centrality.

DOI: 10.1103/PhysRevLett.93.152302 PACS numbers: 25.75.Gz, 25.75.Dw

Following its application in the study of proton-antiproton annihilations [1], the study of Bose-Einstein correlations has been used extensively to measure source distributions in relativistic heavy ion collisions [2,3]. These measurements were originally motivated by theoretical predictions of a large source size and/or a long duration of particle emission [4–6] which would result from a softening of the equation of state in a first-order phase transition to a quark-gluon plasma (QGP). The technique of Bose-Einstein correlations is based upon quantum statistical interference, but final state interactions such as Coulomb repulsion modify the relative momentum distributions for pairs of identical particles emanating from the collision region. Both effects are included in multidimensional Gaussian fits to the normalized relative momentum distributions yielding fit parameters which are the rms widths in each dimension, R_{long}, R_{side}, R_{out} [7,8], also referred to as HBT radii to honor the radio astronomers Hanbury Brown and Twiss who pioneered a similar technique to determine the angular diameters of stars [9]. For dynamic (i.e., expanding) sources, the HBT radii depend on the mean transverse momentum of the particle pairs, $k_{\mathrm{T}} = (\mathbf{p}_{1\mathrm{T}} + \mathbf{p}_{2\mathrm{T}})/2$, and correspond to lengths of homogeneity, regions of the source which emit particles of similar momentum [10]. Measuring the k_{T} dependence of the HBT radii provides essential constraints on dynamical models that include the space-time evolution of the source [11,12].

Most hydrodynamical models for the space-time evolution of a rehadronizing QGP predicted that the measurement of the $R_{\mathrm{out}}/R_{\mathrm{side}}$ ratio at moderate values of k_{T} provides a sensitive measure of the expected long duration of particle emission, a signal of a slowly burning first-order phase transition from QGP to hadrons at the Relativistic Heavy Ion Collider (RHIC) [4]. Predictions that the $R_{\mathrm{out}}/R_{\mathrm{side}}$ ratio should reach ~ 1.5 at k_{T} of ~ 0.5 GeV/c were not borne out by initial measurements of Bose-Einstein correlations of pions from Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV [13,14]. Disagreement between theory and data is known as the "RHIC HBT puzzle" [15].

We present here data on Bose-Einstein correlations of charged pion pairs measured by the PHENIX experiment at RHIC for Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. In this analysis, we adopt a recent fitting technique that provides for a self-consistent treatment of the Coulomb final state interaction for a source that is made up of a smaller core and a more extended halo of long-lived resonances. We introduce a new parametrization in which the strength of the Coulomb interaction is constrained by the measured unlike-sign pion correlation.

The PHENIX detector provides particle identification (PID) capabilities for hadrons, leptons, and photons over a wide momentum range. The setup of the PHENIX detector has been described in detail elsewhere [16]. In this analysis, we use the west arm of the central spectrometer, which covers the pseudorapidity region $|\eta| < 0.35$ and $\Delta\phi = \pi/2$ in an azimuthal angle over a region of $0.2 < k_{\mathrm{T}} < 2.0$ GeV/c. The drift chamber (DC), at a radial distance between 2.0 and 2.4 m, provides trajectory information in the azimuthal direction. A pad chamber (PC1) at 2.5 m provides z-coordinate information. Combining the DC and PC1 information, a track model provides a three-dimensional trajectory and momentum vector for charged particles. The momentum resolution is $\delta p/p \simeq 0.7\% \oplus 1.0\% \times p$ (GeV/c), where the first term is due to the multiple scattering before the DC, and the second term results from the angular resolution of the DC. For this analysis, the electromagnetic calorimeter (EMCal) provides the time of arrival of particles at its front face located 5.1 m from the beam axis. The timing resolution is approximately 400 psec for hadrons. This analysis is based on a sample of 34×10^6 minimum-bias events taken with an integrated magnetic field of 0.78 T m and triggered by the coincidence of the beam-beam counters (BBCs) and zero-degree calorimeters (ZDCs)—corresponding to $92\% \pm 2\%$ of the total inelastic cross section of 6.8 b. Event centrality is determined using a correlation measurement between neutral energy deposited in the ZDCs and fast particles recorded in the BBCs [17]. A Monte Carlo Glauber model [18,19] is used with a simulation of the BBC and ZDC responses to determine the number of nucleons participating in the collisions (N_{part}) for the minimum-bias events. About 23×10^6 events are selected with a requirement that the collision vertex position measured by the BBC is within ± 30 cm from the center of the spectrometer. Each track is required to have an associated hit on the EMCal within 2σ of the track's projection to the EMCal, where σ refers to the resolution of the projection. Charged particles are identified by the time-of-flight technique using timing information between the BBC and the EMCal, combined with momentum and path length calculated by the track model. Charged particles in the PID zone within 1.5σ of the ideal squared-mass peak of pions but 1.5σ away from the kaon bands are identified as pions. After the track quality and PID cuts, $\sim 45 \times 10^6$ positive pions and $\sim 51 \times 10^6$ negative pions are selected in a momentum range from 0.2 to 2.0 GeV/c.

The pion correlation function is experimentally defined as $C_2(\mathbf{q}) = A(\mathbf{q})/B(\mathbf{q})$, where $A(\mathbf{q})$ is the measured two-pion (actual pair) distribution of pair momentum difference $\mathbf{q}$, and $B(\mathbf{q})$ is the background pair (mixed pair) distribution generated using mixed events from the same data sample. Event mixing is done selecting events that have similar multiplicities and event vertices. We remove ghost tracks and inefficiencies by removing pairs of tracks in three regions at the drift chambers: $\Delta Z_{\mathrm{DC}} < 1$ cm and $\Delta\phi_{\mathrm{DC}} < 60$ mr, $\Delta Z_{\mathrm{DC}} < 5$ cm and

$\Delta\phi_{\rm DC} < 30$ mr, and $\Delta\phi_{\rm DC} < 5$ mr. We also remove hits affected by EMCal cluster sharing by eliminating tracks with hits separated by less than 8 cm at the EMCal. The event-mixed background pairs are subjected to the same cuts. After pair cuts, $\sim 110 \times 10^6$ positive and 140×10^6 negative pion pairs remain, approximately 40 times the data sample acquired by PHENIX at $\sqrt{s_{NN}} = 130$ GeV [13]. Remaining inefficiencies in the DC and EMCal are small, and for these we apply a correction from a GEANT-based [20] Monte Carlo simulation of the detector. The multiplicity dependence is estimated by embedding simulated pion pairs into real events. The systematic errors from pair cuts and corrections are estimated to be $\sim 4\%$ for $R_{\rm side}$ and $R_{\rm long}$, and $\sim 8\%$ for $R_{\rm out}$. Systematic errors for the Coulomb correction (discussed below) are $\sim 2\%$, and we assign an additional systematic error of 1% to each radius for the so-called residual HBT effect [21] in the event-mixed background. All systematic errors are determined as a function of $k_{\rm T}$ and centrality.

To compare directly to previous analyses, we fit the correlations using a standard *full* Coulomb correction, in which the Coulomb correction is determined iteratively by calculating the Coulomb wave function [6] for a 3D Gaussian parametrization of the source using the radius fit parameters from the previous iteration. We fit the Bose-Einstein correlation with the *full* Coulomb correction to the 1D $q_{\rm inv}$ parametrization, $C_2^{\rm FC}(q_{\rm inv}) = 1 + \lambda_{\rm inv} \times \exp(-R_{\rm inv}^2 q_{\rm inv}^2)$, and the 3D Bertsch-Pratt parametrization is given by

$$C_2^{\rm FC} = 1 + \lambda \exp(-R_{\rm side}^2 q_{\rm side}^2 - R_{\rm out}^2 q_{\rm out}^2 - R_{\rm long}^2 q_{\rm long}^2). \quad (1)$$

The relative momentum $\mathbf{q}$ is decomposed into $q_{\rm side}$, $q_{\rm out}$, and $q_{\rm long}$, where the longitudinal component ($q_{\rm long}$) is parallel to the beam axis, the out component ($q_{\rm out}$) is parallel to the mean transverse momentum of the pair, $\mathbf{k}_{\rm T}$, and the side component ($q_{\rm side}$) is perpendicular to both $q_{\rm long}$ and $q_{\rm out}$ [7,8]. Analysis is performed in the longitudinal center-of-mass system (LCMS), where the mean longitudinal momentum of the pair vanishes. In this frame, the duration of particle emission couples exclusively to $q_{\rm out}$. Cross terms may appear in Eq. (1), but they vanish in our measurement of central collisions at midrapidity for symmetry reasons [22].

In the core-halo model of the source many relatively long-lived particles (e.g., η, η') decay into pions too far from the core to be experimentally resolved by Bose-Einstein interference [23]. These pions also have Coulomb interactions that are negligible. To account for this effect, and to assess the systematic errors that arise from making a clean distinction between the core and halo components of the source, we perform two fits to the correlation function using Eqs. (2) and (3):

$$C_2^{\rm raw} = C_{\rm core} + C_{\rm halo} = [\lambda(1 + G)F] + [1 - \lambda], \quad (2)$$

$$C_2^{\rm raw} = [\lambda(1 + G)F] + [(\lambda_{+-} - \lambda)F] + [1 - \lambda_{+-}], \quad (3)$$

where G corresponds to the Gaussian term in Eq. (1). In Eq. (2) [24–26], the fit is applied to the correlation function without Coulomb correction ($C_2^{\rm raw}$), and the Coulomb correction term F is included in the fit function itself. In Eq. (3) we introduce a new parameter, λ_{+-}, to decouple the Coulomb and Bose-Einstein fractions. This form extends the formalism to allow for intermediate range decay pions, such as from the ω, which may contribute to the Coulomb strength without being resolved in the measured Bose-Einstein correlation [27]. λ_{+-} is determined by fitting Coulomb correlation functions calculated with several Coulomb strengths, assuming the 1D HBT radius obtained from the like-sign pion data, to the unlike-sign correlation function in the range $0.2 < k_{\rm T} < 2.0$ GeV/c, as shown in Fig. 1(a). The test yields a value of Coulomb strength $\lambda_{+-} = 0.50 \pm 0.04$, where χ^2 of the fit becomes minimum (χ^2/d.o.f. $= 32.9/11$).

Figures 1(b)–1(d) show fits to the $\pi^-\pi^-$ correlation functions for the full [Eq. (1)] and partial [Eq. (2)] Coulomb corrections. Figure 2 shows the fit parameters most affected by the strength of the Coulomb correction, and the physically interesting ratio $R_{\rm out}/R_{\rm side}$ for the full Coulomb correction and two types of partial Coulomb corrections. The partial Coulomb correction leads to a reduction in λ at low $k_{\rm T}$ and increases in $R_{\rm out}$ and $R_{\rm out}/R_{\rm side}$, which are most prominent at intermediate $k_{\rm T}$. In all subsequent results, Eq. (2) is used exclusively, and

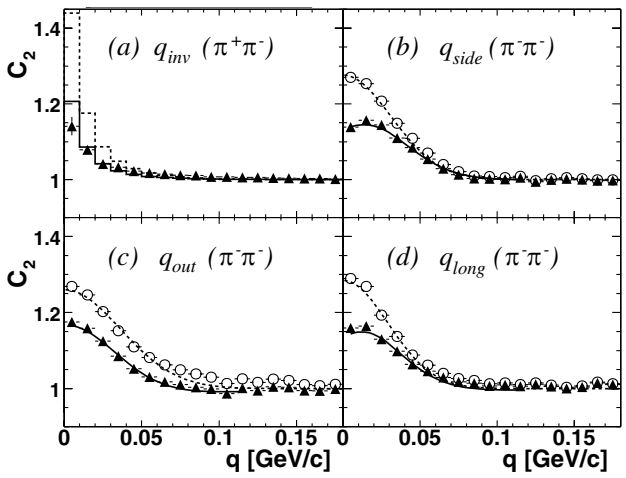

FIG. 1. (a) The one-dimensional correlation function of unlike-sign pions for $0.2 < k_{\rm T} < 2.0$ GeV/c. The two overlaid histograms show calculations for the *full* (dashed) and the 50% partial (solid) Coulomb corrections. (b)–(d) The three-dimensional $\pi^-\pi^-$ correlation function slices for $0.2 < k_{\rm T} < 2.0$ GeV/c and 0%–30% centrality averaged over the lowest 40 MeV/c in the orthogonal directions. The full Coulomb corrected data (open circles) are fit to Eq. (1) (dashed lines), and the data without Coulomb correction (filled triangles) are fit to Eq. (2) (solid lines).

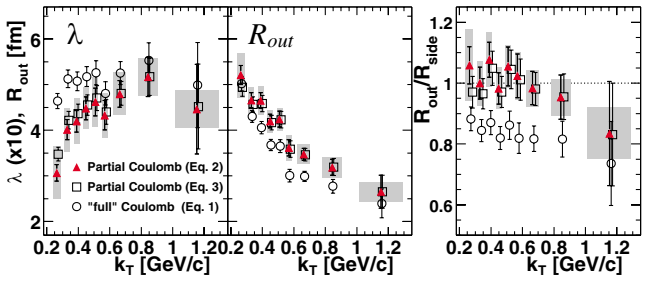

FIG. 2 (color online). The k_T dependence of λ, R_{out}, and R_{out}/R_{side} for $\pi^-\pi^-$ for 0%–30% centrality. Filled triangles show the results from fits to a core-halo structure by Eq. (2), with statistical error bars and systematic error bands. Open circles and squares show the results from the *full* and partial Coulomb corrections by Eqs. (1) and (3), respectively, with statistical error bars.

differences arising from the use of Eq. (3) are incorporated into the total systematic errors.

Figure 3 shows the k_T dependence of all radii and the ratio R_{out}/R_{side}, along with the recently published STAR results [28], and the radii from hydrodynamical model calculations of Hirano [29] and Soff [30]. The results of PHENIX and STAR are in excellent agreement, and reveal in great detail the characteristic ~50% overprediction of these models in R_{out}/R_{side}. The k_T dependence of these radii is reproduced by parametrizations of hydrodynamic freeze-out hypersurfaces [31–33] that are fit to previously published data.

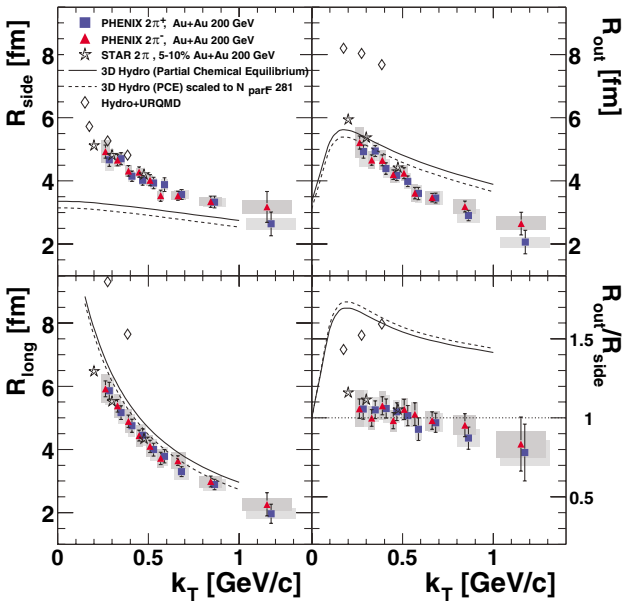

FIG. 3 (color online). The k_T dependence of the Bertsch-Pratt parameters for $\pi^+\pi^+$ (blue square) and $\pi^-\pi^-$ (red triangle) for 0%–30% centrality, from fits to a core-halo structure by Eq. (2), with statistical error bars and systematic error bands. Results from STAR [28] and hydrodynamics models (Hirano [29], solid and dashed lines, and Soff [30], diamonds) are overlaid.

Figure 4 shows that the centrality dependency is well described by a linear function of $N_{part}^{1/3}$. The slope parameters for R_{side} and R_{out} are similar to those measured at 11.6 and 14.6A GeV/c [34], while R_{long} is significantly larger. Therefore the approximate independence of R_{side} and R_{out}, and the increase in R_{long} with $\sqrt{s_{NN}}$ documented in Fig. 2 of [13], can be extended to peripheral collisions as well.

In conclusion, we have presented the Bertsch-Pratt HBT radii in the LCMS for identified charged pions measured by PHENIX in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The k_T dependence of the HBT radii was measured for $\langle N_{part}\rangle = 281$, and the centrality dependence was measured for $\langle k_T\rangle \sim 0.45$ GeV/c. We performed two different partial Coulomb analyses: one based upon a self-consistent treatment of the Coulomb correction, and the other based upon direct comparison to the unlike-sign correlations. The methods give different results for λ, R_{out}, and R_{out}/R_{side} from those of the full Coulomb correction. Using the partial Coulomb correction of Eq. (2), we observe that the value of R_{out}/R_{side}, as a function of k_T, decreases from ~1.1 to ~0.8 over the range of $k_T = 0.2$–1.2 GeV/c for $\langle N_{part}\rangle = 281$. This ratio remains approximately constant at unity when plotted as a function of the number of participants for $\langle k_T\rangle \sim 0.45$ GeV/c. These measurements are consistent with recent results from STAR for the same system, but they

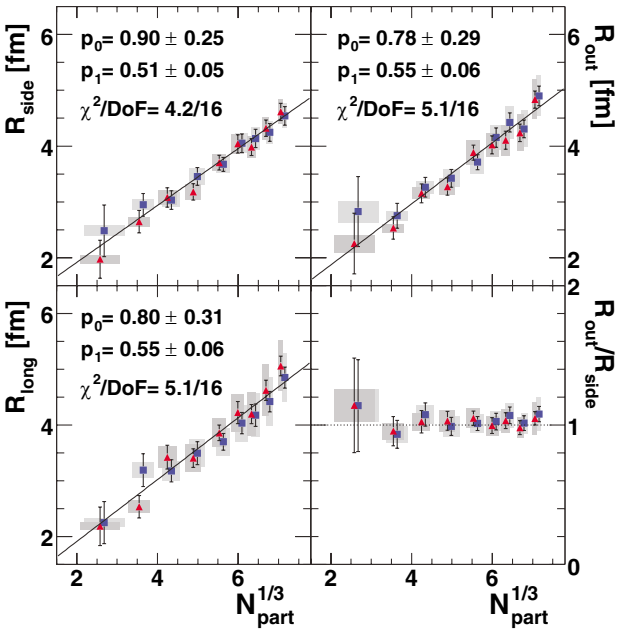

FIG. 4 (color online). Bertsch-Pratt radius parameters versus the cube root of the number of participants ($N_{part}^{1/3}$) for $\pi^+\pi^+$ (blue square) and $\pi^-\pi^-$ (red triangle) for the fits to a core-halo structure by Eq. (2) with statistical error bars and systematic error bands, in the $0.2 < k_T < 2.0$ GeV/c range, with $\langle k_T\rangle \sim 0.45$ GeV/c. The solid line shows fits to $p_0 + p_1 * N_{part}^{1/3}$ for both signs.

are inconsistent with recent hydrodynamical calculations assuming the first-order phase transition from QGP to hadrons. These detailed measurements of the transverse momentum dependence of the HBT radii, in particular, that of $R_{\mathrm{out}}/R_{\mathrm{side}}$, provide extremely strong constraints for models of particle production at RHIC.

Two-particle correlations of direct photons were measured in central ^{208}Pb + ^{208}Pb collisions at 158A GeV. The invariant interferometric radii were extracted for $100 < K_T < 300$ MeV/c and compared to radii extracted from charged pion correlations. The yield of soft direct photons, $K_T < 300$ MeV/c, was extracted from the correlation strength and compared to theoretical calculations.

Hanbury Brown–Twiss (HBT) interferometry provides a powerful tool to explore the space-time dimensions of the emitting source created in elementary particle or heavy ion collisions. Historically, such measurements have concentrated on pion pair correlations, but have also been applied to kaons, protons, and even heavy fragments [1]. Hadron correlations reflect the space-time extent of the emitting source at the time of freeze-out.

The importance of direct photon Bose-Einstein interferometry for investigation of the history of heavy ion

 © 2004 The American Physical Society

collisions, especially of the very early phase, has been extensively discussed in the literature [2–6]. It has been shown that photon-photon correlations can provide information about the space-time distribution of the hot matter prior to freeze-out. Moreover, the correlations of direct photons of different transverse momenta will reflect different stages of the collision. Unfortunately, photon interferometry is faced with considerable difficulties compared to hadron interferometry primarily due to the small yield of photons emitted directly from the hot zone in comparison to the huge background of photons produced by the electromagnetic decay of the final hadrons (π^0's). For this reason, there has been only one experimental measurement of photon-photon correlations in heavy ion collisions obtained at low incident energy and low photon momenta ($K_T \leq 20$ MeV/c) [7]. In this Letter, we present first measurements of direct photon correlations in central ultrarelativistic heavy-ion collisions.

A detailed description of the layout of the CERN experiment WA98 can be found in [8]. Here we briefly discuss those subsystems used in the present analysis. The WA98 photon spectrometer, comprising the LEad-glass photon Detector Array (LEDA), was located at a distance of 21.5 m downstream from the ^{208}Pb target. It provided partial azimuthal coverage over the rapidity interval $2.35 < y < 2.95$. Further downstream, the total transverse energy was measured in the MIRAC calorimeter. The total transverse energy measured in MIRAC was used for offline centrality selection. The analysis was performed on data collected in 1995 and 1996 for the 10% most central and 20% most peripheral fractions of the ^{208}Pb + ^{208}Pb minimum bias cross section with total data samples of 5.8×10^6 and 3.9×10^6 events, respectively. No significant signal was observed in the peripheral data sample, consistent with the absence of any significant direct photon signal reported in [8].

In order to reject most of the hadron background, all showers reconstructed in the LEDA spectrometer were required to have a deposited energy of greater than 750 MeV, well above the minimum ionizing peak energy of 550 MeV. Hadron showers could be further rejected by the requirement that the shower have a narrow width, consistent with an electromagnetic shower in LEDA [8]. In addition, during the 1996 run period, the LEDA charged particle veto was operational and provided a shower sample of $> 98\%$ photon purity.

The two-photon correlation function was calculated for each bin of the photon average transverse momentum, $K_T = |\vec{p}_{T_1} + \vec{p}_{T_2}|/2$ as the ratio of the distribution of photon pair invariant relative momenta, $Q_{\rm inv}$, where both photons were taken from the same event, to the same distribution but with the photons of the pair taken from different events. Sample correlation functions are shown in Fig. 1. The ratio was normalized to have an equal number of pairs in the numerator and denominator.

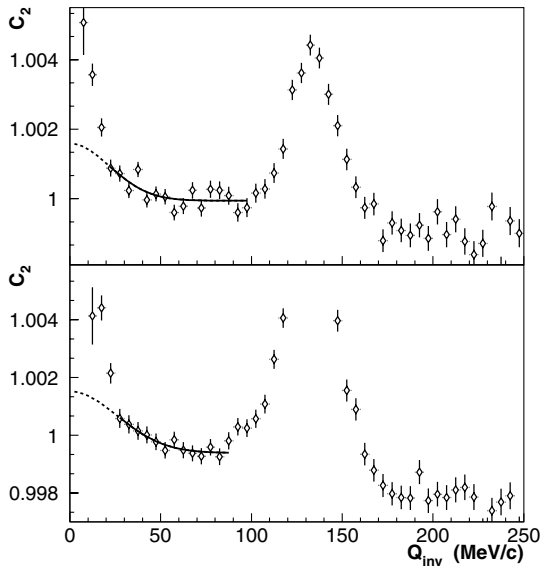

FIG. 1. The two-photon correlation function for narrow showers with $L_{\rm min} > 20$ cm (diamonds) and average photon momenta $100 < K_T < 200$ MeV/c (top) and $200 < K_T < 300$ MeV/c (bottom) fitted with Eq. (1). The solid line shows the fit result in the fit region used (excluding the π^0 peak at $Q_{\rm inv} \approx m_{\pi^0}$) and the dotted line shows the extrapolation into the low $Q_{\rm inv}$ region where backgrounds are large.

The correlation function has been fit with a Gaussian parameterization with normalization A, correlation strength $\lambda_{\rm inv}$, and radius parameter $R_{\rm inv}$:

$$C_2(Q_{\rm inv}) = A[1 + \lambda_{\rm inv} \exp(-R_{\rm inv}^2 Q_{\rm inv}^2)]. \qquad (1)$$

There are a large number of effects which may give rise to small $Q_{\rm inv}$ correlations and mimic a direct photon Bose-Einstein correlation. These include (i) single hadron or photon showers that are split into nearby clusters, (ii) photon conversions, (iii) HBT correlations of charged pions or other hadrons misidentified as photons, (iv) residual photon correlations from π^0 HBT correlations, (v) radiative decays of heavier resonances, and (vi) collective flow.

Apparatus or analysis effects which may result in the splitting of a single shower into multiple clusters, or the merging of nearby showers into a single cluster, may be investigated by studying the dependence of the correlation function on the relative distance L between the showers on the LEDA detector surface. These effects are expected to contribute strongly at small L and so can be suppressed effectively by a distance cut. Such a minimum cut on L introduces a lower cutoff in $Q_{\rm inv}$ [9].

The dependence of the correlation strength parameter $\lambda_{\rm inv}$ on the minimum distance cut $L_{\rm min}$ and the minimum invariant momentum $Q_{\rm min}$ used to define the fit region is shown in Fig. 2 for two K_T regions for narrow showers. The different symbols correspond to minimum distance cuts of $L_{\rm min} = 20$, 25, 30, and 35 cm (note that a single

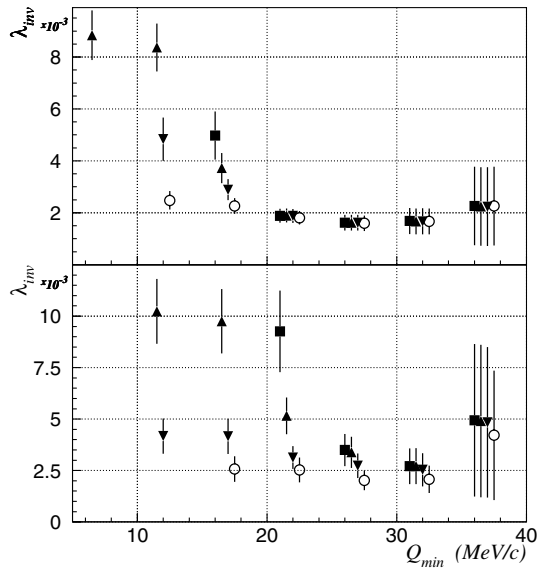

FIG. 2. Comparison of $\lambda_{\rm inv}$ parameter fit results for different fit regions for $100 < K_T < 200$ MeV/c (top) and $200 < K_T < 300$ MeV/c (bottom), calculated for narrow showers with different cuts on the minimum shower separation distance: $L_{\rm min} = 20$ cm, ■; 25 cm, ▲; 30 cm, ▼; 35 cm, ○ (same $Q_{\rm min}$ for each).

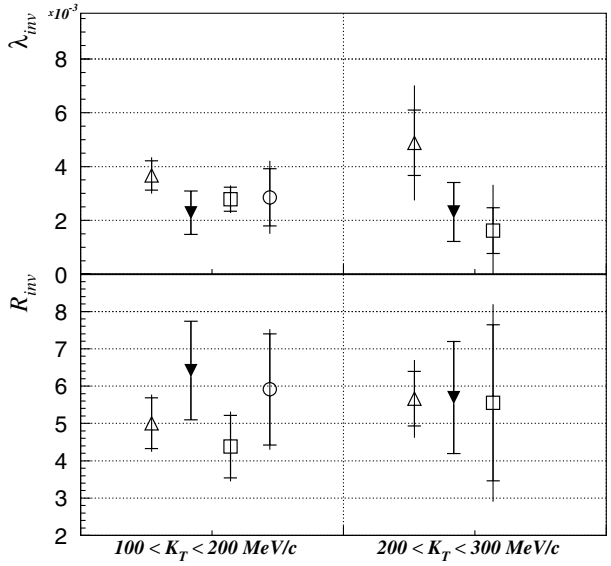

FIG. 3. Comparison of parameters of correlation functions with different particle identification criteria: △, all clusters; ▼, narrow electromagnetic; □, all neutral; ○, narrow neutral electromagnetic (no significant result for high K_T).

LEDA module is 4 cm in width). The results demonstrate that the extracted fit parameters vary strongly with $L_{\rm min}$ when the low $Q_{\rm inv}$ region is included in the fit, a result attributed to apparatus effects and conversion background, but that stable results are obtained with a sufficiently large minimum separation distance cut, or by restricting the $Q_{\rm inv}$ fit region. When no charged veto or narrow shape cuts are applied to the showers, stable results are also obtained, but with larger minimum distance cut (or $Q_{\rm min}$) required, consistent with the larger expected backgrounds.

As mentioned above, the observed correlations could be caused by residual correlations of charged pions, neutrons, antineutrons, or conversion electrons misidentified as photons. To investigate possible contributions from nonphoton contamination, the correlation functions were constructed with four different identification criteria applied to the showers reconstructed in LEDA. These criteria have somewhat different photon efficiencies, which should not affect the photon correlation, but more importantly have very different levels of nonphoton contamination which should only affect $\lambda_{\rm inv}$ if the contamination forms uncorrelated background. The charged hadron contamination decreases from 37% and 22% to 16% and 4%, respectively, for the two K_T bins, after applying the narrow electromagnetic shower shape condition [8] and is negligible after application of the charged veto condition. The correlation parameters extracted from these four types of correlation functions, corrected for contamination, are shown in Fig. 3. The consistency of the parameters extracted with the different identification criteria indicates that the nonphoton contribution to the observed correlation is not significant.

The estimated systematic errors on the correlation fit parameters are summarized in Table I. Besides the uncertainties associated with the apparatus and fit range discussed with respect to Fig. 2, and nonphoton contamination (Fig. 3), the dependence on the fit function has been investigated. In addition to the Gaussian form of Eq. (1), an exponential form and a student's t distribution form have also been used to fit the correlation functions. The student's t distribution provides a good fit to the correlation for parameter $n \geq 2$. The variation of the fit results with n and comparison with the Gaussian fit results has been used to estimate the fit function error. Reasonable fit functions leading to significantly smaller values of $\lambda_{\rm inv}$ could not be found. An exponential form gives larger

TABLE I. Summary of relative systematic errors on the photon-photon correlation parameters (in %).

	$100 < K_T < 200$		$200 < K_T < 300$	
Source	$\lambda_{\rm inv}$	$R_{\rm inv}$	$\lambda_{\rm inv}$	$R_{\rm inv}$
Apparatus	7	5	16	6
Contamination	17	14	42	14
Fit function	5	5	18	6
Fit range	8	5	26	10
$Q_{\rm inv}$ slope (flow + BE)	2	3	12	8
Total systematic error (%)	21	17	56	21
$N_\gamma^{\rm total}$ total error (%)	12	...	4	...

$\lambda_{\rm inv}$ values but also exhibits a strong dependence of the fit parameters on fit range.

Finally, correlations might exist in the background decay photons, e.g., correlations due to collective flow, Bose-Einstein correlations of π^0's, or from decays of heavier resonances. Monte Carlo simulations have been performed to estimate each of these effects. For these simulations, the transverse momentum and rapidity distributions of the π^0's were taken from measurements [8]. The effect of flow was investigated by introducing an elliptic flow pattern with a magnitude equal to that measured for charged pions [10]. Similarly, the effect of π^0 Bose-Einstein correlations was introduced with the same parameters as measured for charged pions [11]. Finally, residual correlations due to decays of heavier resonances were estimated by including all resonances having high yield and large branching ratios for electromagnetic decay: K^0_S, K^0_L, η, and ω. The heavy resonances were included based on experimental spectra where available and thermodynamic extrapolations otherwise. In all simulations, the acceptance, identification cuts, and energy and position resolution of LEDA were applied. The simulations showed that elliptic flow results in the appearance of a small slope in the correlation function and that Bose-Einstein correlations of π^0's lead to a characteristic steplike structure in the photon-pair correlation function at the π^0 mass, with a small slope in the $Q_{\rm inv} < 100$ MeV/c region, also shown by analytical calculations [5]. The height of the step in simulations agrees with that seen in the correlation functions of Fig. 1. The contribution of residual correlations due to decays of heavier resonances results in a deviation from unity which is smaller than 10^{-4}. The combination of these effects in simulation results in a predicted slope in the photon-pair correlation of 5×10^{-6} (MeV/c)$^{-1}$ in the region of fit. The data sample with the highest statistics has been fit with an additional parameter for the slope, and the extracted value of $(5 \pm 3) \times 10^{-6}$ (MeV/c)$^{-1}$ was found to be consistent with the simulation result. However, limited statistics did not allow to extract a slope value for all data samples. Therefore, the final values of the correlation strength and radii have been corrected for the presence of an overall slope using the simulation result (typically a 10% decrease of $\lambda_{\rm inv}$ and 10% increase of $R_{\rm inv}$).

Averaging over the different particle identification criteria, we obtain the following correlation parameters:

$$\lambda^{\rm I}_{\rm inv} = 0.0028 \pm 0.0004({\rm stat}) \pm 0.0006({\rm syst}), \qquad R^{\rm I}_{\rm inv} = 5.9 \pm 0.8({\rm stat}) \pm 0.9({\rm syst})\ {\rm fm},$$

$$\lambda^{\rm II}_{\rm inv} = 0.0029 \pm 0.0007({\rm stat}) \pm 0.0016({\rm syst}), \qquad R^{\rm II}_{\rm inv} = 6.1 \pm 0.8({\rm stat}) \pm 1.2({\rm syst})\ {\rm fm},$$

for regions (I) $100 < K_T < 200$ MeV/c and (II) $200 < K_T < 300$ MeV/c, respectively.

The correlation function can be written as an integral over directions of the relative momenta in the pair c.m. frame. For massless particles it can be expressed as

$$C_2(Q_{\rm inv}, K_T) = 1 + \frac{\lambda}{4\pi} \int d\Omega \exp\{-(Q^2_{\rm inv} + 4K^2_T)R^2_O \cos^2\theta - Q^2_{\rm inv}(R^2_S \sin^2\theta \sin^2\phi + R^2_L \sin^2\theta \cos^2\phi)\},$$

where λ is the correlation strength ($\lambda = 1/2$ for a fully chaotic photon source), R_O, R_S, and R_L are the "out" "side," and "long" radius components of the source, measured in the local comover system. For large K_T ($\gg Q_{\rm inv}$), the photon $R_{\rm inv}$ is an average of R_S and R_L, and almost independent of R_O. However, the measured invariant correlation strength is dependent on R_O as $\lambda_{\rm inv} = \lambda \times \sqrt{\pi}\,{\rm Erf}(2K_T R_O)/4K_T R_O$. Therefore the direct photon invariant radii may be compared to measurements of the side and long components of interferometric radii of π^- for the same centrality selection and similar K_T region [12]: $R_S = 5.55 \pm 0.24$, 5.13 ± 0.32, and 4.81 ± 0.29 fm, $R_L = 5.95 \pm 0.27$, 5.45 ± 0.37, and 5.15 ± 0.34 at $K_T = 125$, 175, and 285 MeV/c, respectively. The similarity of the interferometric radii of direct photons and pions suggests that the direct photons of this K_T region are emitted in the late stage of the collision.

Under the assumption of a fully chaotic photon source, the direct photon yield $N^{\rm direct}_\gamma$ is related to the correlation strength λ and the total inclusive photon yield $N^{\rm total}_\gamma$ as [5]

$$N^{\rm direct}_\gamma / N^{\rm total}_\gamma = \sqrt{2\lambda} = \sqrt{8\lambda_{\rm inv} K_T R_O / \sqrt{\pi}\,{\rm Erf}(2K_T R_O)}.$$

Although the photon R_O has not been measured, a *lower* limit on the yield of direct photons is given by the assumption $R_O = 0$. A *most probable* yield is obtained by assuming a value of $R_O = 6$ fm [12]. The low p_T direct photon yields have been extracted for these two cases and are presented in Fig. 4 (assuming $p_T = \langle K_T \rangle$). The previously published direct photon yield at high transverse momenta obtained with the subtraction method [8] is also shown. The measured direct photon results are compared with recent fireball model predictions [13]. The calculated contributions to the total yield from the quark gluon plasma and hadronic stages of the collision are shown. It is seen that the contribution from the hadron gas phase dominates the direct photon yield at small p_T, with predicted yields below the measured direct photon yield.

In summary, two-photon correlation functions have been measured for the first time in central

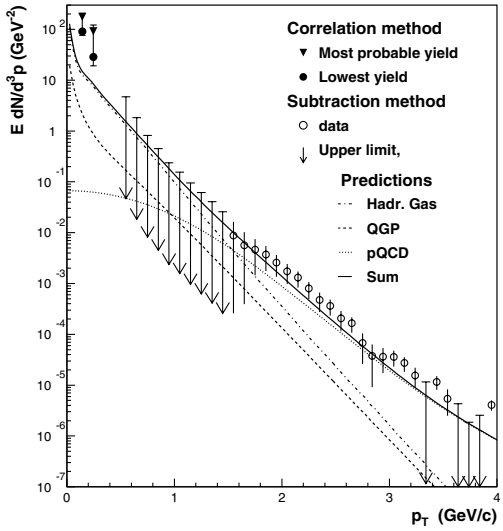

FIG. 4. Yield of direct photons extracted from the strength of the two-photon correlation ($R_O = 0$ fm, closed circles; $R_O = 6$ fm, closed triangles) and by the statistical subtraction method (open circles, or arrows indicating upper limits) [8]. Total statistical plus systematical errors are shown. The calculations are described in the text.

^{208}Pb + ^{208}Pb collisions at 158A GeV. The observed correlations are attributed to Bose-Einstein correlations of directly radiated photons. An invariant photon source radius of about 6 fm is extracted at low momenta, comparable to correlation radii extracted for pions of similar momenta. The correlation strength parameter was used to determine the yield of direct photons at $p_T < 300$ MeV/c. The measured yield exceeds theoretical expectations which attribute the dominant contribution in this p_T region to the hadronic phase.

We wish to acknowledge useful discussions with R. Rapp, C. Gale, and D. Srivastava. (Received 6 October 2003; published 24 August 2004)

Event-by-event fluctuations of the average transverse momentum of produced particles near mid-rapidity have been measured by the PHENIX Collaboration in $\sqrt{s_{NN}} = 200$ GeV Au + Au, and $p + p$ collisions at the Relativistic Heavy Ion Collider. The fluctuations are observed to be in excess of the expectation for statistically independent particle emission for all centralities. The excess fluctuations exhibit a dependence on both the centrality of the collision and on the p_T range over which the average is calculated. Both the centrality and p_T dependence can be well reproduced by a simulation of random particle production with the addition of contributions from hard-scattering processes.

DOI: 10.1103/PhysRevLett.93.092301 PACS numbers: 25.75.Dw

The measurement of fluctuations in the event-by-event average transverse momentum of produced particles in relativistic heavy ion collisions has been proposed as a probe of phase instabilities near the QCD phase transition [1–3], which could result in classes of events with different properties, such as the effective temperature of the collision. Fluctuation measurements could also provide information about the onset of thermalization in the system [4]. The resulting phenomena can be observed by measuring deviations of the event-by-event average p_T, referred to here as M_{p_T}, of produced charged particles from the expectation for statistically independent particle emission [5,6] after subtracting contributions from fluctuations arising from physical processes such as elliptic flow and jet production.

Several M_{p_T} fluctuation measurements have been reported in heavy ion collisions [7–10], including a study by PHENIX [9] in $\sqrt{s_{NN}} = 130$ GeV Au + Au collisions, which set limits on the magnitude of nonrandom fluctuations in M_{p_T}. Recently, STAR has reported fluctuations in excess of the random expectation, within the PHENIX limits, at the same collision energy [10]. For the first results from $\sqrt{s_{NN}} = 200$ GeV Au + Au and $p + p$ collisions reported here, upgrades of the PHENIX central arm spectrometers [11] have expanded the azimuthal acceptance from 58.5° to 180.0° within the pseudorapidity range of $|\eta| < 0.35$. Pad chamber and calorimeter detectors have also been utilized for improved background rejection. As a result, the sensitivity of the PHENIX spectrometer to the observation of fluctuations in M_{p_T} due to event-by-event fluctuations in the effective temperature [9,12] has improved by greater than a factor of 2.

Minimum bias events triggered by a coincidence between the zero degree calorimeters (ZDC) and the beam-beam counters (BBC), with a requirement that the collision vertex, which is measured with an rms resolution of less than 6 mm in central collisions and 8 mm in the most peripheral collisions, be within 5 cm of the nominal origin, are used in this analysis. Event centrality for Au + Au collisions, which is defined using correlations in the BBC and ZDC analog response [13], is divided into several classes, each containing an average of 244 000 analyzed events. These classes are associated to the estimated average number of participants in the collision, $\langle N_{\text{part}} \rangle$, which is derived using a Glauber model Monte Carlo calculation with the BBC and ZDC detector response taken into account [14].

Charged particle momenta are reconstructed in the PHENIX central arm spectrometers with a drift chamber and a radially adjacent pixel pad chamber. Nonvertex track background rejection is provided by pixel pad chambers and calorimeters located further outward radially from the collision vertex [15]. The momentum resolution is $(\delta p/p) \simeq 0.7\% \oplus 1.0\% \times p$ (GeV/c).

M_{p_T} is calculated for each event, which contains a number of reconstructed tracks within a specified p_T range, N_{tracks}. The p_T range is always given a lower bound of 200 MeV/c and a varying upper bound, $p_T^{\max}$, from 500 MeV to 2.0 GeV/c. There is a minimum N_{tracks} cut of three in both Au + Au events (removing 0%, 4.6%, and 29% of events in the 0%–50%, 50%–60%, and 60%–70% centrality ranges, respectively, when $p_T^{\max} = 2.0$ GeV/c) and $p + p$ events (removing 59% of the events).

There are several measures by which the magnitude of nonrandom fluctuations can be quantified, namely ϕ_{p_T} [16,17], ν_{dynamic} [18], and F_{p_T} [9]. The calculation of F_{p_T} is based upon the magnitude of the fluctuation, ω_{p_T}, defined as

$$\omega_{p_T} = \frac{(\langle M_{p_T}^2 \rangle - \langle M_{p_T} \rangle^2)^{1/2}}{\langle M_{p_T} \rangle} = \frac{\sigma_{M_{p_T}}}{\langle M_{p_T} \rangle}. \quad (1)$$

F_{p_T} is defined as the fractional deviation of ω_{p_T} from a baseline estimate defined using mixed events,

$$F_{p_T} = \frac{[\omega_{(p_T,\text{data})} - \omega_{(p_T,\text{mixed})}]}{\omega_{(p_T,\text{mixed})}}. \quad (2)$$

Mixed event M_{p_T} distributions are validated by comparisons to a calculation of M_{p_T} assuming statistically independent particle emission using parameters extracted from the inclusive p_T distributions of the data [19]. For the 0%–5% centrality class, which suffers the most from tracking inefficiency, the effects of two-track resolution, and background contributions, the mixed event M_{p_T} distribution yields a value of $F_{p_T} = 0.04\%$ with respect to the calculation. The results of this comparison are included in the estimates of the systematic errors. Further details on the mixed event procedure and a discussion of contributions to the value of F_{p_T} from detector efficiency and resolution effects can be found in the description of the data analysis of $\sqrt{s_{NN}} = 130$ GeV Au + Au collisions [9].

Comparisons of the data and mixed event M_{p_T} distributions for the 0%–5% and 30%–35% centrality classes are shown in Fig. 1. Any excess fluctuations are small and are difficult to distinguish by eye in a direct overlay of the M_{p_T} distributions. Therefore, the comparison is also shown as residuals of the difference between the data and mixed event distributions in units of standard deviations of the individual data points. The double-peaked shape in the residual distributions is an artifact of the fact that the mixed event distributions, which always have a smaller standard deviation in M_{p_T} than the data, are normalized to minimize the total χ^2 of the residual distribution.

Figure 2 shows the magnitude of F_{p_T}, expressed in percent, as a function of centrality for Au + Au collisions with $p_T^{\max} = 2.0$ GeV/c. The error bars are dominated by time-dependent systematic effects during the data taking period due to detector variations, which are minimized using strict time-dependent cuts on the mean and standard deviations of the inclusive p_T and N_{tracks}

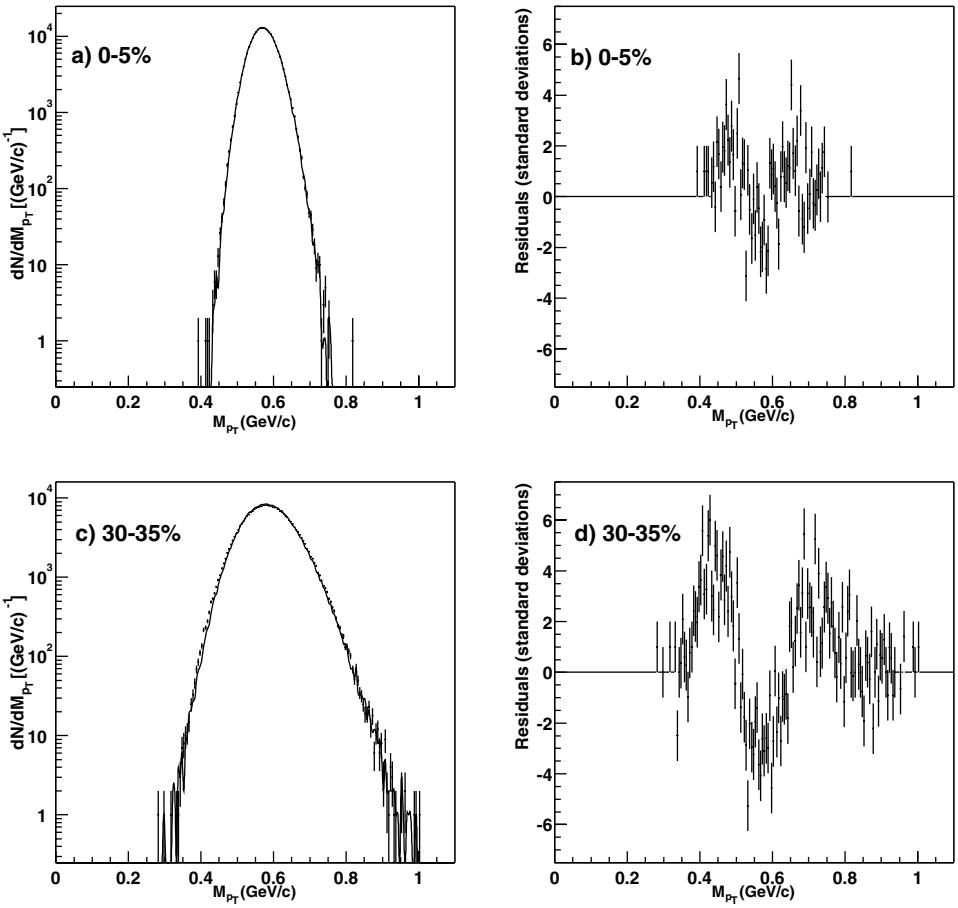

FIG. 1. Comparisons between the data and mixed event M_{p_T} distributions for the representative 0%–5% and 30%–35% centrality classes. Plots (a) and (c) show direct comparisons of the data (points) and normalized mixed event (solid line) M_{p_T} distributions. Plots (b) and (d) show the residuals between the data and mixed events in units of standard deviations of the data points from the mixed event points.

distributions. Statistical errors are below $F_{p_T} = 0.05\%$ for all centralities. The systematic errors are determined by dividing the entire dataset into ten separate subsets for each centrality class and extracting the standard deviation of the F_{p_T} values calculated for each subset. From Fig. 2, a significant nonrandom fluctuation is seen that appears to peak in midcentral collisions. However, the magnitude of the observed fluctuations are within previously published limits [9]. In addition, the value of F_{p_T} for the most peripheral Au + Au collisions is consistent with, albeit slightly below, the value measured by the same PHENIX apparatus in minimum bias $\sqrt{s_{NN}} = 200$ GeV $p + p$ collisions. If the magnitude of F_{p_T} is entirely due to fluctuations in the effective temperature of the system [12], this measurement corresponds to a fluctuation of $\sigma_T/\langle T\rangle = 1.8\%$ at 0%–5% centrality and 3.7% at 20%–25% centrality.

To further understand the source of the nonrandom fluctuations, F_{p_T} is measured over a varying p_T range for which M_{p_T} is calculated, $0.2\ \mathrm{GeV}/c < p_T < p_T^{\max}$. Figure 3 shows F_{p_T} plotted as a function of $p_T^{\max}$ for the 20%–25% centrality class. A trend of increasing F_{p_T} for increasing $p_T^{\max}$ is observed for this and all other centrality classes. The majority of the contribution to F_{p_T} appears to be due to correlations of particles with $p_T > 1.0$ GeV/c, where F_{p_T} increases disproportionately to the small increase (only 14%) of N_{tracks} in this region.

The behavior of F_{p_T} as a function of centrality and p_T is similar to trends seen in measurements of elliptic flow [20]. The contribution of elliptic flow to the magnitude of F_{p_T} is investigated using a Monte Carlo simulation whereby events are generated with a Gaussian distribution of N_{tracks} particles determined by a fit to the data and a random reaction plane azimuthal angle, Φ, between 0 and 2π. Independent particles within an event are generated following the inclusive p_T distribution with azimuthal angles, ϕ, distributed according to collective elliptic flow described by the function $[dN/d(\phi - \Phi)] = 1 + 2v_2\cos[2(\phi - \Phi)]$. The values of the v_2 parameter are linearly parametrized as a function of p_T and centrality using PHENIX measurements of inclusive charged hadrons [20]. Only generated particles that lie within the PHENIX azimuthal acceptance are included in the calculation of M_{p_T}. This simulation estimates that the

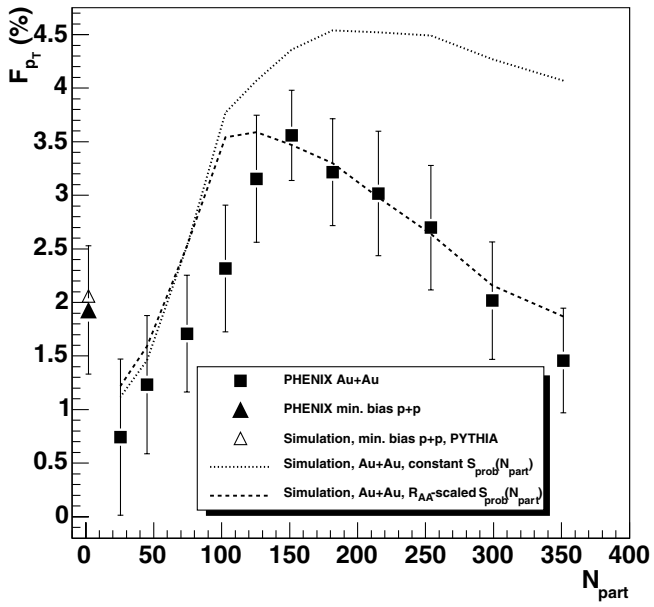

FIG. 2. F_{p_T} (in percent, $0.2\ \mathrm{GeV}/c < p_T < 2.0\ \mathrm{GeV}/c$) as a function of centrality, which is expressed in terms of the number of participants in the collision, N_{part}. The solid squares represent the Au + Au data. The solid triangle represents the minimum bias $p + p$ data point. The open triangle is the result from an analysis of PYTHIA minimum bias $p + p$ events within the PHENIX acceptance. The error bars include statistical and systematic errors and are dominated by the latter. The curves are the results of a Monte Carlo simulation with hard processes modeled using PYTHIA with a constant (dotted curve) and R_{AA}-scaled (dashed curve) hard-scattering probability factor, and include the estimated contribution due to elliptic flow.

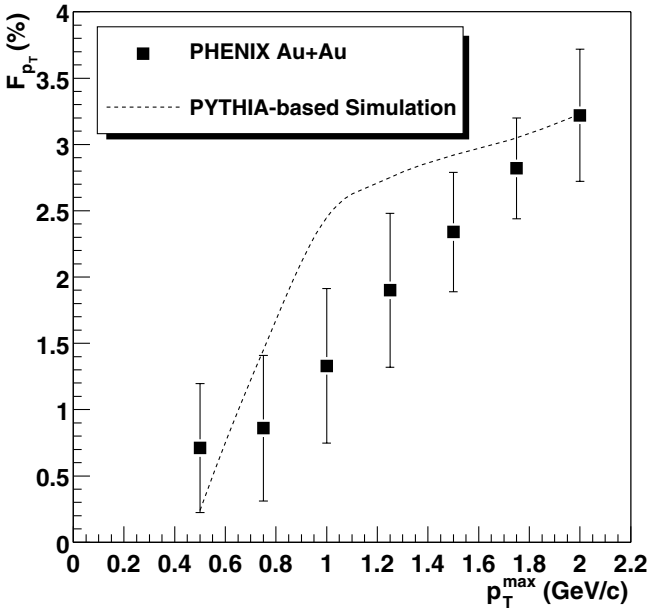

FIG. 3. F_{p_T} (in percent) of nonrandom fluctuations as a function of the p_T range over which M_{p_T} is calculated, $0.2\ \mathrm{GeV}/c < p_T < p_T^{\mathrm{max}}$, for the 20%–25% centrality class ($N_{\mathrm{part}} = 181.6$). The curve is the result of a Monte Carlo simulation with hard-scattering processes modeled using PYTHIA with $S_{\mathrm{prob}}(N_{\mathrm{part}}) = 0.075$ and $R_{AA} = 0.41$ [23]. The error bars include statistical and systematic errors and are dominated by the latter. The contribution of elliptic flow is estimated to be negligible at this centrality.

contribution of elliptic flow to F_{p_T} is largely canceled out by the symmetry of the PHENIX acceptance, and is negligible for central collisions. The estimated elliptic flow contribution to the value of F_{p_T} is less than 0.1% for $N_{\mathrm{part}} > 150$, increasing to about 0.6% for $N_{\mathrm{part}} < 100$. Note that F_{p_T} measured for minimum bias $p + p$ collisions, where collective flow is not expected to contribute, is nonzero ($1.9 \pm 0.6\%$), implying that a nonflow contribution may also be present in peripheral Au+Au collisions.

Figure 3 illustrates that a large contribution to the observed nonrandom fluctuations is due to the correlation of high p_T particles, such as might be expected from correlations due to jet production [21]. In order to estimate the contribution due to jets, a Monte Carlo simulation is again applied. Events are generated with a Gaussian distribution of N_{tracks} particles as independent particles that follow an m_T exponential fit to the inclusive data p_T distribution. Hard processes are defined to occur at a uniform rate per generated particle, $S_{\mathrm{prob}}(N_{\mathrm{part}})$, for each centrality class. This is the only parameter that is allowed to vary in the simulation. As Au + Au events are being generated, single $\sqrt{s_{NN}} = 200$ GeV $p + p$ hard-scattering events generated by the PYTHIA event generator [22] and filtered by the PHENIX acceptance are embedded into the event. The addition of the PYTHIA events affects the mean and standard deviation of the inclusive p_T spectra by less than 0.1%. The value of F_{p_T} has been extracted from 100 000 PYTHIA events for minimum bias $p + p$ collisions, yielding $F_{p_T} = 2.06\%$ within the PHENIX acceptance, which is consistent with the measured value of $F_{p_T} = 1.9 \pm 0.6\%$.

Two scenarios are considered for studies of the centrality dependence of jet contributions to the value of F_{p_T}: (i) with $S_{\mathrm{prob}}(N_{\mathrm{part}})$ set at a constant rate for all centrality classes, and (ii) with $S_{\mathrm{prob}}(N_{\mathrm{part}})$ scaled for each centrality class by the PHENIX measurement of the suppression of high p_T charged particles, which is characterized by the nuclear modification factor, R_{AA}, integrated over $p_T > 4.5\ \mathrm{GeV}/c$ [23]. The p_T value at which R_{AA} is extracted has little effect on the simulation results, which change by less than 0.2% for 0%–5% centrality if the R_{AA} measurement at $p_T = 2.0\ \mathrm{GeV}/c$ is used instead. The latter scenario is intended to model the effect of the suppression of jets due to energy loss in the nuclear medium [24] on the fluctuation signal. The initial value of $S_{\mathrm{prob}}(N_{\mathrm{part}})$ for both scenarios is normalized so that the F_{p_T} result from the R_{AA}-scaled simulation matches that of the data for the 20%–25% centrality class. The results of the simulation

as a function of $p_T^{\max}$, with $S_{\text{prob}}(N_{\text{part}})$ scaled by R_{AA}, are represented by the dashed curve in Fig. 3 for the 20%–25% centrality class, The trend of increasing F_{p_T} with increasing $p_T^{\max}$ observed in the data is reproduced by the simulation reasonably well.

The results of the two hard-scattering simulation scenarios are shown in Fig. 2 as a function of centrality. The model curves include the small contribution estimated from the elliptic flow simulation. The dotted curve is the result with $S_{\text{prob}}(N_{\text{part}})$ fixed for all centralities. The dashed curve is the result with $S_{\text{prob}}(N_{\text{part}})$ scaled by R_{AA} as a function of centrality. Within this simulation, the decrease of F_{p_T} for the more peripheral events is explained as a decrease in the signal strength relative to number fluctuations from the small and decreasing value of N_{tracks}. If $S_{\text{prob}}(N_{\text{part}})$ remains constant, the value of F_{p_T} decreases only slightly when going from midcentral to central collisions, in contradiction with the large decrease seen in the data over this centrality range. When $S_{\text{prob}}(N_{\text{part}})$ is scaled by R_{AA} as a function of centrality, the trend in the simulation of decreasing F_{p_T} with increasing centrality is more consistent with the data.

To summarize, the PHENIX experiment has observed a positive nonrandom fluctuation signal in event-by-event average transverse momentum, measured as a function of centrality and p_T in $\sqrt{s_{NN}} = 200$ GeV Au + Au and $p + p$ collisions. The increase of F_{p_T} with increasing p_T implies that the majority of the fluctuations are due to correlated high p_T particles. A Monte Carlo simulation that includes elliptic flow and a PYTHIA-based hard-scattering description can consistently describe contributions to the signal as a function of centrality and p_T with a simple implementation of jet suppression.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. The PHENIX Collaboration

Abstract

The PHENIX Electromagnetic Calorimeter (EMCal) is used to measure the spatial position and energy of electrons and photons produced in heavy ion collisions. It covers the full central spectrometer acceptance of $70^\circ \leqslant \theta \leqslant 110^\circ$ with two walls, each subtending 90° in azimuth. One wall comprises four sectors of a Pb-scintillator sampling calorimeter and the other has two sectors of Pb-scintillator and two of a Pb-glass Cherenkov calorimeter. Both detectors have very
