good energy, spatial and timing resolution, while the Pb-scintillator excels in timing and the Pb-glass in energy measurements. Also, having two detectors with different systematics increases the confidence level of the physics results. Design and operational parameters of the Pb-scintillator, Pb-glass and special readout electronics for EMCal are presented and running experience during the first year of data taking with PHENIX is discussed. Some examples of data taken during the first run are shown.

1. Introduction

The PHENIX detector [1] at the Relativistic Heavy Ion Collider is designed to measure the properties of nuclear matter at the highest temperatures and energy densities yet produced in terrestrial experiments and to search for new phenomena such as the quark-gluon plasma. The primary role of the Electromagnetic Calorimeter (EMCal) in PHENIX is to provide a measurement of the energies and spatial positions of photons and electrons produced in heavy ion collisions. It also plays a major role in particle identification and is an important part of the PHENIX trigger system. The EMCal system can trigger on rare events with high transverse momentum (p_T) photons and electrons. Its signals are incorporated in Level-1 triggers for high multiplicity or large total transverse energy (E_T) events. In addition the EMCal provides a good measurement of the *hadronic* energy produced at mid-rapidity and thus of the E_T produced in the reaction.

The EMCal system consists of a total of 24,768 individual detector modules divided between the Pb-Scintillator calorimeter, which provides six sectors of azimuthal coverage and the Pb-glass calorimeter comprised of two sectors. Both sub-detectors are read out with photomultipliers and have good energy resolution and intrinsic timing characteristics but their design is quite different and they will be described separately. A description of special EMCal front-end electronics is also given. The position of the EMCal relative to the rest of the PHENIX detector is illustrated in Fig. 2 in the article entitled "PHENIX Detector Overview" in this volume [1] and a view in a cut through the collision vertex is shown in Fig. 1 in the article entitled "PHENIX Central Arm Tracking Detectors" also in this volume [2].

The properties of the Pb-scintillator and Pb-glass calorimeters are very different and they have different strengths and weaknesses. The Pb-scintillator is a sampling calorimeter while the Pb-glass is a Cherenkov detector. For the two detectors the granularity, energy resolution, linearity, response to hadrons, timing properties and shower shape at normal and non-normal impact on the face of the tower differ significantly. For example, the Pb-glass has the best granularity and energy resolution but the Pb-scintillator has the best linearity and timing and the response to hadrons is better understood. Due to this the data analysis, particle identification cuts and the resulting systematic errors are also different and will be discussed in separate sections. Nevertheless choosing two different technologies was a deliberate decision by PHENIX which has the advantage of producing independent cross-checks of results within the same experiment.

2. Lead-scintillator calorimeter

The Pb-scintillator electromagnetic calorimeter is a shashlik type sampling calorimeter made of alternating tiles of Pb and scintillator consisting of 15,552 individual towers and covering an area of approximately 48 m^2. The basic building block is a module consisting of four (optically isolated) towers which are read out individually. The modules were manufactured in Russia and subjected to quality control procedures designed to

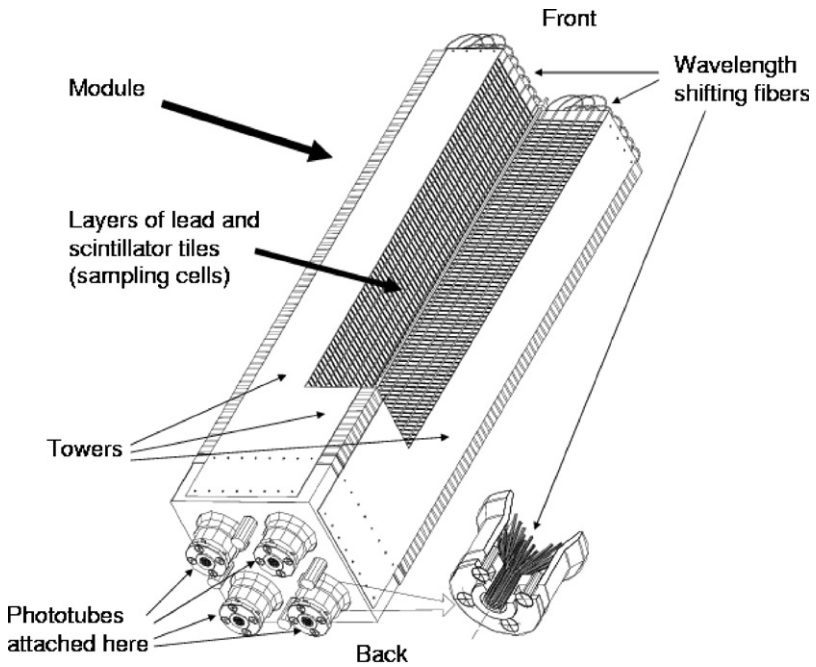

Fig. 1. Interior view of a Pb-scintillator calorimeter module showing a stack of scintillator and lead plates, wavelength shifting fiber readout and leaky fiber inserted in the central hole.

achieve consistent large light yield in all towers ($\sim 12,500$ photons/GeV). The PbSc calorimeter has a nominal energy resolution of $8.1\%/\sqrt{E(\mathrm{GeV})} \oplus 2.1\%$ and an intrinsic timing resolution better than 200 ps for electromagnetic showers [3]. A high precision calibration and monitoring system has been developed to achieve an absolute energy calibration better than 5% for day one operation at RHIC, and to maintain an overall long term gain stability of the order of 1%. Details of the two calorimeter types are given in Sections 2 and 3 below and the front-end electronics for both are discussed in Section 4.

2.1. Pb-scintillator calorimeter design

2.1.1. Opto-mechanical design

Each Pb-scintillator tower contains 66 sampling cells consisting of alternating tiles of Pb and scintillator. The edges of the tiles are plated with Al. These cells are optically connected by 36 longitudinally penetrating wavelength shifting fibers for light collection. Light is read out by 30 mm FEU115M phototubes at the back of the towers. Four towers are mechanically grouped together into a single structural entity called a module as shown in Fig. 1. Thirty six modules are attached to a backbone and held together by welded stainless-steel skins on the outside to form a rigid structure called a supermodule. Eighteen supermodules make a "sector", a $2 \times 4\ \mathrm{m}^2$ plane with its own rigid steel frame. Details of the design and methods of construction of the Pb-scintillator modules have been given in an earlier publication [4]. All major Pb-scintillator design parameters are listed in Table 1. The scintillating plastic contains an organic scintillator p-bis[2-(5-phenyloxazolyl)]-benzene (POPOP) and a fluorescent additive p-terphenyl (PT).

2.1.2. Monitoring system design

The calibration and monitoring system is based on a UV laser which supplies light to the calorimeter through a series of optical splitters and fibers. The block diagram of the monitoring system is shown schematically in Fig. 2 [5].

Table 1
Individual Pb-scintillator calorimeter tower parameters

Parameter	Value
Lateral segmentation	5.535×5.535 cm^2
Active sampling cells	66
Scintillator	Polystyrene (1.5% PT/0.01% POPOP), 0.4 cm
Absorber	Pb, 0.15 cm
Cell thickness	0.56 cm (0.277 $X_\circ$)
Active depth	37.5 cm
Radiation length	18
Nuclear interaction Length	0.85
WLS fiber	BCF-99-29a, 0.1 cm
WLS fibers per tower	36
PMT type	FEU115M, MELS, Russia, 3.0 cm
Photocathode	Sb–K–Na–Cs
Luminous sensitivity	$\geqslant$80 μa/lm
Rise time (20–80%)	$\leqslant$5 ns

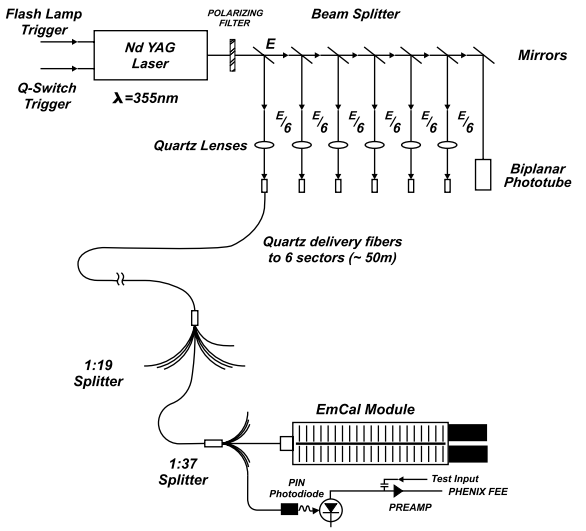

Fig. 2. Laser light distribution and monitoring system.

Light from a high power YAG laser is initially split into six equal intensity beams using a set of partially reflecting mirrors. The beam from each mirror passes through a quartz lens and is focused to a point just in front of a quartz fiber which is used to transport the light over a distance of approximately 50 m to one sector of the calorimeter. Optical splitters are used to distribute the light to each of the individual calorimeter modules. At the very last stage the light is injected into a 38 cm long, 2 mm diameter plastic fiber that penetrates the center of the module (there is a small gap in the optical isolation of the towers). This "leaky fiber" is grated such that light exits along its length simulating the depth profile of a 1 GeV electromagnetic shower in the four surrounding towers. The overall efficiency to produce one photoelectron in each of the 15,592 towers from the primary photons of the laser is of the order of 4×10^{-12}. Given that the calorimeter has an intrinsic light output of $\sim$1500 photoelectrons per GeV, this leads to an energy requirement of $\sim$0.2 mJ per pulse from the YAG laser to deliver 1 GeV of equivalent energy into each tower.

2.2. Energy calibration and gain monitoring

The initial calibration coefficients were established as follows. The calorimeter response to cosmic ray muons penetrating the supermodule in a direction nearly orthogonal to the tower axis was recorded along with the response to laser pulses. The absolute energy scale for muons was in turn established by test-beam measurements using electrons of known energy [4]. During the same test-beam exposure the response to relativistic (1 GeV/c)$\pi^{\pm}$ charged particles which traverse the calorimeter was characterized by the minimum ionizing peak (MIP).

A lego plot of the energies deposited by a laterally penetrating muon in neighboring towers of a supermodule is shown in the bottom left plot of Fig. 3. The top left plot in the same figure shows the energy spectrum in one tower exposed to laterally penetrating muons. The MIP peak corresponds to 38 MeV in this case (270 MeV for longitudinally traversing particles) and has a nearly gaussian shape with $\sigma(E)/E \sim 30\%$. On average the EMCal towers produce 12,500 photons per GeV of deposited electromagnetic energy. The distribution of the light yield (normalized to an average value) for $\sim$8000 towers is also shown in the same figure. Both the precalibration and original light yield measurements were performed with a "standard set" of phototubes,

whose quantum efficiencies and gains differ from the actual tubes used in the final assembly. The laser monitoring system was used to transfer the initial calibration into the RHIC operational environment. After renormalization, the dispersion in the actual response of each tower with respect to the original muon calibration was only 2.3%. This residual dispersion is due mainly to the non-uniformities in the quantum efficiencies of the phototubes over the active photocathode area. The implemented scheme for calorimeter precalibration and further monitoring ensured a very low uncertainty in the absolute energy scale for day one operation at RHIC, well below the design goal of 5%.

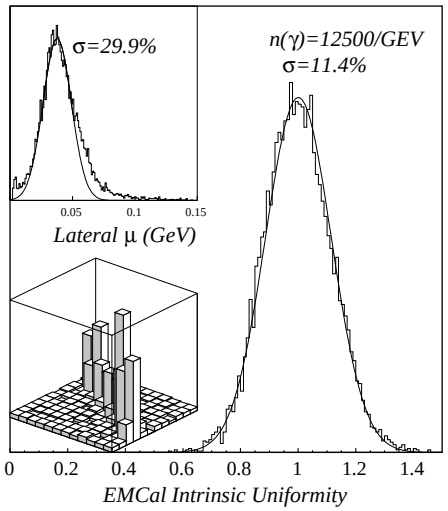

Fig. 3. Light yield uniformity in the Pb-scintillator calorimeter. The energy distribution in the towers exposed to laterally penetrating cosmic muons is shown in the top left inset and a lego plot of energies deposited in the towers by laterally penetrating cosmic muons is shown at the bottom left.

2.3. Energy and position measurements with the test beam

The Pb-scintillator calorimeter went through a rather extensive sequence of preconstruction tests in the particle beams from U70 (IHEP, Protvino), from the AGS (BNL) and finally from the SPS (CERN). The correlation plot between the incident beam energy and the energy measured in the calorimeter is presented in Fig. 4. Data are normalized to 1 GeV. The finite light attenuation length (100 cm) in the WS fibers is a major contributor to the response non-uniformities at the low end of the energy scale, although this effect

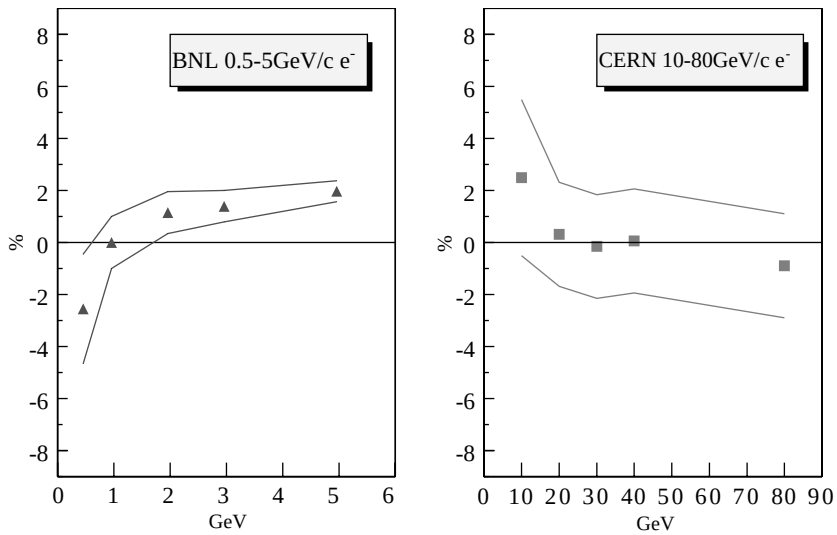

Fig. 4. Pb-scintillator EMCal energy linearity measured in beam tests at BNL (left) and CERN (right). The residual (calorimeter measured energy less the beam energy, divided by the beam energy) is for the 5×5 tower energy sum. The solid lines show total systematic uncertainties in the analysis.

is mitigated by the fact that each fiber is looped back (see Fig. 1), and the light collected always has a short and a long path to the phototube. Other contributors at low energies are coarse sampling [6] and energy leakage at the front face [7]. At high momenta the "positive" effect of the light attenuation in the fibers is overcompensated by the "negative" effect of energy leakage from the back of the calorimeter. The resulting nonlinearity is about a factor of 2 lower than what one would expect from the effect of light attenuation alone.

The calorimeter energy resolution (corrected for the noise contribution) is shown in Fig. 5. The resolution is given by

$$8.1\%\sqrt{E(\mathrm{GeV})}\oplus 2.1\%. \quad (1)$$

The 8.1% value for the stochastic term is close to the expected resolution from sampling as predicted by GEANT.

The main contributors to the constant term are intrinsic non-uniformities, in particular tower boundaries, hot spots at fiber positions and shower depth fluctuations. (The latter are responsible for the variations in the amount of the light seen and in the energy leaking from the calorimeter via the front and back surfaces.)

In order to study the lateral response non-uniformity, different areas of the calorimeter were exposed to 1 GeV/c electrons whose impact point was measured to better than 3 mm. The response variation was $\pm 2.5\%$. The 8% loss in the calorimeter response from particles hitting the corner of the towers is the main factor in the relatively large constant term in the expression for the energy resolution.

The depth of the Pb-scintillator electromagnetic calorimeter measured in units of nuclear interaction length at normal incidence is 0.85 L_{abs}. Lineshapes for protons and pions are shown in Fig. 6 along with electrons of the same momentum for comparison.

Both simulated (GEANT) and experimental data (taken at different impact angles) show that the measured shower shape (the projection onto the front face of the calorimeter) becomes skewed for non-normal angles of incidence. The data also show a gradual spread of the shower core mainly related to the longitudinal shower fluctuations contributing to the observed width, which in turn depends on impact angle θ as

$$b(\theta) = b_0 \oplus a(E) \times \sin^2(\theta) \quad (2)$$

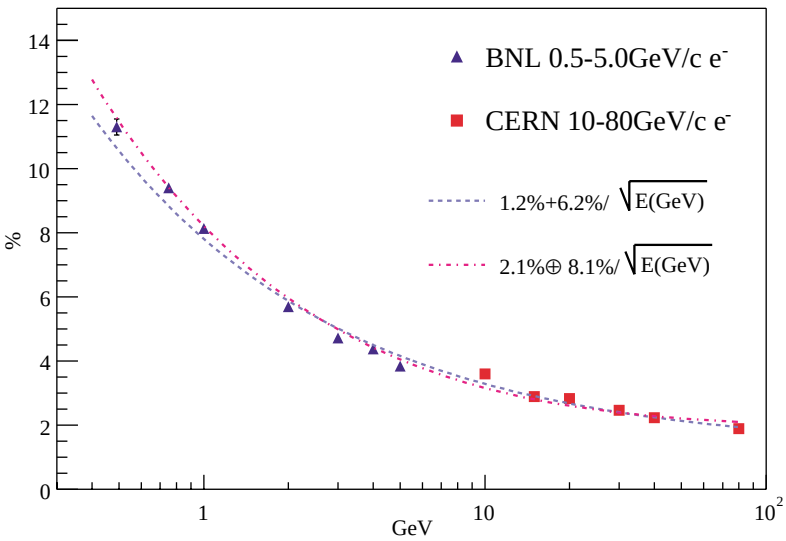

Fig. 5. Pb-scintillator EMCal energy resolution obtained by beam tests at CERN and BNL. The dashed line shows a fit to the linear formula $\sigma(E)/E = 1.2\% + 6.2\%/\sqrt{(E(\mathrm{GeV}))}$. The dashed-dotted line shows the fit to the quadratic formula $\sigma(E)/E = 2.1\% \oplus 8.1\%/\sqrt{(E(\mathrm{GeV}))}$.

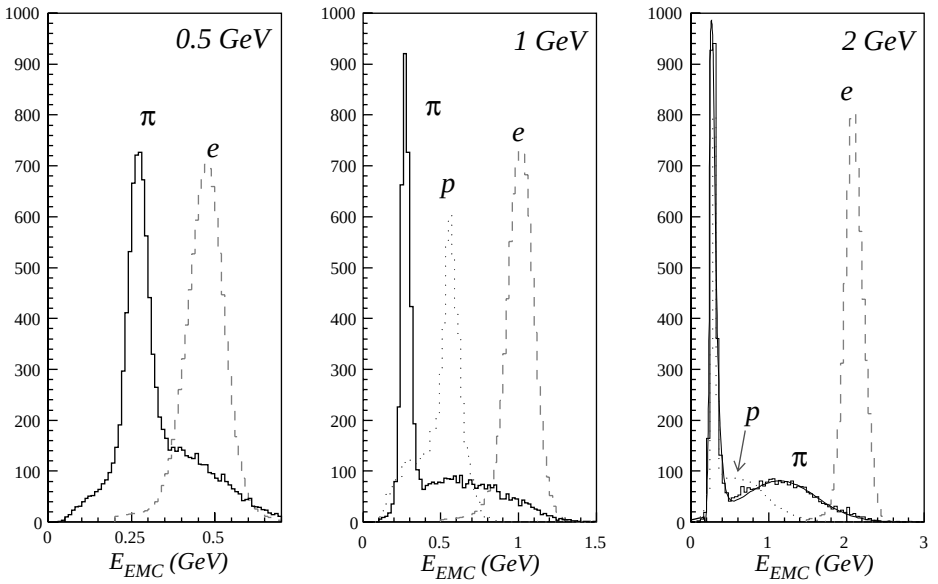

Fig. 6. The energy spectra measured in the PHENIX EMCal when exposed to electrons, pions and protons of 0.5, 1 and 2 GeV/c.

where $b_0 = 7.3$ mm is the average width of 1 GeV electromagnetic showers for $\theta = 0$ (orthogonal impact). At larger angles the contribution from longitudinal fluctuations becomes dominant and the position resolution degrades. All available data on position resolution can be well described by the simple formula

$$\sigma_x(E,\theta) = \sigma_0(E) \oplus \Delta \times \sin(\theta) \tag{3}$$

where

$$\sigma_0(E) = 1.55 \oplus \frac{5.7}{\sqrt{E}}(\text{mm}), \quad E(\text{GeV}) \tag{4}$$

is the position resolution for normal incidence and $\Delta \sim L_{\text{rad}}$.

2.4. Particle identification with the Pb-scintillator calorimeter

2.4.1. Effect of shower-shape measurements on photon identification and hadron rejection

Since electromagnetic and hadronic particles produce quite different patterns of energy sharing between calorimeter towers, second moments of the measured showers are often used to differentiate between them. However, in an earlier paper [8] we introduced a model which uses an analytical parametrization of the energy sharing and its fluctuations based upon measurements of identified electrons. The parameterization is used to compute $\chi^2 = \sum_i (E_i^{\text{pred}} - E_i^{\text{meas}})^2/\sigma_i^2$ where E_i^{meas} is the energy measured in tower i and E_i^{pred} is the predicted energy (using the parametrization and the actual measured impact point) for an electromagnetic particle of total energy $\sum_i E_i^{\text{meas}}$. This χ^2 value characterizes how "electromagnetic" a particular shower is and can be used to discriminate against hadrons. The important new feature of this model is that the fluctuations are also parameterized. Therefore, the resulting χ^2 distribution is close to the theoretical one and it is nearly independent of the energy or the impact angle of the electron. The χ^2 distributions for 2 GeV/c electrons and pions (with energy deposit above minimum ionization) are shown in Fig. 7. The arrow marks the χ^2 cut corresponding to 90% electron efficiency.

2.4.2. Time-of-flight measurements with the calorimeter

Timing information from the calorimeter is used both for particle identification and in the pattern

recognition to find overlapping showers. In particular, timing is the only tool to reject neutral baryons, and interacting antineutrons are a major contributor to clusters with energy ~ 2 GeV. Also, large inconsistencies between the measured times in different towers of the same cluster often indicate the overlap of two particles with very different time-of-flight.

Slew corrected arrival times measured by exposing the calorimeter to electrons, pions and protons at 1 GeV/c momenta are shown in Fig. 8 (top). The distribution for electrons has a perfectly Gaussian shape with only a few events in the tails. Both the pion and proton distributions show the presence of tails and are slightly asymmetric. The timing resolution curves (stochastic term) plotted in Fig. 8 combine the points measured by exposing the calorimeter to the particles in the 0.3–1.0 GeV/c momentum range.

For energy deposits in the calorimeter $\geqslant 0.5$ GeV the calorimeter timing resolution is nearly constant at ~ 120 ps for electrons and protons and ~ 270 ps for pions where shower fluctuations are the major contributor to the measured resolution. In general the data can be well fitted by the function:

$$\sigma_t = \sigma_{t0} + \sigma_{t1}/(E - E_{\text{threshold}}) \quad (5)$$

which includes a pole type divergence close to the threshold. Here σ_{t0} is an intrinsic timing resolution limit, presumably due to fluctuations in the localization of the shower, and σ_{t1} includes contributions due to photon statistics as well as pulse shape fluctuations.

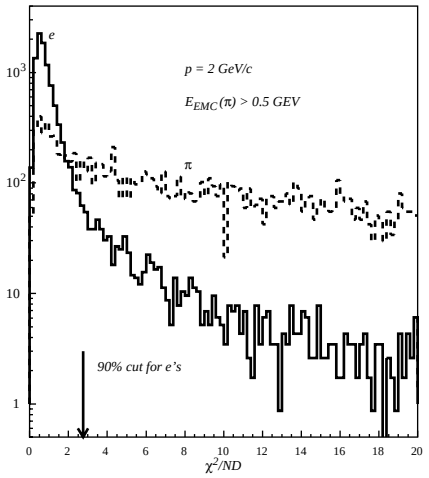

Fig. 7. χ^2 distribution for showers induced by 2 GeV/c electrons and pions in the Pb-scintillator calorimeter.

2.5. Pb-scintillator performance during first year running

Photons are identified using time-of-flight and showershape (χ^2) cuts. The inset in Fig. 9 shows the $\gamma\gamma$ invariant mass distribution for minimum bias data of the same reaction.

2.6. Summary for the Pb-scintillator calorimeter

We have designed and successfully constructed a 15,552 channel electromagnetic calorimeter covering a total area of 48 m^2 using an approach optimized for industrial mass production. We relied heavily on industrial style quality control procedures to insure conformity to physics specifications. The calorimeter has a light yield of $\sim 12{,}500$ photons/GeV of electromagnetic energy. The calorimeter has energy and position resolutions $\sim 8\%$ and ~ 7 mm, respectively, for 1 GeV photons and electrons at normal incidence and gives a π^0 mass with resolution of ~ 15 MeV. It has an excellent timing resolution of ~ 100 ps for electromagnetic and ~ 270 ps for hadronic showers which is nearly independent of the energy well above a threshold of about 10 MeV.

3. Lead-glass calorimeter

The Pb-glass calorimeter array comprises 9216 elements of a system previously used in CERN experiment WA98 [9]. It has a nominal energy resolution of $6\%/\sqrt{E(\text{GeV})}$ and an intrinsic timing resolution of better than 300 ps for electromagnetic showers above the minimum ionizing peak energy.

3.1. Pb-glass calorimeter design

3.1.1. Mechanical design

The Pb-glass calorimeter occupies the two lower sectors of the East Central arm of PHENIX. The

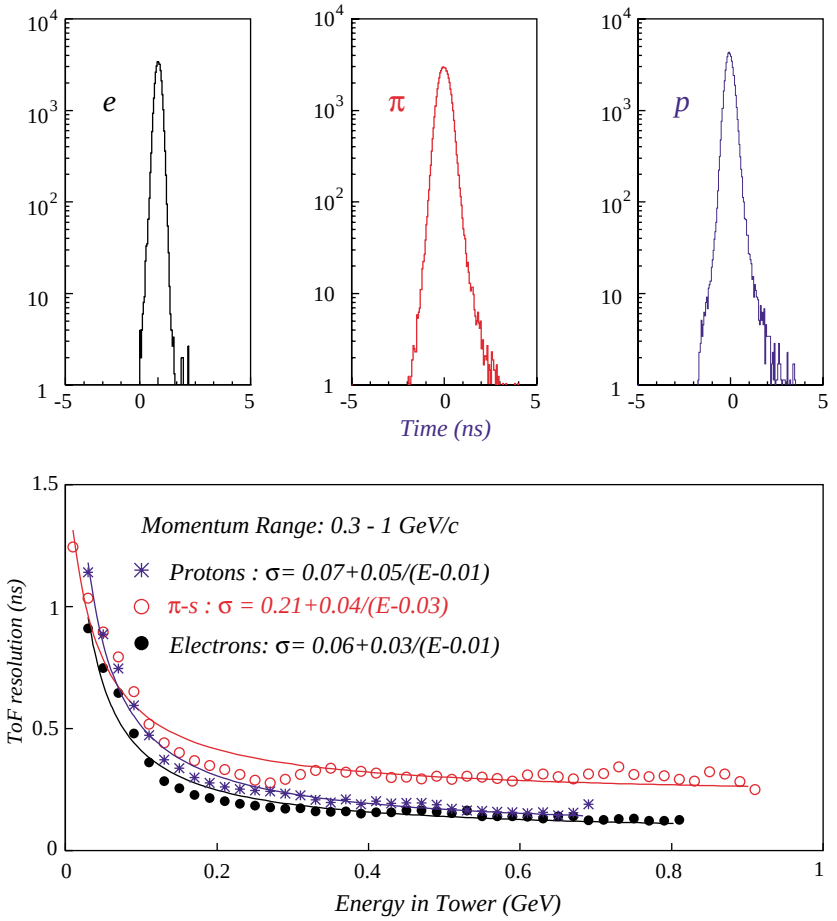

Fig. 8. Pb-scintillator timing resolution for different particles. Top: lineshape for 1 GeV/c electrons, pions and protons. Bottom: resolution in the momentum range 0.3–1.0 GeV/c.

PHENIX Time-of-flight system [10] is located on the Pb-glass sectors. Each Pb-glass sector comprises 192 supermodules (SM) in an array of 16 Pb-glass SM wide by 12 SM high as shown in Fig. 10. Each Pb-glass SM comprises 24 Pb-glass modules in a array of 6 Pb-glass modules wide by 4 modules high. Each Pb-glass module is 40 mm × 40 mm × 400 mm in size. The Pb-glass modules within a SM are individually wrapped with aluminized mylar and shrink tube and 24 modules are glued together with carbon fiber and epoxy resin to form a self-supporting SM with a shared calibration system (see Fig. 10). Steel sheets 0.5 mm in thickness were used to house the phototubes and bases. The sheets were incorporated during the gluing process. An aluminized plastic foil on the front of the SM contains a hole for each Pb-glass module which allows entry for the LED light used for gain monitoring. A polystyrene reflective dome encloses the LED system on the front surface of the SM.

Each Pb-glass module is read out with an FEU-84 photomultiplier. The high voltage for each photomultiplier is generated in a Cockcroft–Walton type photomultiplier base [11]. The high voltage for each module is individually controlled and read out with a custom VME based control system (HIVOC). Each HIVOC VME control

The insert shows the $\gamma\gamma$ invariant mass distribution for minimum bias data of the same reaction. Closed squares show measured widths and open circles show simulated widths.

module can control up to 2048 photomultipliers. Six PbGl SMs, 2 SM wide by 3 SM high, (144 individual Pb-glass modules) are read out with a single Front End Electronics (FEE) motherboard. The physical parameters of the Pb-glass detector system are summarized in Table 2.

3.1.2. Calibration and monitoring system

Each Pb-glass supermodule (SM) has its own gain monitoring system based on a set of 3 LEDs which are viewed by all 24 Pb-glass modules within a SM [12]. Three LEDs with different characteristics are employed. They are a fixed amplitude avalanche yellow LED with pulse shape most like real showers together with a yellow and a blue LED which have amplitudes which may be varied. The absolute light yields of the LEDs of each SM are monitored by a photodiode which, together with preamp, is permanently attached to the SM. The photodiode-normalized avalanche yellow LED signal observed in each Pb-glass module was calibrated in GeV-equivalents using 10 GeV electrons in the CERN X1 beamline in Fall 1993 and Spring 1994. The GeV equivalent of the avalanche yellow LEDs in individual modules ranged from 5 to 10 GeV. The Pb-glass calibration has been maintained to within approximately 10% for PHENIX using the LED/photodiode system.

3.2. Test beam performance

The response of the Pb-glass electromagnetic calorimeter was studied extensively in test beams at the AGS(BNL) and SPS(CERN) to investigate the performance of the device with respect to energy, position and timing measurements and their variation with energy, position and angle of incidence.

3.2.1. Energy and position measurements

The measured energy resolution of e^+ showers versus the incident energy is shown in Fig. 11 for various angles of incidence on the calorimeter surface. The energy resolution results of Fig. 11 are shown with the fit parameterization

$$\frac{\sigma(E)}{E} = \frac{[5.9 \pm 0.1]\%}{\sqrt{E/\mathrm{GeV}}} \oplus [0.8 \pm 0.1]\%. \quad (6)$$

The measured position resolution can be fit with the parameterization

$$\sigma_x(E) = \frac{[8.4 \pm 0.3]\mathrm{mm}}{\sqrt{E/\mathrm{GeV}}} \oplus [0.2 \pm 0.1]\ \mathrm{mm}. \quad (7)$$

3.2.2. Particle identification

The EMCal is designed to identify and measure the total energy of electrons and photons. The identification is assisted by the fact that hadrons typically do not shower or they deposit only a small fraction of their total energy in the calorimeter, since it is only about one interaction length in thickness (see Table 2). The hadron response of the PbGl calorimeter is further reduced by the fact that it observes only Cherenkov light. The Cherenkov threshold momenta (energies) for muons, pions and protons are 81, 106 and 715 MeV/c (27, 36 and 241 MeV), respectively. When the hadron momenta fall below

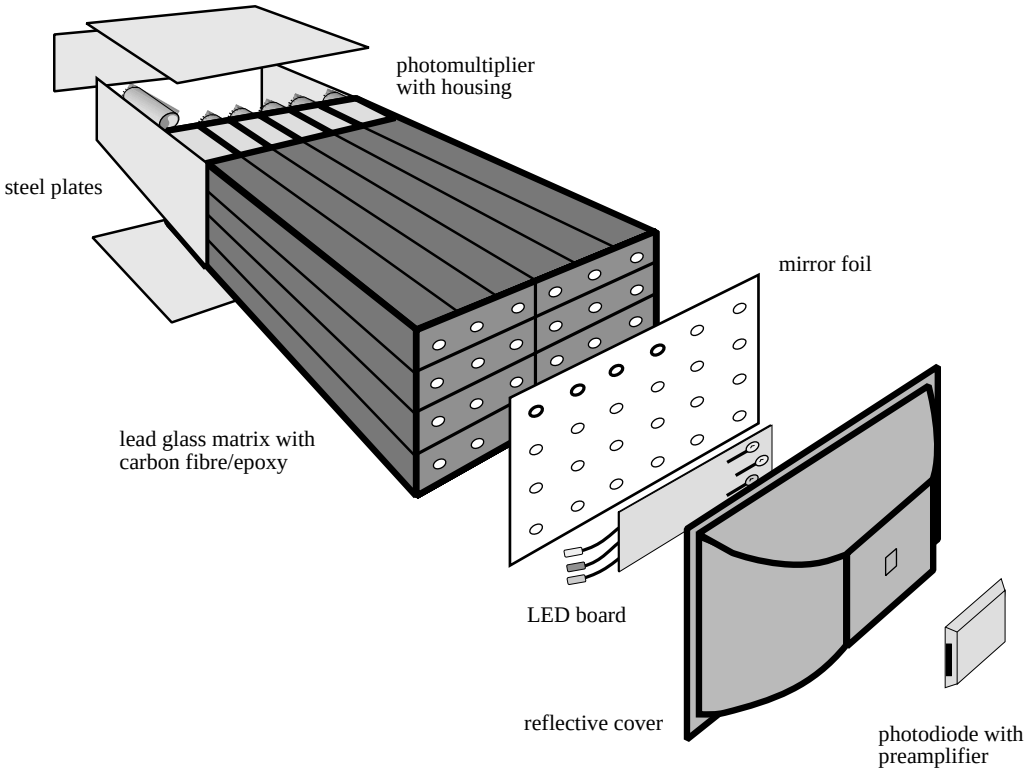

Fig. 10. Exploded view of a lead-glass detector supermodule.

these thresholds they will no longer produce Cherenkov light and their signal will be reduced. This is illustrated in Fig. 12 for 1 GeV/c protons and pions in comparison to electrons. The pions show a peak at around 460 MeV on a broad tail below the peak while the protons peak at around 80 MeV. At 4 GeV/c both protons and pions show a peak at about 540 MeV. At 500 MeV/c no significant signal is observed for protons and the pions show only a broad plateau from 0 to 500 MeV. At 150 MeV/c muons and pions deposit 55 and 25 MeV of apparent energy, respectively, when the electron signal is normalized to 150 MeV.

When the momentum of the charged hadron is measured in the PHENIX tracking system, the mismatch between the measured momentum and the deposited energy in the EMCal can be used to differentiate between hadrons and electrons. This is illustrated in the lower panel of Fig. 12. Using the fact that a 1 GeV/c track has been identified by the tracking system, the figure illustrates the fraction of electron tracks which would be accepted, as well as the fraction of pion tracks rejected, as a function of the required corresponding energy deposit in the Pb-glass. The pion rejection factors which can be obtained for various electron acceptance fractions as a function of the incident energy are shown in Fig. 13. An additional factor of about 2 can be obtained based on differences in the shower shape for hadrons which deposit the same energy as electromagnetic energy above about 1 GeV of energy deposit.

3.2.3. *Time-of-flight measurements*

The EMCal provides time-of-flight information to assist with hadron identification in the tracking system and to reject neutron and anti-neutron showers. The measured time-of-flight resolution as a function of the energy deposited in a single Pb-glass module is shown in Fig. 14 for electrons of various incident energies and pions of 1 GeV/c.

Table 2
Lead-glass physical parameters

Quantity	Value
Geometry:	384 Super Modules
Number of SM per sector	192 (16 wide by 12 high)
Number of modules per SM	24 (6 wide by 4 high)
Total number of modules	9216
Module gront surface	4 cm × 4 cm
Module length	40 cm ($14.4X_0$)
Mylar foil thickness	12 μm
Shrink tube thickness	150 μm
Super module front surface	24.6 ± 0.02 cm × 16.4 ± 0.02 cm
Pb-glass: Type	TF1
Pb-oxide content	51%
Density	3.85 g/cm^2
Weight per module	2.46 kg
Index of refraction	1.648
Total internal reflection angle	36°
Radiation length	2.8 cm
Moliere radius	3.68 cm
Interaction length	38.0 cm
Critical energy	16 MeV

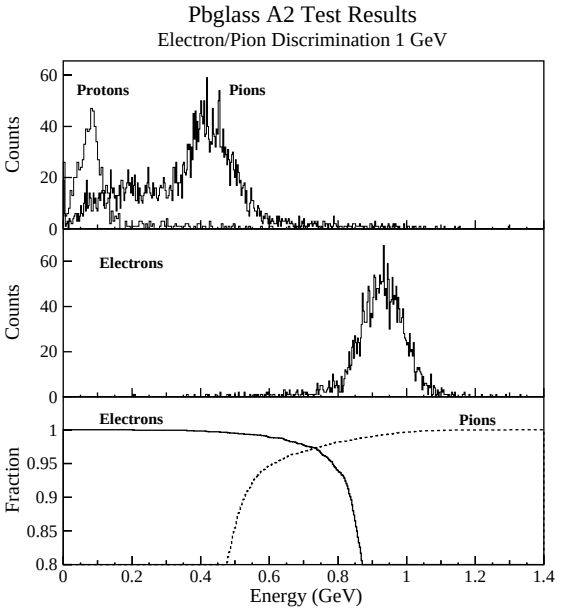

Fig. 12. Measured energy signal for protons, π^+ and e^+ of 1 GeV/c incident momentum. The lower panel shows the fraction of e^+ accepted or π^+ rejected for a varying threshold on the measured energy.

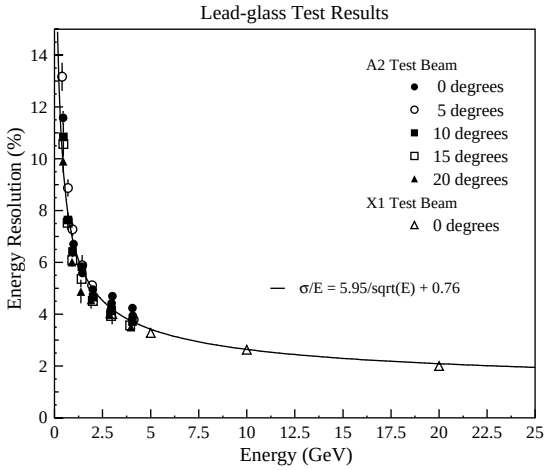

Fig. 11. PbGl energy resolution versus incident energy.

The timing resolution can be parameterized in the form

$$\sigma_t(E_{\mathrm{Dep.}}) = \frac{3.75\ \mathrm{ns}}{\sqrt{500 E_{\mathrm{Dep.}}/\mathrm{GeV}}} \oplus 0.075\ \mathrm{ns}. \qquad (8)$$

The intrinsic timing resolution is seen to be similar for electromagnetic showers and decreasing with the increasing energy deposit according to the light produced (about 500 photoelectrons per GeV). The resolution falls below 200 ps in the upper range of momenta of interest to PHENIX. However, the use of the timing information from the PbGl is complicated by the fact that the arrival time of hadrons or hadron showers which pass through the PbGl (those which deposit more than about 500 MeV) have apparent arrival times which are about 800 ps faster than an electron of the same momentum. This is due to light from the faster transit time of the hadron to the rear of the lead-glass module compared to that of the Cherenkov light from the electromagnetic shower produced near the front of the module.

3.3. Pb-glass calorimeter performance in PHENIX

One full sector of the Pb-glass calorimeter was fully instrumented for the first PHENIX run

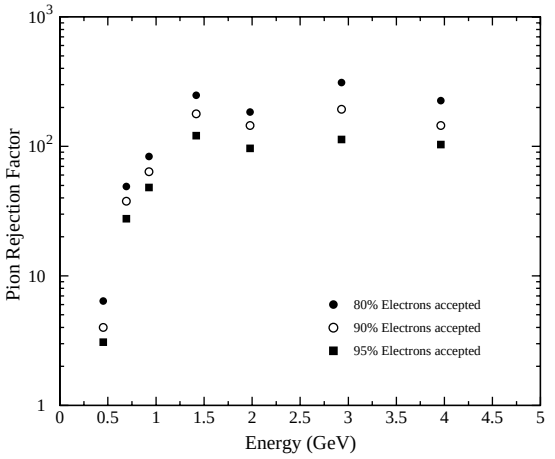

Fig. 13. Pion rejection factor versus incident energy.

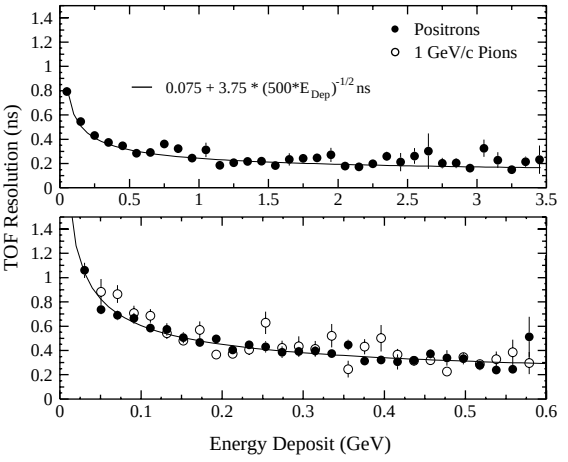

Fig. 14. Pb-glass timing resolution versus energy deposit in a single module for positrons of incident momenta 0.5, 0.75, 1.0, 1.5, 2,3 and 4.0 GeV/c and for 1.0 GeV/c pions.

period at RHIC with Au beams. An example of the performance is shown in Fig. 15 where the π^0 peak is observed in the two photon invariant mass distribution. The result is shown for peripheral Au–Au collisions at $\sqrt{s} = 130$ GeV per nucleon for photon pair transverse momentum in the range of 1.5–2.0 GeV/c.

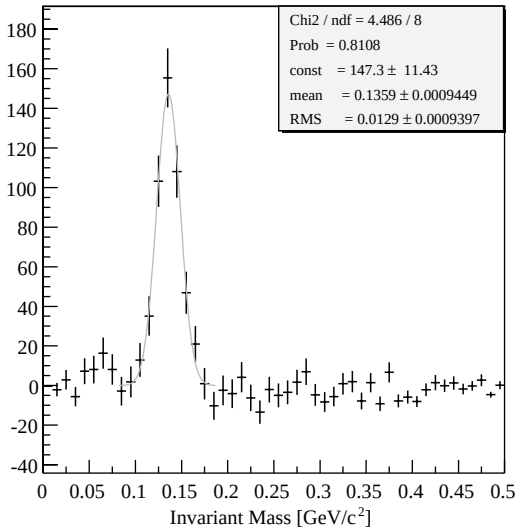

Fig. 15. The two photon invariant mass distribution after subtraction of the combinatorial pair background. The result is shown for peripheral Au–Au collisions at $\sqrt{s} = 130$ GeV per nucleon for photon pair transverse momentum in the range of 1.5–2.0 GeV/c.

4. Calorimeter front-end electronics

The readout electronics for the EMCal system conform to the general PHENIX Front-End Electronics (FEE) scheme [13] which includes periodic sampling synchronous with the RHIC RF clock and pipelined, deadtime-less conversion and readout. This section describes those features unique to the EMCal readout electronics and the way in which they satisfy the needs of the physics measurements made with the EMCal detector. Analog processing, digital processing and triggering are discussed below in Sections 4.1–4.3, respectively.

4.1. Analog processing

On every event, for either physics or calibration data, each EMCal PMT emits a negative current pulse and each of these is processed by a chain as shown in Fig. 16. The salient features of the chain are discussed below.

There is no preamp or shaping stage other than passive integration. The 93 Ω resistor terminates

the signal line from the PMT so the voltage profile at point A in Fig. 16 simply follows the current profile from the PMT which is a pulse with a $\leqslant 5$ ns rise time. The charge is collected onto the 500 pF capacitor so the voltage profile at point B in Fig. 16 follows the integral of the current. The current pulse is a step function with a ~ 100 ns rise time. The large resistor sets the quiescent voltage at this stage to +4 V to allow for negative-going pulses.

The fast voltage pulse discussed above is the "timing signal" that is used to measure the arrival time of the EM shower in the detector. During the pulse integration process a voltage step function is generated whose height is proportional to the total charge collected and thus the energy.collected during the time window of the event. All of the remaining analog processing stages up to ADC conversion are carried out within an ASIC [14] chip, as illustrated in Fig. 16. This chip was custom designed for the EMCal system. Each of these ASIC chips services four PMT channels and also contains the circuitry for the fast trigger function which is described below.

In the arrival time measurement the voltage pulse is discriminated, either in a leading-edge mode or a constant-fraction mode. The choice of mode, as well as the threshold voltages, are remotely selected in situ via ARCNet [13] which is the system used for monitoring and slow control of the PHENIX FEMs. The discriminator firing starts a voltage ramp generator. The ramp is stopped on the next edge of the RHIC clock providing a *common-stop mode* TAC for each channel. After stopping the ramp voltage is held for two clock cycles where it settles and is then sampled and converted in the AMU/ADC stage (see Section 4.2). The final reported ADC value then varies linearly with the pulse arrival time. The relationship between time and the resulting ADC output voltage can be adjusted by programming the ramp slope and offset voltage remotely via ARCNet.

The energy signal is first put through a Variable Gain Amplifier (VGA). Each PMT channel has its own VGA and each of whose gains can be set remotely in the range $\times 4$–$\times 12$ with 5-bit resolution. This allows the readout electronics to compensate, to within a few percent over its range, for gain variations among PMTs which share the same high voltage supply. Uniform response for the energy signal is useful in the performance of the trigger circuit (see Section 4.3) and in general for maximizing the use of the ADC dynamic range for all channels.

The dynamic range of physics signals from the EMCal is quite large and the detector is expected to resolve energy deposits from 20 MeV up to 15–30 GeV with a noise contribution from the electronics of no more than 0.1% for large signals and 5 MeV for small signals. This range is impossible to cover with a single 12-bit ADC

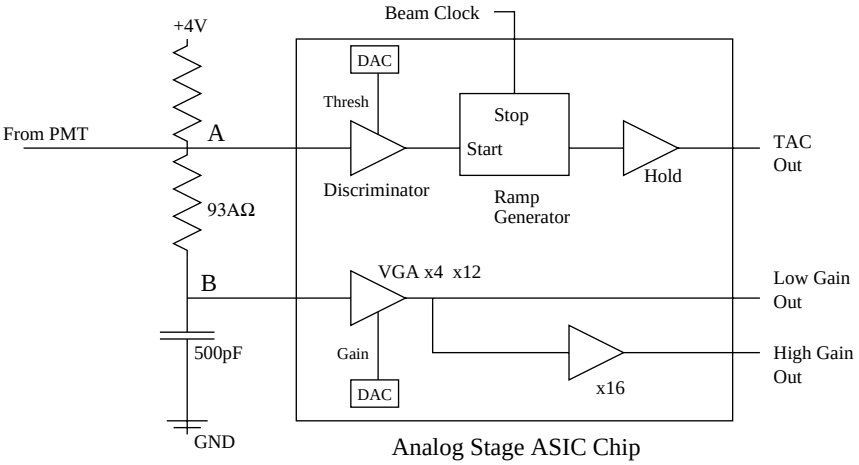

Fig. 16. Block diagram of the energy and timing measurement circuits.

conversion. Thus the energy signal is converted twice with two different levels of amplification. The "low gain" signal is converted straight from the VGA and the "high gain" signal is converted separately after a second stage of $\times 16$ amplification. The results of both conversions are available when the digital output packet is assembled as discussed in Section 4.2.

4.2. Conversion and digital processing

The voltage waveforms from the high- and low-gain energy stages and the TAC for each channel are sampled once per RHIC clock tick and stored in a series of Analog Memory Units (AMUs) as in several other PHENIX FEE systems [13]. Each waveform is sampled into a ring buffer of 64 AMUs, effectively preserving it for 64 RHIC clock ticks or about 7 μs, which easily covers the PHENIX LVL-1 (Level-1) trigger [13] latency of 40 RHIC clock ticks.

Upon receiving a LVL-1 Accept instruction the FEM identifies the energy and TAC AMU cells corresponding to the event. These AMU cells are then taken out of the ring buffer and converted in the ADC. The AMU rings and the ADC units are contained within another ASIC chip which was custom-designed for PHENIX and is used in several PHENIX readout systems. These ADC outputs are controlled, collected and reformatted by several Xilinx FPGAs, which are programmable remotely in situ. The formatted data "packet" for each event is then sent to a PHENIX Data Collection Module (DCM) [13] via GLINK across a PHENIX standard optical fiber.

4.3. EMCal fast trigger function

At design luminosities, the rate of basic interactions in both A–A and p–p running in RHIC is too high for PHENIX to digitize and record all events. Since it is an explicit goal of PHENIX to use the full available luminosity to measure rare processes such as the production of heavy flavors and very high-energy secondaries, an ability to trigger on such processes is necessary. The EMCal FEE provides a fast-trigger function intended to signal the presence of a high-energy shower in the EMCal detector. Electromagnetic showers with a large energy deposit (generally taken as above several GeV) are natural indicators of several kinds of interesting rare events, including high-energy photons and neutral mesons as well as high-energy electrons from heavy-flavor decays.

A traditional approach for a high-energy cluster trigger in a laterally segmented calorimeter is to make a fast analog sum of a group of towers and discriminate that sum against a threshold. In the simplest scheme each tower contributes to only one sum leaving the summed trigger groups disjointed. This arrangement has the drawback that the effective threshold is position dependent since showers which spread across more than one group need to have a much higher energy than those contained within one group.

The PHENIX EMCal fast trigger avoids this problem by summing over non-disjoint overlapping groups of towers. The design is illustrated in Fig. 17. Groups of 2×2 towers are served by one ASIC chip described above. Within each ASIC the four analog PMT signals are summed creating an array of disjoint 2×2 sums. To negate the influence of "hot" PMTs, each channel in each ASIC can be masked out of the sum individually by remote ARCNET control. Each ASIC relays copies of its signal generated by summing the current to three immediate neighbors. These are relayed between FEMs at supermodule boundaries making the trigger circuitry effectively seamless.

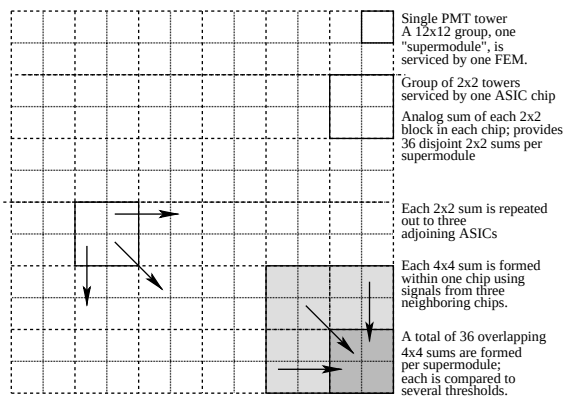

Fig. 17. Schematic of the EMCal fast trigger summing operation.

Each ASIC also receives three signals from its neighbors and combines them with its own to form a 4×4 sum. The entire circuitry then produces 36 overlapping 4×4 sums in each FEM. Within each ASIC the 4×4 sum signal is compared to three separate thresholds, each remotely programmable, to provide extra flexibility for different physics processes.

The PHENIX Collaboration

Abstract

The PHENIX detector is designed to perform a broad study of A–A, p–A, and p–p collisions to investigate nuclear matter under extreme conditions. A wide variety of probes, sensitive to all timescales, are used to study systematic variations with species and energy as well as to measure the spin structure of the nucleon. Designing for the needs of the heavy-ion and polarized-proton programs has produced a detector with unparalleled capabilities. PHENIX measures electron and muon pairs, photons, and hadrons with excellent energy and momentum resolution. The detector consists of a large number of subsystems that are discussed in other papers in this volume. The overall design parameters of the detector are presented.

1. Introduction

The Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory accelerates nuclear beams from protons to gold. For the heaviest beams an energy of 100 GeV/nucleon is reached. Four detectors, BRAHMS, PHENIX, PHOBOS and STAR, are operating to study collisions ranging from p–p to Au–Au. The Pioneering High Energy Nuclear Interaction eXperiment (PHENIX) is carried out by a collaboration of about 500 physicists and engineers from 54 participating institutions in 13 countries [1]. Fig. 1 shows a subset of the Collaboration standing in front of parts of the PHENIX detector.

The PHENIX experiment probes several fundamental features of the strong interaction. A prime goal for experiments with heavy ion beams is to produce a deconfined state of nuclear matter called the Quark Gluon Plasma (QGP) and study it's properties. This is thought to be the state of the universe a μs after its birth in the "big bang". Measuring leptons and photons probes the QGP phase directly, while studying the copiously produced hadrons gives information on the later hadronization of the QGP. RHIC also provides the opportunity to study collisions of polarized protons. The aim is to measure the spin structure of the nucleon [2].

In order to carry out this broad physics agenda the PHENIX detector utilizes a variety of detector technologies. It uses global detectors to characterize the collisions, a pair of central spectrometers at mid-rapidity to measure electrons, hadrons, and photons, and a pair of forward spectrometers to measure muons. Each spectrometer has a large geometric acceptance of about one steradian and excellent energy and momentum resolution and particle identification.

2. Physics goals of PHENIX

Quantum Chromodynamics (QCD) predicts that heavy nuclei colliding at ultrarelativistic energies will undergo a phase transition from hadronic matter to a deconfined state of quarks and gluons moving freely over a volume approximately 10 fm^3, namely the QGP.

This process can be thought of as proceeding through a series of steps from the initial collision through QGP formation (deconfinement) and

Fig. 1. Members of the PHENIX collaboration in front of the PHENIX detector.

possible chiral symmetry restoration. The QGP would thermalize followed by expansion and cooling leading to hadronization. PHENIX is able to probe each phase of the above process by virtue of its ability to study the rare processes involving photons, electrons and muons as well as the predominant hadronic production. The experiment has a high rate capability and fine granularity combined with excellent momentum, energy and mass resolution.

Direct photons and lepton pairs which emerge from the collision with a minimum of final state interaction are sensitive to the full time evolution from the initial state through thermalization. The capability to measure direct photons over a wide range of p_T is unique to PHENIX and is important for relating their momentum to the temperature of the emitting source.

Jets from the hard scattering of constituent quarks and gluons are produced in the initial state and are sensitive to the properties of the medium during the evolution so that a significant modification of the structure of the jet is expected if a QGP is formed. PHENIX studies the deconfined state and Debye screening by observing the yields of the J/Ψ and Ψ' relative to that of the Υ. Chiral symmetry restoration is predicted to result in the reduction of quark masses and possible changes in the lifetime and width of the ϕ and possibly the ρ and ω. All of the above vector mesons are studied by observation of their decays into lepton pairs.

After hadronization the expansion of the fireball is studied by measurement of Hanbury–Brown–Twiss correlations and the coalescence probabilities of various nuclei and anti-nuclei give insights into the space-time evolution of the collision. Precision time-of-flight (ToF) allows measurement of the identified charged hadron spectrum over a wide p_T range. Many of the above signals can also be produced from interactions between particles in hot hadronic matter. It is thus necessary to understand the purely hadronic effects. For this reason PHENIX studies the above signals using p–p and p–A collisions to gain a better understanding of effects distorting signals from the QGP.

A second major goal of the PHENIX experiment is to measure the spin structure of the nucleon. RHIC accelerates beams of polarized protons up to 250 GeV with polarizations up to 50%. Work of the EMC [3] collaboration and others indicated that the fraction of the proton spin carried by the quarks was only about half of the expected value. PHENIX studies the gluon polarization by measuring high p_T prompt photon production using the highly segmented EM Calorimeter to minimize interference from photons from π^0 decays. The anti-quark polarization is measured by observing the parity violating asymmetry for W production. The W particles are identified by the detection of muons or electrons with $p_T \geqslant 20$ GeV/c using the PHENIX north and south muon arms or the central spectrometer, respectively.

3. PHENIX detector subsystems

The PHENIX detector comprises four instrumented spectrometers or arms and three global detectors [4]. The detector consists of a number of subsystems. The rapidity and ϕ coverages and other features of these subsystems is given in Table 1 and a perspective drawing of the PHENIX detector with the major subsystems labeled is shown in Fig. 2. Also an overview of the subsystems is given below. The east and west central arms are centered at zero rapidity and instrumented to detect electrons, photons and charged hadrons. The north and south forward arms have full azimuthal coverage and are instrumented to detect muons. Each of the four arms has a geometric acceptance of approximately one steradian. The global detectors measure the start time, vertex and multiplicity of the interactions. A photograph of the PHENIX detector from above is shown in Fig. 3.

3.1. Global detectors

In order to characterize the nature of an event following a heavy ion collision, three global detectors are employed. They consist of Zero-Degree Calorimeters (ZDC), Beam-Beam Counters (BBC) and the Multiplicity-Vertex Detector (MVD). A pair of ZDCs [5] detect neutrons from grazing collisions and form a trigger for the most peripheral collisions. The ZDC is used by all four RHIC detectors and is discussed elsewhere in this volume [6]. A pair of BBCs [7] provide a measure of the ToF of forward particles to determine the time of a collision, provide a trigger for the more central collisions and provide a measure of the collision position along the beam axis. The MVD [7] provides a more precise determination of event position and multiplicity and measures fluctuations of the charged particle distributions. It is composed of concentric barrels of silicon-strip detectors and endcaps made of silicon pads. Recently a Normalization Trigger Counter (NTC) [7] has been added between the MVD endcaps and the central magnet pole tips. The NTC extends the coverage of the BBC for p–p and p–A running.

3.2. Central spectrometers

The magnetic field for the central spectrometer is supplied by the central magnet [8] that provides an axial field parallel to the beam and around the interaction vertex. The central arms consist of tracking systems for charged particles and electromagnetic calorimetry. The calorimeter [9] is the outermost subsystem on the central arms and provides measurements of both photons and energetic electrons. A lead-scintillator (PbSc) calorimeter is used for good timing and a lead–glass (PbGl) calorimeter gives good energy resolution.

The tracking system uses three sets of Pad Chambers (PC) [10] to provide precise three-dimensional space points needed for pattern recognization. The precise projective tracking of the drift chambers (DC) [10] is the basis of the excellent momentum resolution. A Time Expansion Chamber (TEC) [10] in the east arm provides additional tracking and particle identification. The ToF and Ring-Imaging Cherenkov (RICH) detectors also provide particle identification [11]. The 85 ps timing resolution of the ToF allows separation of kaons from pions up to 2.5 GeV/c and proton identification out to 5 Gev/c. For p–p

Table 1
Summary of the PHENIX detector subsystems

Element	$\Delta\eta$	$\Delta\phi$	Purpose and special features
Magnet			
Central (CM)	± 0.35	360°	Up to 1.15 T m
Muon (MMS)	-1.1–-2.2	360°	0.72 T m for $\eta = 2$
Muon (MMN)	1.1–2.4	360°	0.72 T m for $\eta = 2$
Silicon (MVD)	± 2.6	360°	$d^2N/d\eta\, d\phi$, precise vertex, Reaction plane determination
Beam–beam (BBC)	$\pm(3.1$–$3.9)$	360°	Start timing, fast vertex
NTC	$\pm(1$–$2)$	320°	Extend coverage of BBC for p–p and p–A
ZDC	± 2 mrad	360°	Minimum bias trigger
Drift chambers (DC)	± 0.35	$90^\circ \times 2$	Good momentum and mass resolution $\Delta m/m = 1.0\,\%$ at $m = 1$ GeV
Pad chambers (PC)	± 0.35	$90^\circ \times 2$	Pattern recognition, tracking for nonbend direction
TEC	± 0.35	90°	Pattern recognition, dE/dx Good momentum resolution for $p_T > 4$ GeV/c
RICH	± 0.35	$90^\circ \times 2$	Electron identification
ToF	± 0.35	45°	Good hadron identification, $\sigma < 100$ ps
T0	± 0.35	45°	Improve ToF timing for p–p and p–A
PbSc EMCal	± 0.35	$90^\circ + 45^\circ$	For both calorimeters, photon and electron detection and energy measurement
PbGl EMCal	± 0.35	45°	Good $e^\pm/\pi^\pm$ separation at $p > 1$ GeV/c by EM shower and $p < 0.35$ GeV/c by ToF $K^\pm/\pi^\pm$ separation up to 1 GeV/c by ToF
μ *tracker*			
(μTS)	-1.15 to -2.25	360°	Tracking for muons
(μTN)	1.15 to 2.44	360°	Muon tracker north installed for year-3
μ *identifier*			
(μIDS)	-1.15 to -2.25	360°	Steel absorbers and Iarocci tubes for
(μIDN)	1.15 to 2.44	360°	muon/hadron separation

running the ToF timing resolution would be poorer than for heavy ions due to a reduced number of particles in the BBC. The ToF timing is improved by the use of a T0 counter [11] outside the barrel of the MVD. This is needed for p–p and p–A experiments. The RICH provides separation of electrons from the large number of copiously produced pions. Using information from the RICH, the TEC and the electromagnetic calorimeter it is possible to reject pion contamination of identified electrons to one part in 10^4 over a wide range of momentum.

3.3. Muon spectrometers

The two forward muon spectrometers [12] give PHENIX acceptance for J/Ψ decaying into dimuons at rapidities of $-2.25 \leqslant y \leqslant -1.15$ for the south arm and $1.15 \leqslant y \leqslant 2.44$ for the north arm. Each spectrometer is based on a muon tracker inside a radial magnetic field [8] followed by a muon identifier, both with full azimuthal acceptance. The muon trackers consist of three stations of multi-plane drift chambers that provide precision tracking. The muon identifiers consist of

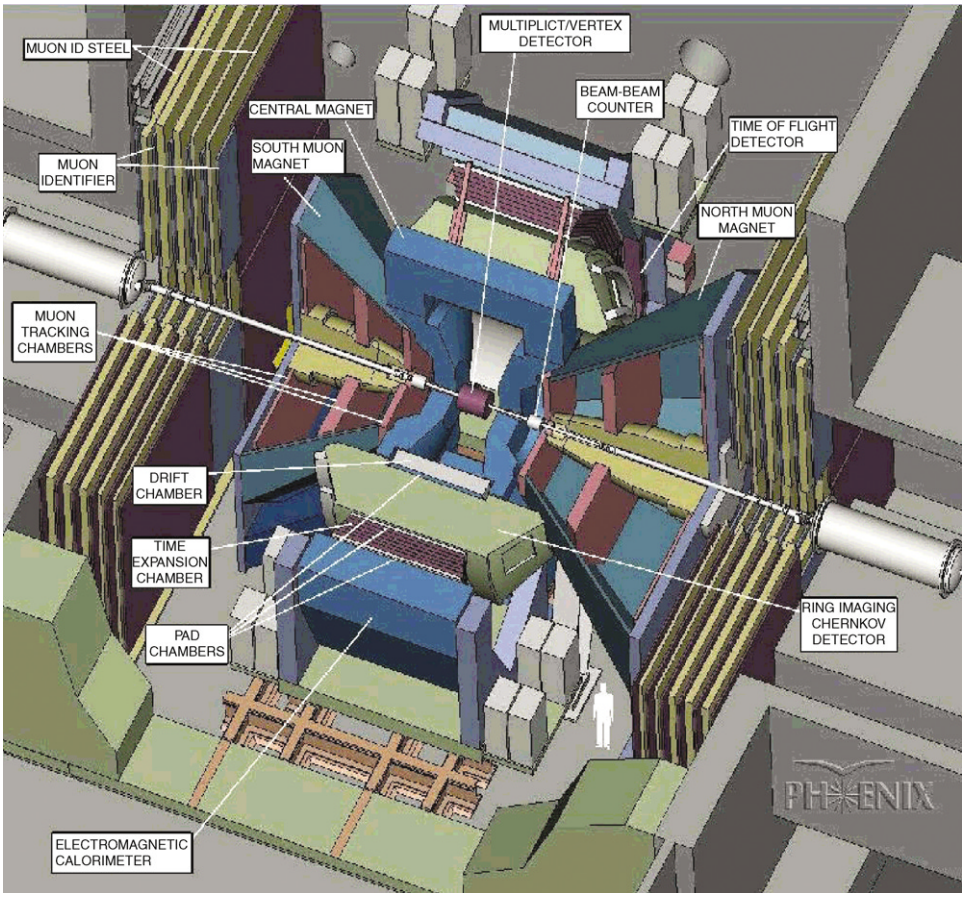

Fig. 2. A cutaway drawing of the PHENIX detector. Labeled arrows point to the major detector subsystems.

alternating layers of steel absorbers and low resolution tracking layers of streamer tubes of the Iarocci type. With this combination the pion contamination of identified muons is typically 3×10^{-3}. The complete north arm will be installed prior to the year-3 PHENIX run.

3.4. Electronics and computing

PHENIX selects and archives events of potential physics interest at the maximum rate consistent with the available RHIC luminosity. The channel count for the PHENIX detector is large and details for the various subdetectors is given in Table 2. Note that for some subsystems two ADCs are required per channel to get the needed dynamic range. In order to obtain a high data-collection efficiency a high degree of coordination between the electronics and computing efforts is required. Custom Front-End Electronics (FEE) were designed for the PHENIX subsystems. Signals from the FEEs [13] are transported by optical fibers to the level-1 trigger [13] that processes signals from a number of subsystems and then either accepts or rejects the event. The trigger operates in a synchronous pipelined mode with a latency of 40 beam crossings, and thus generates a decision for each crossing. The timing of the above operations is coordinated by a master timing system [13] that distributes the RHIC clocks to granule timing modules that communicate with the FEEs.

In order to study the rare event physics for which PHENIX was designed, it is necessary to have a higher level of event rejection than possible

with the level-1 trigger alone. Therefore a level-2 software trigger [13] that makes its selection after a complete event is assembled was developed.

Table 2
Channel counts, digitizer channels and LVL-1 trigger bits/sums for PHENIX

Subsystem symbol	Detector channels	ADC channels	TDC channels	LVL-1 inputs
BB	128	128	256	128 bits
MVD	20,736	20,736		
NTC	8	8	16	8 bits
DC	12,800		12,800	
PC	172,800		172,800	
TEC	20,480	20,480		
RICH	5120	5120	5120	256 bits
ToF	1920	1920	1920	1920 bits
T0	22	22	44	22 bits
EMCal	24,768	49,536	24,768	688 bits
μTR	43,968	43,968		
μID	6340		6340	6340 bits

Once the level-1 trigger accepts an event, the data from the various subsystems is routed via fiber-optic cable to the data collection modules [13]

Table 3
Performance of the PHENIX detector

Physics	Year-2 version
Electrons	$\pi/e < 10^{-4}$ at $p \leqslant 4.7$ GeV/c RICH for <4.7 GeV/c TEC (dE/dx) for <2 GeV/c EMCal for >0.5 GeV/c
Photons	$p_T \geqslant 1$ GeV/c for 0.5 sr with PbGl $p_T \geqslant 1$ GeV/c for 1.5 sr with PbSc Single γs resolved from merging $\pi^0 \to \gamma + \gamma$ out to $p_T \geqslant 25$ GeV/c
Hadrons	$\leqslant 2.3$ GeV/c π for 0.38 sr $\leqslant 1.6$ GeV/c K for 0.38 sr $\leqslant 5.0$ GeV/c p for 0.38 sr ToF with $\sigma < 100$ ps
Muons	$\pi/\mu < 3 \times 10^{-3}$ at $p \geqslant 2.3$ GeV/c with 5 layers of μID.
Global	$d^2N/d\eta\, d\phi$ for $\lvert\eta\rvert < 2.6$

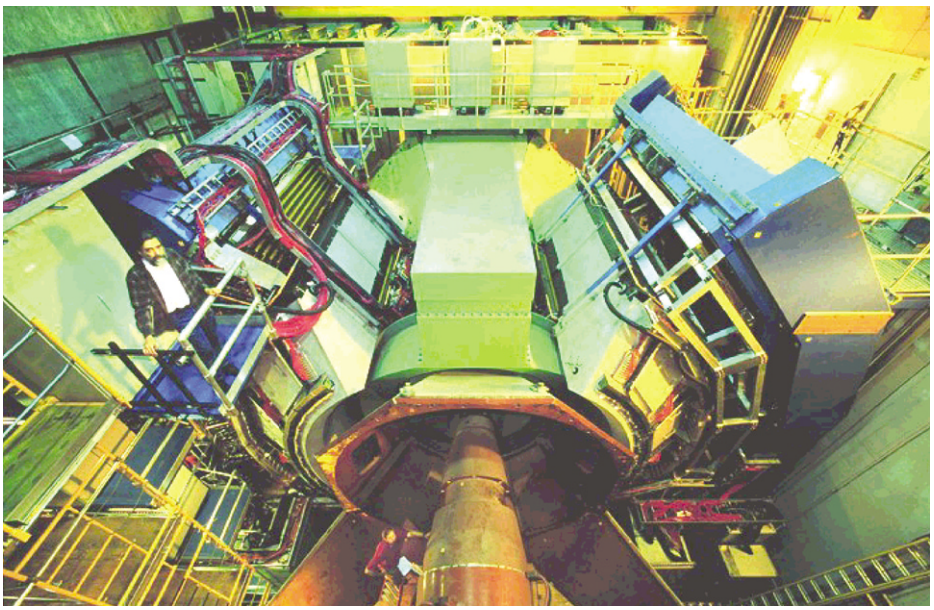

Fig. 3. Photograph of the PHENIX detector viewed from north to south. The central arms are visible on the right (west) and east (left) sides. In the back the south muon magnet and the muon identifier detectors are visible.

that interact with the subsystems by means of daughter cards that format and zero-suppress the data. Data packets are generated by digital signal processors and sent to event builders [13] that assemble the events in their final form. The control and monitoring of the electronics and triggering is handled by the On-Line Computing System (ONCS) [14]. ONCS configures and initializes the on-line system, monitors and controls the data flow and interlocks the data acquisition process with the slow controls systems. After the data is collected the off-line system [14] provides event reconstruction, data analysis and information management. It provides the tools to convert raw data into physics results.

4. Conclusion

The performance of the PHENIX detector is summarized in Table 3. It is designed to carry out the broadest possible study of collisions from Au–Au to p–p. The goal is to examine nuclear matter under a variety of extreme conditions using a variety of probes sensitive to all time scales. In addition, studies of various signals are carried out as a function of both energy and nuclear species in order to separate QGP signals from those of hadronic origin. Another goal is to measure the spin structure of the nucleon by determining the contributions from anti-quarks and gluons. The above goals have resulted in the production of a detector with unparalled capabilities. In the summer of 2000 a number of Au–Au collisions were observed between Au ions with energies of 65 GeV/nucleon using the central spectrometer. In the first PHENIX physics publication [15] results from the measurement of the charged-particle multiplicity are presented. Subsequently results from the first measurement of energy transverse to the beam direction [16], on mass dependence of two-pion correlations [17], on measurement of single electrons with implications for charm production [18] and on the centrality dependence of pion, kaon, proton and antiproton production [19] have been published and studies of results from Au–Au collisions with 100 Gev/nucleon beams are underway.

(Received 8 August 2003; published 30 March 2004)

The PHENIX experiment at the Relativistic Heavy Ion Collider has measured charged hadron yields at midrapidity over a wide range of transverse momenta ($0.5<p_T<10$ GeV/c) in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The data are compared to π^0 measurements from the same experiment. For both charged hadrons and neutral pions, the yields per nucleon-nucleon collision are significantly suppressed in central compared to peripheral and nucleon-nucleon collisions. The suppression sets in gradually and increases with increasing centrality of the collisions. Above 4–5 GeV/c in p_T, a constant and almost identical suppression of charged hadrons and π^0's is observed. The p_T spectra are compared to published spectra from Au+Au at $\sqrt{s_{NN}}=130$ in terms of x_T scaling. Central and peripheral π^0 as well as peripheral charged spectra exhibit the same x_T scaling as observed in $p+p$ data.

I. INTRODUCTION

Lattice quantum chromodynamic (QCD) calculations predict a new state of matter of deconfined quarks and gluons at an energy density exceeding ~ 1 GeV/ fm^3 [1]. It has long been suggested that such a "quark gluon plasma" may be produced in collisions between ultrarelativistic heavy nuclei [2]. Indeed, measurements of transverse energy produced in high-energy Pb+Pb and Au+Au collisions suggest that energy densities above 3 GeV/fm^3 at the CERN SPS [3] and 5 GeV/fm^3 at the Relativistic Heavy Ion Collider (RHIC) [4,5] have been reached. However, this conclusion relies on model assumptions [6–9] to relate the properties of the hadronic final state to the initial state dynamics.

The spectra of high transverse momentum (p_T) hadrons resulting from the fragmentation of hard-scattered partons potentially provide a direct probe of the properties of the initial state. Theoretical calculations show that the outgoing high-p_T partons radiate substantially more energy when propagating through dense matter than when propagating in the vacuum, resulting in a softening of the hadron p_T spectrum [10], with the energy loss of the partons depending on the gluon density of the matter [11,12]. Formation time considerations suggest that hard scattered partons are "produced" at the earliest stage of the collision, thus directly probe the dense matter from the time of their creation. Therefore, a detailed analysis of high-p_T hadron production may reveal information on the properties of the dense medium created early in the collisions [12–14].

At the energies reached at RHIC, high-p_T hadrons are copiously produced. In nucleon-nucleon collisions, it has been well established that hadrons with $p_T \geqslant 2$ GeV/c result primarily from the fragmentation of hard-scattered partons, and that the p_T spectra of these hadrons can be calculated using perturbative QCD (pQCD) [15,16]. Initial measurements of hadron p_T spectra in Au+Au collisions at $\sqrt{s_{NN}}$ =130 GeV led to the discovery of a substantial suppression of hadron yields per nucleon-nucleon collision relative to pp data [17–19]. Data from $\sqrt{s_{NN}}$=200 GeV confirm these results [20–23]. The suppression is observed in central but not in peripheral collisions. These observations are consistent with pQCD-inspired modeling of parton energy loss in dense matter [24,25]. However, alternative interpretations that do not assume the formation of a deconfined phase have been proposed based on the modifications of the parton distribution functions in the initial state [26] or final-state hadronic interactions [27].

In addition to hadron suppression, an unexpectedly large fraction of baryons has been observed in central Au+Au collisions for p_T up to 4–5 GeV/c [28–30], which complicates the interpretation of the high-p_T results. The observed baryon to meson ratio from PHENIX [29] is inconsistent with jet fragmentation in $p+p$ [31] and e^+e^- collisions [32]. While the origin of this effect is unclear, it could point towards bulk particle production ("soft physics") contributing to the p_T spectra out to 4–5 GeV/c. It has been suggested that coalescence of thermalized quarks combining with energy loss of hard-scattered partons can account for the unusual particle composition, which shifts the region dominated by hard scattering to higher p_T [33].

Systematic measurements of the p_T, centrality, particle species, and $\sqrt{s_{NN}}$ dependence of the suppression can constrain competing descriptions of high-p_T hadron production. In this paper, we present new data on inclusive charged hadron production for $0.5 < p_T < 10$ GeV/c, measured over a broad range of centrality in Au+Au collisions at $\sqrt{s_{NN}}$ =200 GeV by the PHENIX Collaboration at RHIC. These data are compared to data on neutral pion production [21] and to data from Au+Au collisions at $\sqrt{s_{NN}}$=130 GeV [17,19], all measured within the same experiment.

The remainder of the paper is organized as follows. Section II gives a detailed account of the charged particle analysis. Centrality and p_T dependence of the charged hadron p_T spectra are discussed in Sec. III A. Section III B studies the charged hadron suppression and compares the results to π^0 data. In Sec. III C, we discuss the $\sqrt{s_{NN}}$ dependence of both charged hadron and neutral pion production and test possible x_T scaling. A summary is given in Sec. IV.

II. DATA ANALYSIS

A. PHENIX detector

The PHENIX experiment consists of four spectrometer arms—two around midrapidity (the central arms) and two at forward rapidity (the muon arms)—and a set of global detectors. The central arm and south muon arm detectors were completed in 2001 and took data during Au+Au operation of RHIC the same year (RUN-2). The layout of the PHENIX experiment during RUN-2 is shown in Fig. 1. Each central arm covers $|\eta| < 0.35°$ in pseudorapidity and 90° in azimuthal angle ϕ. In each of the central arms, charged particles are tracked by a drift chamber (DC) positioned from 2.0 to 2.4 m radially outward from the beam axis and two or three layers of pixel pad chambers [PC1, (PC2), PC3 located at 2.4 m, (4.2 m), 5 m in radial direction, respectively]. Particle identification is provided by ring imaging Cerenkov counters (RICH), a time of flight scintillator wall (TOF), and two types of electromagnetic calorimeters (lead scintillator and lead glass). The magnetic field for the central spectrometer is axially symmetric around the beam axis. Its component parallel to the beam axis has an approximately Gaussian dependence on the radial distance from the beam axis, dropping from 0.48 T at the center to 0.096 T (0.048 T) at the inner (outer) radius of the DC. A pair of zero-degree calorimeters (ZDC) and a pair of beam-beam counters (BBC) were used for global event characterization. Further details about the design and performance of PHENIX can be found in Ref. [34].

B. Event selection

During RUN-2, PHENIX sampled an integrated luminosity of 24 μb^{-1} for Au+Au collisions at $\sqrt{s_{NN}}$=200 GeV. Minimum bias events were selected by a coincidence between the ZDCs and the BBCs. This selection corresponds to $92.2^{+2.5}_{-3.0}$% of the 6.9 b Au+Au inelastic cross section. The event centrality is determined by correlating the charge detected in the BBCs with the energy measured in the ZDCs. Two sets of centrality definitions are used in this analysis: a

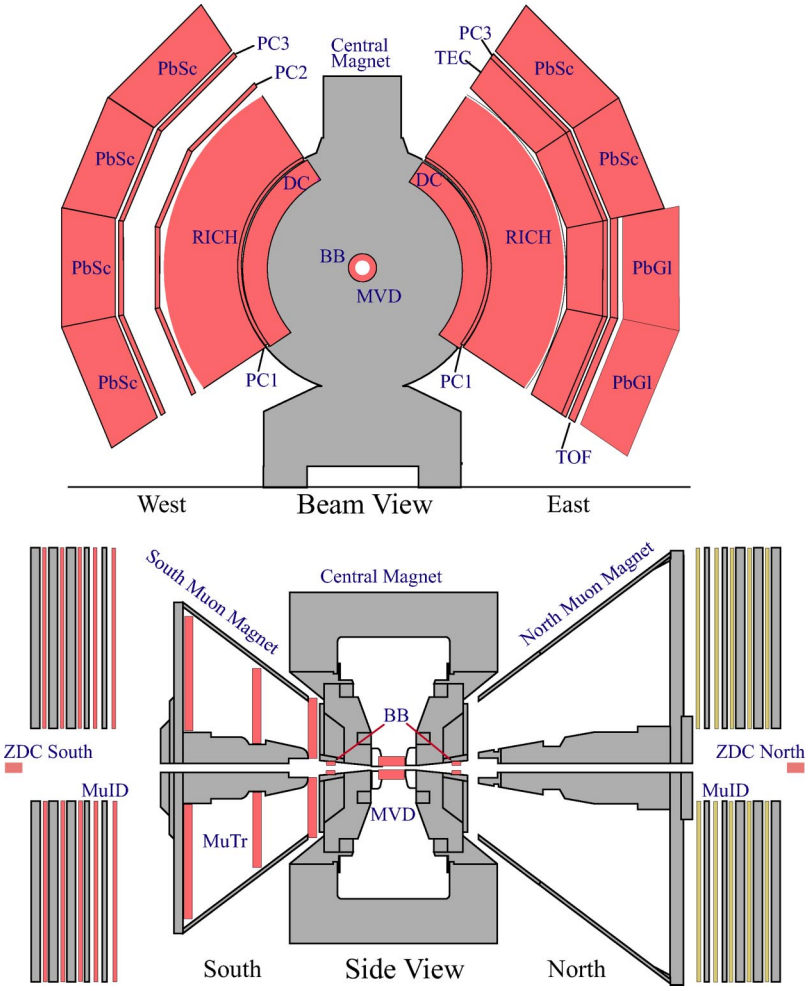

FIG. 1. (Color online) PHENIX experimental layout for the Au+Au run in 2001. The top panel shows the PHENIX central arm spectrometers viewed along the beam axis. The bottom panel shows a side view of the PHENIX muon arm spectrometers.

"Fine" set of centralities, which corresponds to 0–5%, …, 15–20%, 20–30%, …, 80–92%, and a "Coarse" set of centralities, which corresponds to 0–10%, 10–20%, 20–30%, …, 80–92%. A Glauber model Monte Carlo simulation [35–38] that includes the responses of BBC and ZDC gives an estimate of the average number of binary collisions $\langle N_{coll}\rangle$, participating nucleons $\langle N_{part}\rangle$, and nuclear overlap function $\langle T_{\mathrm{AuAu}}\rangle$ for each centrality class. The calculated values of $\langle N_{coll}\rangle$, $\langle N_{part}\rangle$, and $\langle T_{\mathrm{AuAu}}\rangle$ for each centrality class are listed in Table I.

In addition to the event selection, the BBCs also allow us to reconstruct the collision vertex in the beam direction (z) with a resolution of 0.5 cm. An offline z-vertex cut, $|z_{vtx}|<30$ cm, was applied to the minimum bias events. After this selection, a total of 27×10^6 minimum bias Au+Au events were analyzed to obtain the charged hadron spectra presented in this paper.

C. Charged particle tracking and momentum measurement

Charged hadron tracks are measured using information from the DC, PC1, PC2, and PC3 detectors of the west central arm and the BBC. The projections of the charged particle trajectories into a plane perpendicular to the beam axis are detected typically in 12 wire planes in the DC. The wire planes are spaced at 0.6 cm intervals along the radial direction from the beam axis. Each wire provides a projective measurement, with better than 150 μm spacial resolution in the azimuthal (ϕ) direction. Eight additional wire planes in the DC provide stereoscopic projections, which together with the space point measured at the PC1 and the vertex position measured by the BBC determine the polar angle of the track. Trajectories are confirmed by requiring matching hits at both PC2 and PC3 to reduce the secondary background.

Tracks are then projected back to the collision vertex through the magnetic field to determine the momentum $\vec{p}$. The transverse momentum p_T is related to the deflection angle α measured at the DC with respect to an infinite momentum trajectory. For tracks emitted perpendicular to the beam axis, this relation can be approximated by

$$\alpha \simeq \frac{K}{p_T}, \tag{1}$$

where $K=87$ mrad GeV/c is the effective field integral.

The momentum scale is verified by comparing the known proton mass to the value measured for charged particles identified as protons from their time of flight. The flight time is measured in the TOF detector, which cover $\pi/4$ of the

TABLE I. Centrality classes, average number of $N+N$ collisions, average number of participant nucleons, and average nuclear overlap function obtained from a Glauber Monte Carlo simulation of the BBC and ZDC responses for Au+Au at $\sqrt{s_{NN}}=200$ GeV. Each centrality class is expressed as a percentage of $\sigma_{\mathrm{AuAu}}=6.9$ b. Two sets of centrality definitions are used in this analysis: a "Fine" set of centralities, which corresponds to 0–5%, …, 15–20%, 20–30%,…, 80–92%, and a "Coarse" set of centralities, which corresponds to 0–10%, 10–20%, 20–30%, …, 80–92%.

Centrality (%)	$\langle N_{coll}\rangle$	$\langle N_{part}\rangle$	$\langle T_{\mathrm{AuAu}}\rangle$ (mb^{-1})

Minimum bias	257.8±25.4	109.1±4.1	6.14±0.45

azimuthal acceptance in the east arm. The absolute value of the momentum scale is known to be correct to better than 0.7%.

The momentum resolution is directly related to the α resolution,

$$\delta p/p = \delta\alpha/\alpha = \frac{1}{K}\sqrt{\left(\frac{\sigma_{ms}}{\beta}\right)^2 + (\sigma_\alpha p)^2}, \tag{2}$$

where $\delta\alpha$ is the measured angular spread, which can be decomposed into the contribution from multiple scattering σ_{ms} and the contribution from the intrinsic pointing resolution σ_α of the DC. At high p_T, σ_α is the dominating contribution, i.e., $\delta_\alpha \simeq \sigma_\alpha$. We measure $\sigma_\alpha \approx 0.84\pm0.05$ mrad/(GeV/c) using zero field data, where we select high-momentum tracks by requiring energetic hadronic showers in the electromagnetic calorimeters. The width of the proton mass as function of p_T independently confirms the momentum resolution. In summary, the momentum resolution is determined to be $\delta p/p \simeq 0.7\% \oplus 1.0\% p$ (GeV/c). Further details on track reconstruction and momentum determination can be found in Ref. [39].

D. Background rejection and subtraction

Approximately 95% of the tracks reconstructed by the DC originate from the event vertex. The remainder have to be investigated as potential background to the charged particle measurement. The main background sources include secondary particles from decays and e^+e^- pairs from the conversion of photons in materials between the vertex and the DC. Depending on how close the conversion or decay point is to the DC, or depending on the Q value of the decay, these tracks may have a small deflection angle α at the DC. Thus, according to Eq. (1), they are incorrectly assigned a large momentum. In this analysis, the p_T range over which charged particle production is accessible in PHENIX is limited by this background. We exploit the track match to PC2 and PC3 to reject as much of the background as possible, then employ a statistical method to measure and subtract the irreducible background.

For primary tracks, the distance in both the $r-\phi$ and the z direction between the track projection point and the measured PC hit position is approximately Gaussian with a mean of 0 and a width given by

$$\sigma_{match} = \sqrt{\sigma_{det}^{match2} + \left(\frac{\sigma_{ms}^{match}}{p\beta}\right)^2}, \tag{3}$$

where σ_{det}^{match} is the finite detector resolution [which includes DC pointing (or α) resolution and the PC2, PC3 spacial resolution], and σ_{ms}^{match} is the multiple scattering contribution.

Despite being incorrectly reconstructed with large p_T, the majority of the background particles have low momenta. While traveling from the DC to the PC2 and PC3, they multiple scatter and receive an additional deflection from the fringe field. This causes a correlated deflection between the measured positions at PC2, PC3, and the projections calculated from tracks measured by the DC and PC1. The displacements in $r-\phi$ and z directions are represented by D_ϕ and D_z. Since the residual bend depends on the z component of the fringe field, which decreases rapidly at large $|\eta|$, a fiducial cut of $|\eta|<0.18$ was applied to ensure that the residual bend due to the fringe field is almost independent of z.

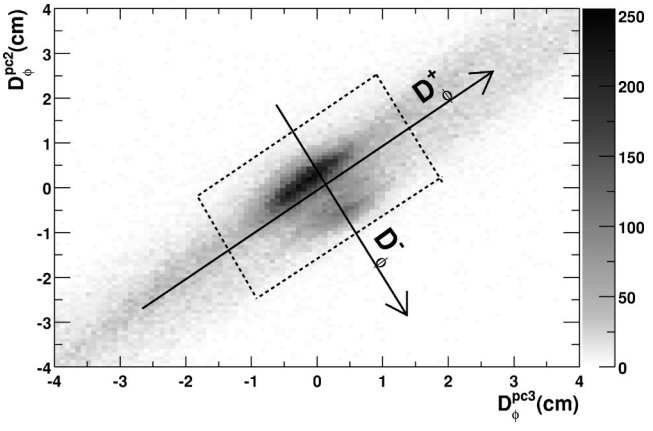

FIG. 2. D_ϕ^{pc2} (the difference between projection and hit location in r-ϕ direction at PC2) vs D_ϕ^{pc3} in centimeters for tracks with reconstructed $p_T>4$ GeV/c. PC2, PC3 matching differences are correlated, with signal tracks peaked around 0 and background tracks extend along the D_ϕ^+ direction. The double-peak structure along D_ϕ^- is related to the finite granularity of PC2 and PC3 pads. The positive directions of D_ϕ^+ and D_ϕ^- are indicated by the arrow. A $\pm 2\sigma$ cut on these variables is illustrated by the box region inside the dashed lines.

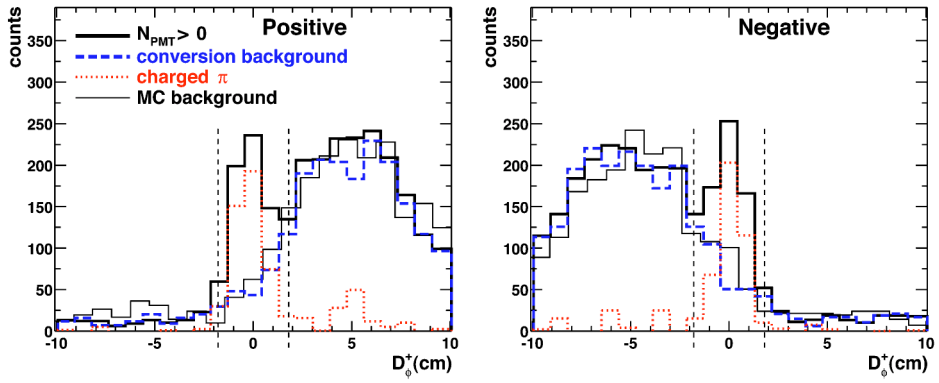

FIG. 3. (Color online) Background contamination due to electrons, illustrated by the track match in D^+_ϕ for tracks with associated RICH PMTs and $6<p_T<7$ GeV/c. The matching distributions are shown for minimum bias events and separately for positive (left) and negative (right) charged tracks. The first three distributions represent the raw counts for all tracks with RICH association (thick solid line), estimated conversion backgrounds (dashed line), and charged pions (dot-dashed line) that were obtained by subtracting the dashed line from the solid line. The thin solid line represents the matching distribution of background electrons from Monte Carlo simulation, arbitrarily scaled to match the data. The $\pm 2\sigma$ matching windows are illustrated by the vertical dashed line. Since e^+ and e^- are deflected in opposite directions by the fringe field, they are shifted to positive and negative directions, respectively.

We focus on the displacement in $r-\phi$, D_ϕ, which are large for low momentum tracks due to the residual bend. The D_ϕ's at PC2 and PC3 are correlated with each other, as shown in Fig. 2. Most of the tracks lie in a narrow window around the diagonal line. The width of this window is given by the PC2 and PC3 detector resolutions, which are of the order of a few millimeters. Multiple scattering and residual bend broaden the matching distribution along the diagonal line. To optimize background rejection, we define two orthogonal projections,

$$D^+_\phi = \frac{1}{\sqrt{2}}(D^{pc2}_\phi + D^{pc3}_\phi),$$

$$D^-_\phi = \frac{1}{\sqrt{2}}(D^{pc2}_\phi - D^{pc3}_\phi). \quad (4)$$

D^+_ϕ is the variable along the correlated direction, D^-_ϕ is the direction normal to D^+_ϕ. A $\pm 2\sigma$ cut on these variables is applied in the data analysis. In the remaining discussion, unless stated otherwise, only tracks satisfying these cuts are included.

After matching cuts, the background level is less than 6% for $p_T<4$ GeV/c, but increases rapidly at higher p_T. For $4<p_T<10$ GeV/c, the most significant remaining background sources are e^+e^- from conversion of photons close to the DC and particles from weak decays of long lived particles, mainly of $K^\pm$ and K^0_L. These backgrounds are estimated and subtracted separately from the D^+_ϕ distribution for all tracks, as will be discussed in the rest of this section.

To separate the two background sources, we take advantage of the RICH to tag electrons. Charged particles with velocities above the Cherenkov threshold $\gamma_{th}=35$ (CO_2 radiator) will emit Cherenkov photons, which are detected by photon multiplier tubes (PMTs) in the RICH [40]. We characterize the Cherenkov photon yield for a charged particle by N_{PMT}, the number of PMTs with signals above threshold associated with the track. For reconstructed electrons ($p_T>150$ MeV/c), the average number of associated PMTs is $\langle N_{PMT}\rangle \approx 4.5$. The probability to find at least one PMT above threshold is more than 99%. For pions, the Cherenkov threshold is 4.8 GeV/c, and the number of associated PMTs reaches its asymptotic value only well above 10 GeV/c; $\langle N_{PMT}\rangle$ increases from 1.4 at 6 GeV/c to 2.8 at 8 GeV/c and 3.6 at 10 GeV/c.

Tracks (N_R) with at least one associated RICH PMT contain both conversion electrons and real pions. Their matching distributions in D^+_ϕ are presented in Fig. 3 for a sample range of $6<p_T<7$ GeV/c. Also shown is the matching distribution for conversion electrons from Monte Carlo simulation. The contributions from pions and electrons are clearly distinguishable. For pions with $p_T<10$ GeV/c, $\langle N_{PMT}\rangle$ has not reached its asymptotic value. A requirement of $N_{PMT}\geqslant 5$ rejects most of the pions while preserving a well-defined fraction (R_e) of the electrons. To measure R_e from the data, we select tracks with an apparent $p_T>10$ GeV/c. [1] The fraction of tracks with $N_{PMT}\geqslant 5$ is measured to be $R_e=0.458\pm 0.05$. Both Monte Carlo and data show a small variation of R_e with p_T and centrality. This variation is included in the error on R_e. The total electron background is calculated using tracks with $N_{PMT}\geqslant 5(N_e)$ as, N_e/R_e. The number of real pions in the RICH-associated sample for each p_T bin is then calculated as

$$S_R = N_R - \frac{N_e}{R_e}. \quad (5)$$

With this method, a small fraction of genuine pions, which satisfy $N_{PMT}\geqslant 5$, is subtracted. This fraction is negligible

[1] In this p_T range, the background yield decreases slowly with p_T, while the true π yield decreases rapidly as p_T increases. By comparing the measured π^0 spectrum from PHENIX [21] with the charged hadron spectrum before background subtraction at $p_T>10$ GeV/c, the integrated signal yield is estimated to be less than 3% and thus may be neglected.

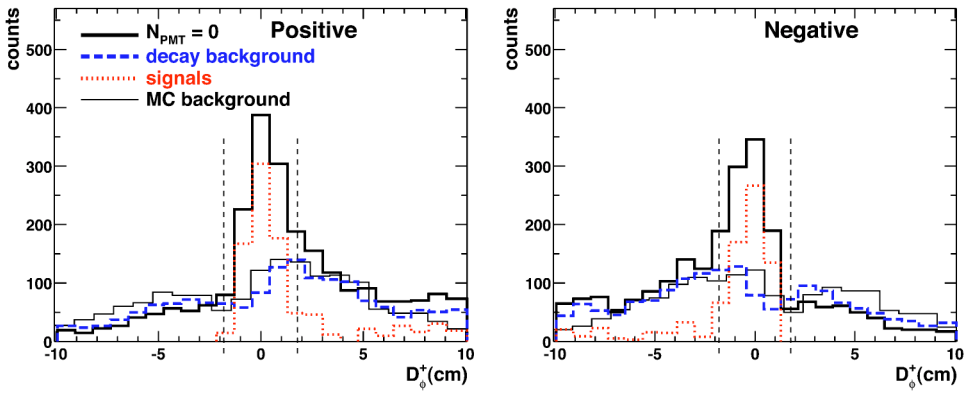

FIG. 4. (Color online) Background contamination due to decays, illustrated by the track match in D_ϕ^+ for tracks without an associated RICH PMT and with $6<p_T<7$ GeV/c, shown for minimum bias events and separately for positive (left) and negative (right) charged tracks. The first three distributions represent the raw counts for all tracks without RICH association (thick solid line), estimated decay backgrounds (dashed line), and signal tracks (dot-dashed line) that were calculated as the difference of the two. The thin solid line represents the matching distribution of decay background from Monte Carlo simulation, arbitrarily scaled to match the data. The two $\pm 2\sigma$ matching windows are illustrated by the vertical dashed line. Outside the signal window, the shape of the dashed line matches the solid line rather well, the difference of 10% level is taken into account in the error estimation of R_{decay}.

below 7 GeV/c, but increases rapidly towards higher p_T. This loss is corrected using the PHENIX Monte Carlo simulation. In this case, a 100% error on the correction is assigned.

The sample of tracks (N_{NR}) with no associated RICH PMT contains a mixture of π, K, p, contaminated by the decay background. Their matching distributions in D_ϕ^+ are shown in Fig. 4 for $6<p_T<7$ GeV/c, together with the matching distribution for decay particles from MC simulation. A Monte Carlo study shows that the apparent momentum of these tracks is nearly uncorrelated with true momentum and therefore the distribution of this background in D_ϕ^+ is nearly independent of the apparent momentum. We select a nearly pure background sample using tracks with reconstructed $p_T>10$ GeV/c and measure the ratio of the number of tracks passing a $|D_\phi^+|<2\sigma$ cut to tracks in the interval $3\sigma<|D_\phi^+|<9\sigma$:

$$R_{decay}=\frac{N_{NR}(p_T>10\ \text{GeV/}c, |D_\phi^+|<2\sigma)}{N_{NR}(p_T>10\ \text{GeV/}c, 3\sigma<|D_\phi^+|<9\sigma)} = 0.424\pm 0.05. \quad (6)$$

The error quoted takes into account the small variation of R_{decay} with p_T and centrality. Since the average yield of real hadrons in this interval is small, we estimate the decay contribution as a function of p_T to be $N_{NR}(3\sigma<|D_\phi^+|<9\sigma)\times R_{decay}$. Finally, the signal is calculated as

$$S_{NR}=N_{NR}(|D_\phi^+|<2\sigma)-N_{NR}(3\sigma<|D_\phi^+|<9\sigma)\times R_{decay}. \quad (7)$$

Figure 5 gives the total signal, obtained as S_R+S_{NR}, with the decay and conversion background subtracted. On the right hand side, the signal-to-background ratio is shown. The background increases with increasing p_T. At 4 GeV/c the signal-to-background ratio is about 10, and decreases to 1 at 7.5 GeV/c and to ~0.3 at 10 GeV/c.

Weak decays of short lived particles, mainly K_s^0, Λ, and $\overline{\Lambda}$ within the magnetic field provide an additional source of background. A significant fraction of this background is subtracted using the R_{decay} method described above. However, secondary particles from decays close to the event vertex are not subtracted since they are nearly indistinguishable from primary particles. This "feed-down" contaminates the track sample without the associated RICH PMTs, S_{NR} (about 40% of all charged particles at high p_T), and needs to be subtracted from the data.

To estimate the feed-down contribution we generate Au+Au events with HIJING [41], reconstruct them through the PHENIX Monte Carlo simulation, and count the secondaries which survive all analysis cuts. The secondaries from Λ and $\overline{\Lambda}$ decays are counted relative to the reconstructed $(p+\overline{p})$, and correspondingly, those from K_s^0 relative to $(K^++K^-)/2$. We tune the $(\Lambda+\overline{\Lambda})/(p+\overline{p})$, $K_s^0/[0.5(K^++K^-)]$ ratios by weighting the particle distributions generated according to HIJING such that they reproduce the nearly p_T independent experimentally observed ratios from Au+Au collisions at $\sqrt{s_{NN}}=130$ GeV [42,43].

The final feed-down contribution depends on the choice of the Λ and K_s^0 p_T spectra and of their yields in the high-p_T range where they are not measured. Both yields and spectral shapes are varied within limits imposed by the spectrum for tracks that do not fire the RICH. The average feed-down contribution depends on p_T and varies between 6% to 13% relative to the total charged hadron yield; it is subtracted from the charged spectra. The systematic uncertainties are estimated from the spread of the feed-down contributions obtained with different assumptions. The uncertainties are approximately 60% of the subtraction, and depend on p_T and centrality.

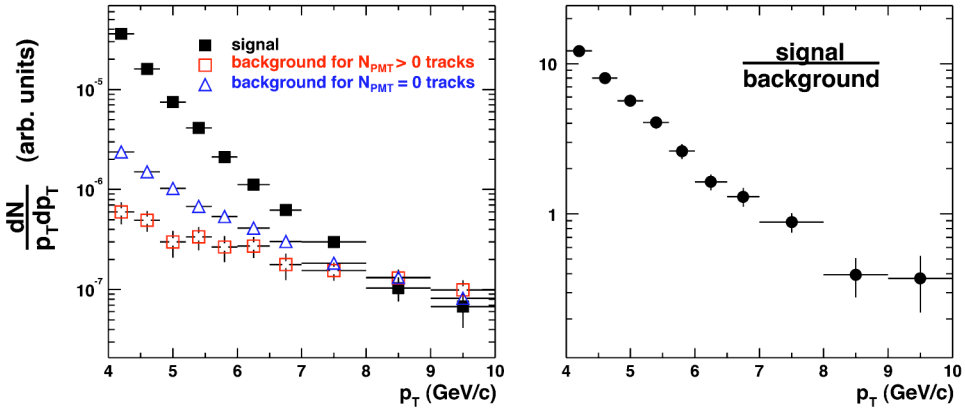

FIG. 5. (Color online) Amount of background estimated as a function of p_T for minimum bias collision. The left part shows the background subtracted charged hadron spectra (filled square), the background from γ conversions (open square), and decays (open triangle). The right part shows the signal to background ratio. Only statistical errors are shown.

Table II summarizes the systematic errors on the background subtraction.[2] All errors are correlated with p_T and are presented as relative errors to the charged hadron yield. The uncertainty on the pion oversubtraction correction ($\delta_{\pi loss}$) was rescaled by the fraction of signal tracks with RICH association, i.e., $S_R/(S_R+S_{NR})$. Errors on the scaling factors R_e and R_{decay} were individually folded with the signal-to-background ratios in the two samples. The resulting uncertainties on the charged yields were then added in quadrature ($\delta_{R_e \oplus R_{decay}}$). The uncertainty of the K_s^0, Λ, and $\bar{\Lambda}$ feed-down subtraction is denoted by $\delta_{feeddown}$.

E. Corrections and systematic uncertainties

After background subtraction, we have determined a single, p_T-dependent correction function to correct the hadron spectra for acceptance, decay in flight, reconstruction efficiency, and momentum resolution. This function is determined using a GEANT [44] Monte Carlo simulation [45] of the PHENIX detector in which simulated single tracks are reconstructed using the same analysis chain applied to the real data. Because of decays and multiple scattering, the correction function depends on the particle species. This is reflected in Fig. 6, where the correction functions averaged between π^+ and π^-, K^+ and K^-, p^+ and p^- are shown separately. At $p_T<3$ GeV/c, the kaon correction function is significantly larger than those for pions and protons. For $p_T>3$ GeV/c, this difference is less than 15%. To take into account this species dependence, we determine the correction function separately for pions, kaons, protons, and their antiparticles. The final correction function is then obtained by combining the correction functions for the different particle species weighted by the measured p_T-dependent particle composition from Ref. [46]. Above 2 GeV/c, where kaon data are not available, we assume the K/π ratio is constant within ±10% from the value observed at 2 GeV/c. This assumption leads to a 2.5% systematic error in the correction function. The resulting correction function is plotted in the upper left panel of Fig. 7. The sharp rise below 2 GeV/c is due to loss in acceptance and decays in flight. Above 2 GeV/c, the correction decreases only slowly with p_T. For $p_T>4$ GeV/c, the correction varies by less than ±5%.

The data are also corrected for efficiency losses due to detector occupancy. Though this is negligible for peripheral collisions, these losses are important in central collisions, and are evaluated by embedding simulated tracks into real events. The average track reconstruction efficiency in the active detector area is larger than 98% for peripheral collisions, but decreases to (70±3.5)% for central collisions. As shown in the lower part of Fig. 7, the efficiency loss is independent of p_T within a ±3% systematic uncertainty from 1.5 to 10 GeV/c. Based on this observation, the full correction can be factorized into centrality-dependent (i.e., detector occupancy dependent) correction function $c(N_{part})$, and p_T-dependent correction function $c(p_T)$. The centrality-dependent correction function is shown on the upper right panel of Fig. 7. Most of the efficiency loss is due to hit overlaps, which can shift the hit positions in the DC or PC's outside of the matching windows. The $\pm 2\sigma$ matching windows are larger at low p_T to account for multiple scattering [see Eq. (3)], thus the tracks are less vulnerable to the effect of hit merging. This effect has been taken into account by applying a slightly smaller, p_T-dependent, occupancy correction at $p_T<1.5$ GeV/c.

Figure 7 also shows systematic errors on the correction functions. These errors include not only the errors on the correction itself, but also the uncertainty due to the background subtraction procedure.

Finally, the inclusive charged hadron yield is obtained by multiplying the p_T-dependent correction function $c(p_T)$ and centrality-dependent correction function $c(N_{part})$ with the background subtracted spectra and dividing by the number of events for every centrality class as

$$\frac{1}{N_{evts}}\frac{dN}{2\pi p_T dp_T d\eta} = \frac{1}{N_{evts}} \times c(p_T) \times c(N_{part}) \times \left(\frac{dN}{p_T dp_T d\eta}\right)^{bgr\text{-}subtracted}. \quad (8)$$

The systematic errors on the spectra, which are common to all centrality classes, are listed in Table III. Sources of systematic uncertainties are the matching cuts (δ_{match}), normalization (δ_{norm}), particle composition (δ_{mix}), momentum

[2]We should emphasize that, in the remaining discussion unless stated otherwise, all systematic errors listed in tables have been adjusted to 1σ errors.

TABLE II. Systematic errors on background subtraction. All errors are given in percent and are quoted as 1σ errors. These errors are correlated with p_T.

p_T (GeV/c)	$\delta_{\pi loss}$ (%)	$\delta_{R_e \oplus R_{decay}}$ (%)	$\delta_{feeddown}$ (%)	Total (%)
<5	0.3	0.3	5	5
5–6	0.6	1.8	5	5.3
6–7	1.4	4.1	8.5	9.5
7–8	4.6	7.1	7.8	11.5
8–9	9.9	17.6	6	21.1
9–10	19.4	23.5	6	31.1

resolution (δ_{reso}), momentum scale (δ_{scale}), and background subtraction (δ_{bgr}) from Table II. The normalization error is independent of p_T. All other errors vary with p_T but are highly correlated bin-to-bin, which means that points in neighboring p_T bins can move in the same direction by similar factors.

The centrality-dependent systematic errors are quantified in terms of the central-to-peripheral ratio R_{cp}, as given in Table IV. Besides the uncertainty on the occupancy correction ($\delta_{occupancy}$) illustrated in Fig. 7, the background subtraction procedure has a centrality-dependent uncertainty. As discussed in Sec. II D, the errors on R_e and R_{decay} reflect the p_T and centrality dependencies. The centrality-dependent part contributes about half of the error on both R_e and R_{decay}, and hence does not cancel in R_{cp}. Since the errors on R_e and R_{decay} are independent, the uncertainty on R_{cp} is approximately equal to $\delta_{R_e \oplus R_{decay}}$ from Table II. Finally, $\delta_{feeddown}$ is the centrality-dependent error from feed-down subtraction.

III. RESULTS

A. Inclusive charged hadron p_T spectra

Figure 8 shows the inclusive charged hadron p_T spectra for various centrality classes. All spectra exhibit power-law tails at high p_T. But for peripheral collisions, the power-law shape is more concave than for central collisions. More details of the centrality dependence of the spectral shape can be seen from Fig. 9, which shows for each centrality class the ratio of the spectra to the minimum-bias spectrum. In these ratios, most systematic errors cancel or affect the overall scale only. The characteristic centrality dependence of the shape already observed in $\sqrt{s_{NN}}$=130 GeV Au+Au collisions

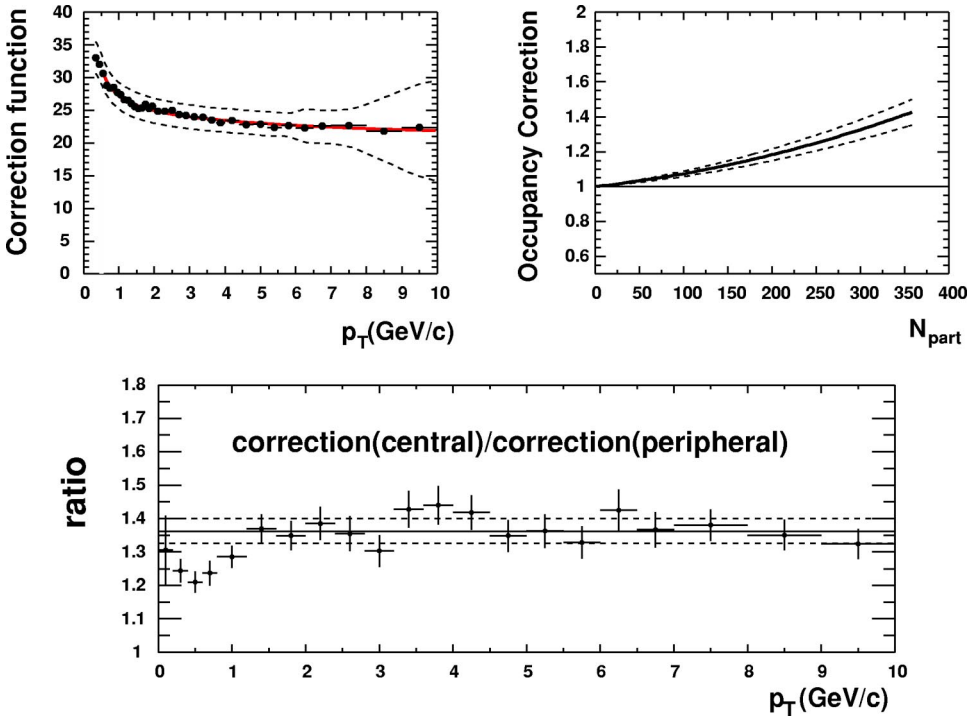

FIG. 7. (Color online) Functions used to correct the charged particle p_T spectra. The upper left panel shows the p_T-dependent correction $c(p_T)$. The upper right panel shows the centrality dependent correction $c(N_{part})$. Systematic uncertainties are indicated by the dashed lines. The two corrections factorize at $p_T > 1.5$ GeV/c, so that for given centrality the full correction function is given by $c(p_T) \times c(N_{part})$. The accuracy of this factorization is demonstrated in the lower panel. The ratio of the full correction for central collisions (5% most central) to the correction for single particle events varies by less than 3% above 1.5 GeV/c (the error bar is the statistical error from the Monte Carlo calculation).

TABLE III. Systematic errors on the p_T spectra. All errors are given in percent and are quoted as 1σ errors. They are either normalization errors or are p_T correlated errors.

p_T (GeV/c)	δ_{match} (%)	δ_{norm} (%)	δ_{mix} (%)	δ_{reso} (%)	δ_{scale} (%)	δ_{bgr} (%)	Total (%)
<1	3.5	3.2	2.4	0.6	0.6	5	7.3
1–5	3	3.2	2.4	0.6	3	5	7.6
5–6	3	3.2	1.8	0.6	3.6	5.3	7.9
6–7	3	3.2	1.8	0.6	3.3	9.5	11.1
7–8	3	3.2	1.8	0.6	3.1	11.5	12.8
8–9	3	3.2	1.8	0.9	3.1	21.1	21.9
9–10	3	3.2	1.8	5.3	3.1	31.1	32.1

[18,19] is more apparent at $\sqrt{s_{NN}}=200$ GeV. In peripheral collisions, the ratio decreases up to $p_T\sim 2$ GeV/c and then rises up to about 4 GeV/c. The trends are reversed in the most central collisions. In the range above 4–5 GeV/c, all ratios appear to be constant as a function of p_T, which would imply that they have a similar centrality independent shape.

Based on the different trends observed in Fig. 9, we can distinguish three p_T regions: 0.5–2, 2–4.5, and >4.5 GeV/c. The different centrality dependence of the spectral shape in these regions can be quantified by a truncated average p_T:

$$\langle p_T^{trunc}\rangle \equiv \frac{\int_{p_T^{min}}^{8\ \mathrm{GeV}/c} p_T\, dN/dp_T}{\int_{p_T^{min}}^{8\ \mathrm{GeV}/c} dN/dp_T} - p_T^{min}, \tag{9}$$

which is insensitive to the normalization of the spectra. The upper bound of 8 GeV/c in the integral is given by the limited p_T reach for peripheral centrality classes as shown in Fig. 8. In Fig. 10, the values of $\langle p_T^{trunc}\rangle$ for the three p_T^{min} values are plotted as a function of centrality, represented by the average number of participating nucleons (N_{part}) for each centrality class.

For $p_T^{min}=0.5$ GeV/c, where particle production is expected to be governed by soft physics, $\langle p_T^{trunc}\rangle$ increases with N_{part}. This trend is also seen for the average p_T of identified charged hadrons, and reflects the increased radial flow of soft particles in more central collisions [46]. For $p_T^{min}=2$ GeV/c, the trend is significantly different. For peripheral collisions, $\langle p_T^{trunc}\rangle$ is substantially larger than the value obtained with $p_T^{min}=0.5$ GeV/c due to the presence of the power-law tail. With increasing N_{part}, $\langle p_T^{trunc}\rangle$ for $p_T^{min}=2$ GeV/c decreases and the values obtained with $p_T^{min}=0.5$ and 2 GeV/c approach each other, which indicates an almost exponential spectrum in central collisions between 0.5 and 2 GeV/c. For the highest p_T range ($p_T^{min}=4.5$ GeV/c), $\langle p_T^{trunc}\rangle$ is approximately constant. This implies that the shape of the spectrum is nearly independent of centrality, as would be expected if this region is dominated by hard scattering.

However, the yields at high p_T do not scale with the number of nucleon-nucleon collisions; they are suppressed comparing to the binary collision scaling expected for hard scattering processes. This can be clearly seen from Fig. 11, which shows R_{cp}, the ratio of yields for central and peripheral collisions normalized to the average number of nucleon-nucleon collisions in each event sample. The ratio is below unity for all p_T. The three p_T regions show different trends as outlined in the discussion of Fig. 10.

(i) In the "soft" region with $p_T<2$ GeV/c, the ratio increases as a function of p_T.

(ii) In the "hard" region with $p_T>4.5$ GeV/c, the suppression appears to be constant at $\sim$0.3, which again indicates that the spectra have a similar shape, but with the yield in central collisions being suppressed by a constant factor from 4.5 to 10 GeV/c.

(iii) In the transition region from 2 to $\sim$4.5 GeV/c, the ratio decreases as a function of p_T.

TABLE IV. Systematic errors on the central-to-peripheral ratio. All errors are given in percent and are quoted as 1σ errors. Most of the systematic errors listed in Table III cancel in the central-to-peripheral ratio. Only those errors that are uncorrelated with centrality are shown here.

p_T (GeV/c)	$\delta_{occupancy}$ (%)	$\delta_{feeddown}$ (%)	$\delta_{R_e\oplus R_{decay}}$ (%)	Total (%)
<6	5	5	1.8	7.3
6–7	5	5	4.1	8.2
7–8	5	5	7.1	10
8–9	5	5	17.6	19
9–10	5	5	23.5	24.6

B. Suppression of high-p_T hadrons in Au+Au at $\sqrt{s_{NN}}=200$ GeV

At finite Q^2, nuclear modifications of the parton distribution [26,47] and initial [48] and final state [10] interactions of the scattering partons can modify the high-p_T hadron production rates in hard scattering processes. Medium modifications of hadron spectra are often quantified by the "nuclear modification factor" R_{AA}, which we calculate for each centrality class as the ratio of the yield per nucleon-nucleon collision in Au+Au to the yield in nucleon-nucleon collisions:

$$R_{AA}(p_T,\eta) = \left(\frac{1}{N_{evt}}\frac{d^2N^{A+A}}{dp_T d\eta}\right) \Bigg/ \left(\frac{\langle N_{coll}\rangle}{\sigma_{inel}^{N+N}}\frac{d^2\sigma^{N+N}}{dp_T d\eta}\right), \tag{10}$$

$\langle N_{coll}\rangle/\sigma_{inel}^{N+N}$ is the average Glauber nuclear overlap function, $\langle T_{\mathrm{AuAu}}\rangle$, for each centrality class. In order to calculate R_{AA},

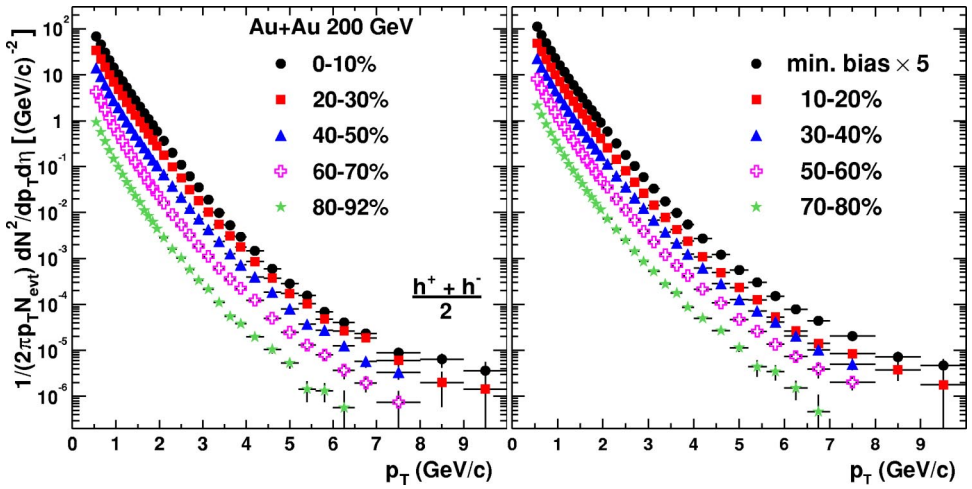

FIG. 8. (Color online) p_T spectra of charged hadrons for minimum bias collisions along with spectra for nine centrality classes derived from the pseudorapidity region $|\eta|<0.18$. The minimum bias spectrum has been multiplied by 5 for visibility. Only statistical errors are shown in the spectra. Most of the p_T-dependent systematic errors are independent of centrality and are tabulated in Table III.

we need a reference spectrum for nucleon-nucleon collisions. Due to the lack of charged hadron data with sufficient reach in p_T from our own experiment, we construct the $N+N$ reference for charged hadrons from the π^0 spectra in $p+p$ collisions at $\sqrt{s}=200$ GeV/c measured by PHENIX [16], and the charged hadron to pion ratio observed in other experiments, as described below.

The PHENIX π^0 spectra from $p+p$ collisions are measured out to 14 GeV/c. These data can be parametrized by a power-law function,

$$\frac{1}{2\pi p_T}\frac{d^2\sigma^{\pi^0}_{N+N}}{dp_T d\eta} = A\left(\frac{p_0}{p_0+p_T}\right)^n, \tag{11}$$

with $A=386$ mb/(GeV/c)^2, $p_0=1.219$ GeV/c, and $n=9.99$ [16].

In $p+p$ experiments at the ISR, the h/π ratio was measured to be 1.6 ± 0.16, independent of p_T from 1.5 to 5 GeV/c, and independent of $\sqrt{s}$ from 23 to 63 GeV [31]. Below 1.5 GeV/c, h/π decreases towards lower p_T. The ISR data are consistent with data on π, K, P production from FNAL E735 experiment [49] at $\sqrt{s}=1.8$ TeV. The h/π ratio computed from these data increases with p_T and reaches a value of 1.6 at the end of the measured p_T range, ~1.5 GeV/c. At high momentum, a h/π ratio of ~1.6 is also observed for quark and gluon jet fragmentation in e^+e^- collisions at LEP by the DELPHI Collaboration [32]. Finally, charged hadron data measured by PHENIX in $p+p$ collisions and data measured by UA1 [50] in $\bar{p}+p$ collisions, both at $\sqrt{s}=200$ GeV/c, give consistent h/π ratios when compared to the PHENIX $p+p$ π^0 data.

Based on these findings, we assume that h/π is constant above 1.5 GeV/c in $p+p$ collisions at RHIC and that we can scale up the π^0 cross section [Eq. (11)] by this factor to obtain a reference for charged hadron production. To be consistent with the data described above, we correct this reference below 1.5 GeV/c using an empirical function,

$$r(p_T) = \begin{cases} R_{h/\pi} - a(p_{max}-p_T)^2 & \text{for } p_T \leqslant p_{max} \\ R_{h/\pi} & \text{for } p_T > p_{max}, \end{cases} \tag{12}$$

where $R_{h/\pi}=1.6$, $p_{max}=1.6$ GeV/c, and $a=0.28$ (GeV/c)$^{-2}$. The charged hadron reference used in this analysis is then given by the product of the power-law function from Eq. (11) and the empirical correction from Eq. (12) as

$$\frac{1}{2\pi p_T}\frac{d^2\sigma^{h^++h^-}_{N+N}}{dp_T d\eta} = A\left(\frac{p_0}{p_0+p_T}\right)^n \times r(p_T). \tag{13}$$

The systematic errors on the charged hadron $N+N$ reference are summarized in Table V. The main sources of uncer-

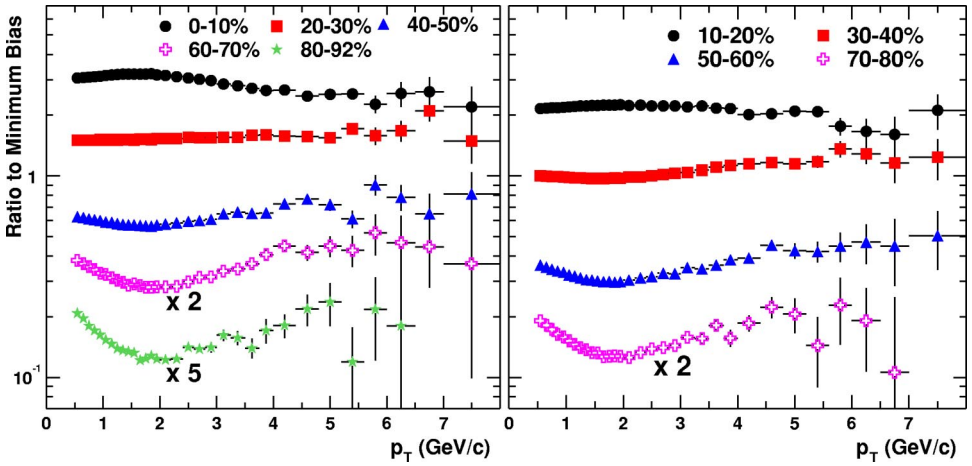

FIG. 9. (Color online) Ratios of centrality selected p_T spectra to the minimum bias spectrum. Ratios for peripheral classes are scaled up for clarity. For the p_T range shown, most of the systematic errors cancel in the ratio. The remaining systematic errors that can change the shape are less than 10% (see Table IV) and are correlated bin-to-bin in p_T.

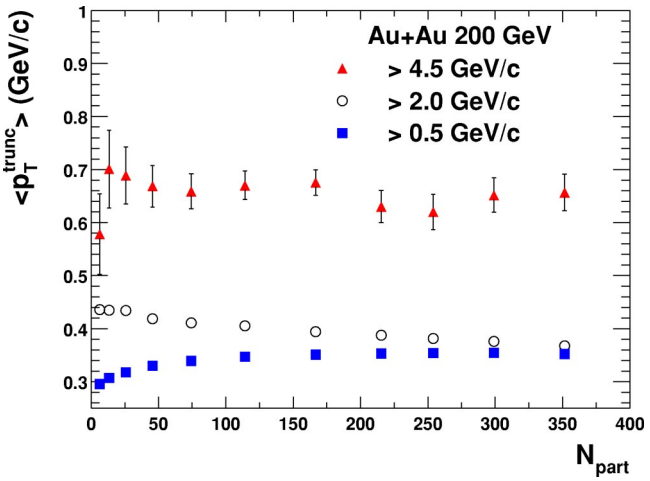

FIG. 10. (Color online) Centrality dependence of $\langle p_T^{trunc} \rangle$, the average p_T of charged particles above a p_T threshold as defined in Eq. (9). Shown are $\langle p_T^{trunc} \rangle$ values for three p_T^{min} cuts, with p_T^{min} =0.5, 2, and 4.5 GeV/c, respectively. The errors shown are statistical only. The systematical errors for all data points are less than 3%.

TABLE V. Systematic errors on the charged hadron $N+N$ reference spectrum. All errors are given in percent and are quoted as 1σ errors. Positive and negative errors are given separately where appropriate. Most of the errors are correlated with p_T.

p_T(GeV/c)	$\delta^{\pi^0}_{norm}$ (%)	$\delta^{\pi^0}_{fit}$ (%)	$\delta_{R_{h/\pi}}$ (%)	Total (%)
0.75	±10.4	−3.9+9.1	−15.1+5.9	−18.7+15.0

9.50	±10.4	−19.3+25.9	−5.9+5.9	−22.7+28.5

tainties include: (i) the systematic errors on the absolute normalization of the PHENIX π^0 data ($\delta^{\pi^0}_{norm}$), which are independent of p_T; (ii) uncertainties due to the power-law fit to the π^0 data ($\delta^{\pi^0}_{fit}$); and (iii) uncertainties on $R_{h/\pi}$ ($\delta_{h/\pi}$), which are estimated from the spread of $R_{h/\pi}$ obtained from different data sets used to constrain h/π^0.

Figure 12 shows the nuclear modification factor $R_{AA}(p_T)$ for charged hadrons from minimum bias and nine centrality classes. The systematic errors on R_{AA} are described in the figure captions. At low p_T, the charged hadron R_{AA} increase monotonically up to 2 GeV/c for all centrality classes. At $p_T>2$ GeV/c, R_{AA} remains constant and close to unity for the most peripheral centrality class. However, in central collisions, it decreases at higher p_T, down to an approximately constant value of 0.2–0.3 for $p_T>4$–5 GeV/c. This is consistent with Fig. 11, where the central to peripheral ratio also saturates above 4–5 GeV/c. This approximately p_T independent suppression pattern has been interpreted as a result of the detailed interplay between the Cronin effect, nuclear shadowing, and partonic energy loss [51].

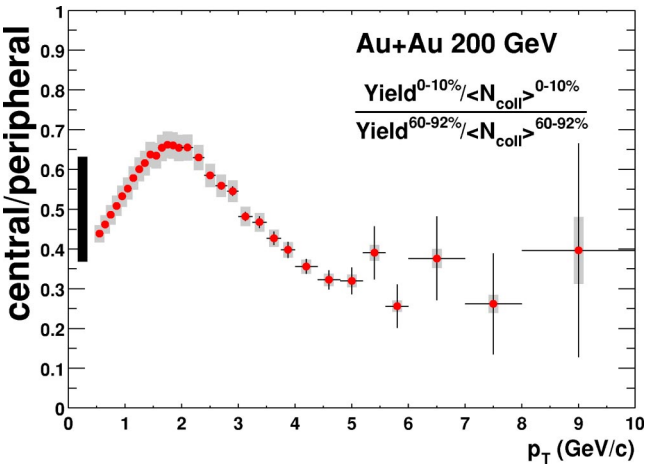

FIG. 11. (Color online) Ratio of charged hadron yields per nucleon-nucleon collision between central (0–10%) and peripheral (60–92%) Au+Au collisions. The solid error bars on each data point are statistical. The error bar on the left hand side of the figure is the overall scale error relative to 0.5, which is the quadrature sum of (i) the uncertainty of $\langle N_{coll} \rangle$ (see Table I) and (ii) the uncertainty on the occupancy correction ($\delta_{occupancy}$). The shaded error band on each data point is the p_T-dependent systematic error from $\delta_{R_e \oplus R_{decay}}$ and centrality dependent feed down correction ($\delta_{feeddown}$) as given in Table IV.

Also shown in Fig. 12 are R_{AA} for neutral pions from Ref. [21]. The neutral pion R_{AA} values also seem to reach maximum around 2 GeV/c, but the changes are smaller than those for charged hadrons. Except for the most peripheral bin, the neutral pion R_{AA} are always below the charged R_{AA} in the range of $2<p_T<4.5$ GeV/c. However, at $p_T>4.5$ GeV/c, R_{AA} for both neutral pions and hadrons saturate at roughly the same level, indicating a similar suppression for neutral pions and charged hadrons at high p_T.

The fact that the neutral pion R_{AA} values are smaller than inclusive charged hadron R_{AA} at intermediate $p_T(2<p_T<4.5$ GeV/$c)$ has already been observed at $\sqrt{s_{NN}}$ =130 GeV [17]. This difference can be explained by the large p/π ratio observed in the same p_T range in central Au+Au collisions [28,29]. This large relative proton and antiproton yield indicates a deviation from the standard picture of hadron production at $p_T>2$ GeV/c, which assumes that the hadrons are created by the fragmentation of energetic partons. Such a deviation has led to models of quark coalescence [33] or baryon junctions [52] as the possible mechanisms to enhance the proton production rate at medium p_T. Both models predict that baryon enhancement is limited to $p_T<5$ GeV/c, beyond which jet fragmentation should eventually become the dominant production mechanism for all particle species. In that case, one would expect a similar

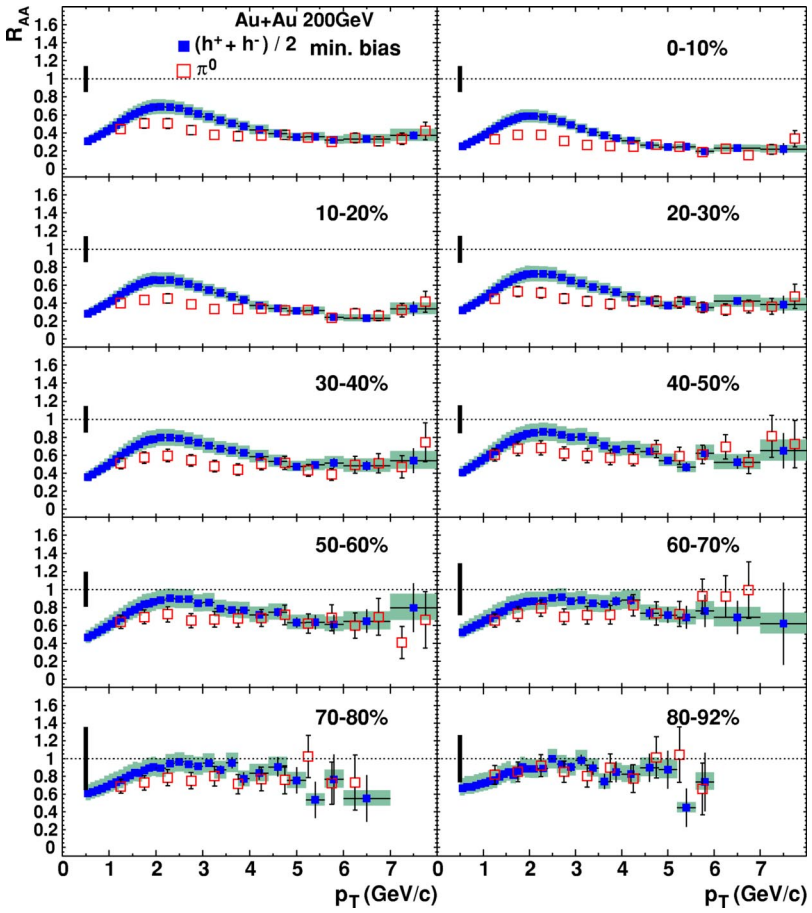

FIG. 12. (Color online) R_{AA} for $(h^+ + h^-)/2$ and π^0 as a function of p_T for minimum bias and nine centrality classes according to the "Fine" type of centrality classes defined in Table I. The error bars on the π^0 data points include statistical and systematical errors on the Au+Au data and the $N+N$ reference. The error bars on $(h^+ + h^-)/2$ data points are statistical errors only. The common normalization errors ($\delta^{\pi^0}_{norm}$ from Table V) on the references for charged hadrons and π^0's are added in quadrature with the uncertainly on $\langle N_{coll}\rangle$ and are indicated by the black bar on the left side of each panel. This error ranges from 15% to 36% from central to peripheral collisions and can shift all points in the charged and neutral pion R_{AA} up and down together. The shaded band on charged R_{AA} includes the remaining systematic errors on the charged $N+N$ reference summed in quadrature with the systematic errors from the Au+Au spectra. This error amounts to $-12.5\% + 18\%$ at low p_T and changes to $\pm 12.5\%$ at $p_T = 4.5$ GeV/c and $\pm 18.5\%$ at $p_T = 8$ GeV/c.

suppression factor for charged hadron and π^0, in agreement with the data at $p_T > 4.5$ GeV/c. Recently, the difference of R_{AA} between charged hadrons and pions was also argued as the consequence of centrality and particle species dependent $\langle k_T\rangle$ broadening effect [53].

If hard-scattering dominates charged hadron production at $p_T > 4.5$ GeV/c, the particle composition should be determined by the jet fragmentation function, similar to nucleon-nucleon collisions. Figure 13 shows h/π^0 for all centrality classes. The systematic errors are explained in the figure captions. In the most peripheral collisions, the h/π^0 ratio is consistent with the $p+p$ values down to $p_T \approx 2$ GeV/c . In central collisions, the h/π^0 ratio is enhanced by as much as 50% above the $p+p$ value in the region $1 < p_T < 4.5$ GeV/c. This enhancement gradually decreases towards more peripheral collisions and reflects the difference of R_{AA} between the charged hadrons and π^0's, which is due to large baryon contribution. The enhancement also strongly depends on p_T. It reaches a maximum between 2.5 and 3.5 GeV/c, then decreases. At $p_T > 4.5$ GeV/c, the h/π^0 ratios for all centralities reach an approximately constant value of 1.6, which is consistent with the h/π value observed in $p+p$ [31] collisions and in jet fragmentation in e^+e^- [32] collisions. The similarity of the spectral shape and of the particle composition between Au+Au and $p+p$ collisions suggest that fragmentation of hard-scattered partons is the dominant mechanism of particle production in Au+Au collisions above p_T of 4–5 GeV/c, regardless of the fact that the yields do not scale with N_{coll}.

Since R_{AA} values for charged hadrons and π^0's are approximately constant at $p_T > 4.5$ GeV/c, we can quantify the centrality dependence of the R_{AA} value by calculating it from yields integrated above 4.5 GeV/c. The upper panel of Fig. 14 shows R_{AA} for $p_T > 4.5$ GeV/c as a function of N_{part}. The R_{AA} values for charged hadrons and π^0 agree for all centrality classes within errors. In peripheral collisions with $N_{part} < 50$, R_{AA} is consistent with binary collision scaling. With increasing N_{part}, R_{AA} decreases monotonically, reaching a value of 0.23 ± 0.03 (0–5% most central) for charged hadrons and 0.24 ± 0.02 (0–10% most central) for π^0's. There is an additional 14% error common to charged hadrons and π^0's, which originates from the uncertainty on the $N+N$ reference and N_{coll}.

To address suggestions that the yield of high-p_T hadrons in Au+Au collisions may be proportional to N_{part} instead of N_{coll} [26,54], we have investigated a different ratio,

$$R_{AA}^{N_{part}} = 2\langle N_{coll}\rangle / \langle N_{part}\rangle \times R_{AA}. \tag{14}$$

$R_{AA}^{N_{part}}$ for $p_T > 4.5$ GeV/c is shown in the lower panel of Fig. 14, together with solid (or dashed) bands representing the allowed range if the data follow binary collision (or participant) scaling. As discussed above, for peripheral collisions, $R_{AA}^{N_{part}}$ follows more closely the binary collision scaling. Above 50 participants, $R_{AA}^{N_{part}}$ varies by only ±20%.

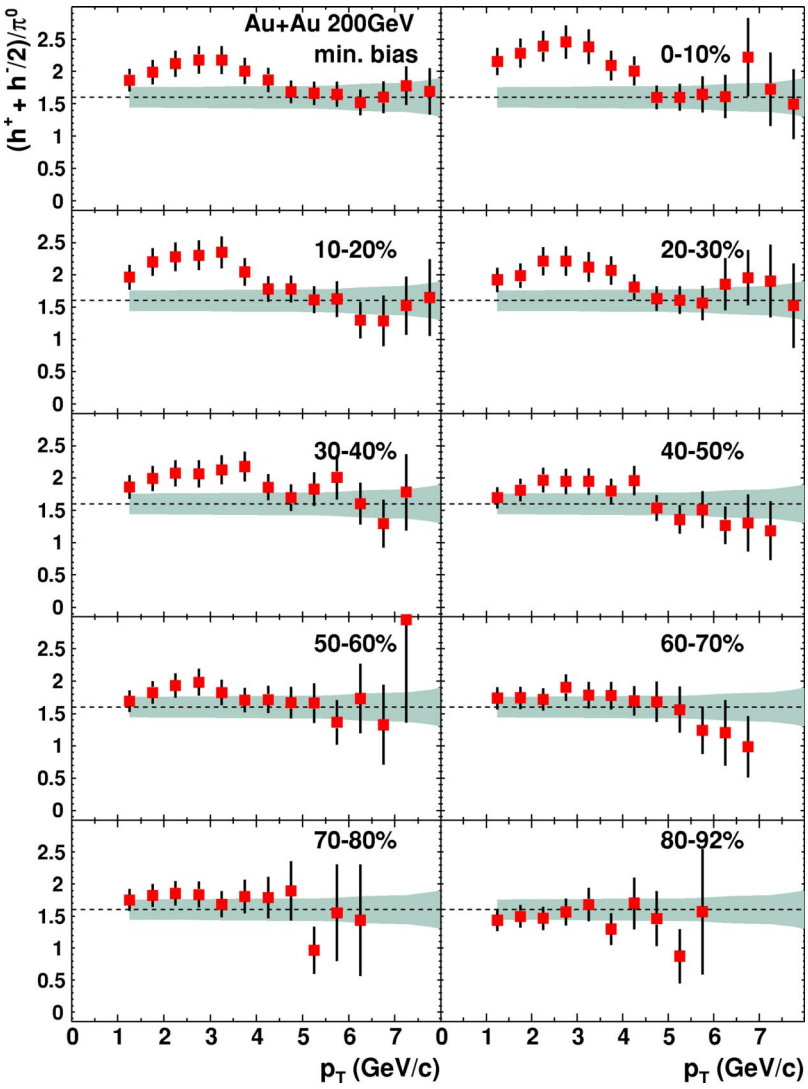

FIG. 13. (Color online) Charged hadron to π^0 ratios for minimum bias events and nine centrality classes according to the "Fine" type of centrality classes defined in Table I. The error bars represent the quadratic sum of statistical and point-by-point systematic errors from $(h^+ + h^-)/2$ and π^0. The shaded band shows the percent normalization error [dominantly from $(h^+ + h^-)/2$ data] common to all centrality classes. The dashed line at 1.6 is the h/π ratio measured in $p+p$ [31] and e^+e^- [32] collisions.

However, it peaks at $\langle N_{part} \rangle = 100$ and decreases monotonically towards more central collisions.[3]

The decrease of $R_{AA}^{N_{part}}$ could be a natural consequence of energy loss of hard scattered partons in the medium [54]. If the energy loss is large, hard scattered partons may only escape near the surface of the reaction volume. In a cylindrical collision geometry, for which the number of collisions from the surface is proportional to N_{part}, binary collision scaling is reduced to an approximate participant scaling. Detailed calculations show that in this case, $R_{AA}^{N_{part}}$ slightly decreases with N_{part} depending in details on how the energy loss is modeled [54]. This interpretation is also consistent with our previous conclusion that, above 4.5 GeV/c, hadron production is dominated by hard scattering although the yield does not scale with the number of binary collisions. Gluon saturation scenarios [26] also suggest approximate participant scaling, with a 30% increase in R_{AA} over the p_T range 4.5–9 GeV/c in central collisions. This increase cannot be excluded by the data.

C. Energy dependence and x_T scaling

The inclusive charged hadron and $\pi^0 p_T$ spectra and h/π^0 ratios suggest that fragmentation of hard scattered partons is the dominant production mechanism of high-p_T hadrons not only in $p+p$ but also in Au+Au collisions. For $p+p$ collisions this fact was demonstrated on general principles well before the advent of QCD by the method of "x_T scaling." This method does not depend on whether the initial projectiles are protons or Au ions, so it should be directly applicable to Au+Au collisions. Since our data show a suppression of high-p_T particles in central Au+Au collisions with respect to pointlike scaling from $p+p$ and peripheral Au+Au collisions, it is important to investigate whether the production dynamics of high-p_T particles in central (and peripheral) Au+Au collisions are the same or different from those in $p+p$ collisions. We first review the x_T-scaling method in $p+p$ collisions and then apply it to the present Au+Au data.

[3]In the p_T range from 3–4 GeV/c, $R_{AA}^{N_{part}}$ for charged hadrons is approximately constant, which is consistent with earlier measurements at $\sqrt{s_{NN}} = 130$ GeV [19] and $\sqrt{s_{NN}} = 200$ GeV [20]. To interpret this constancy as participant scaling is misleading, since pion and proton yields change differently with centrality in this p_T region, and $R_{AA}^{N_{part}}$ accidentally appears constant for inclusive charged hadron. The data above 4.5 GeV/c shown in Fig. 14 are free of this effect.

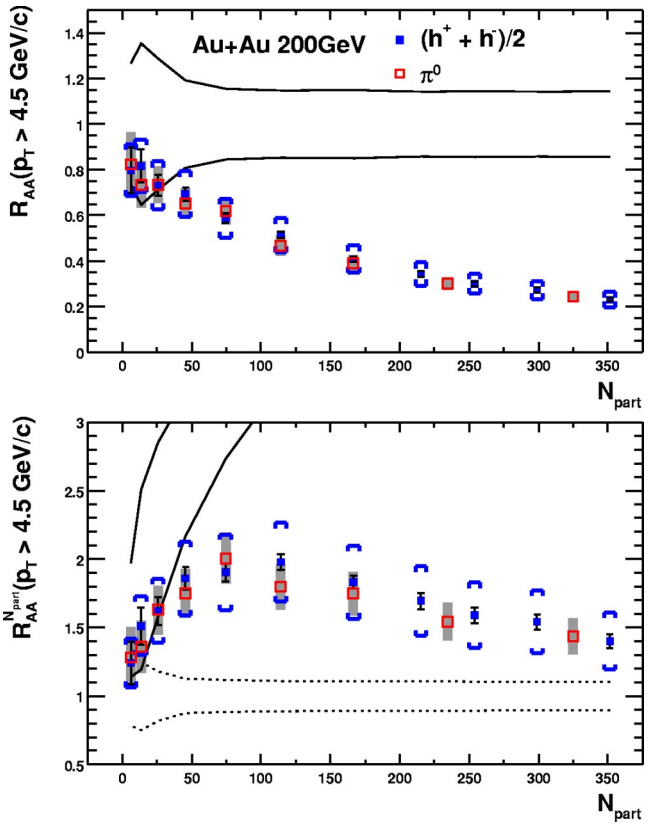

FIG. 14. (Color online) Au+Au yield integrated for $p_T > 4.5$ GeV/c over the $N+N$ yield, normalized using either N_{coll} (R_{AA} in the top panel) or N_{part} ($R_{AA}^{N_{part}}$ in the bottom panel), plotted as a function of $\langle N_{part}\rangle$. The bands represent the expectation of binary collisions (solid) and participant pair (dashed) scaling. The width of the bands gives the systematic errors on $N_{coll}(N_{part})$ added in quadrature with the common normalization errors on the $N+N$ references for charged hadrons and neutral pions. For charged hadrons, the statistical errors are given by the bars. The systematic errors, which are not common with the errors for neutral pions and which are correlated in p_T, are shown as brackets. The shaded bars around each neutral pion point represent the systematic and statistical errors; these errors are not correlated with the errors shown for the charged hadron data.

The idea of hard scattering in $N+N$ collisions dates from the first indication of pointlike structure inside the proton, in 1968, found in deep inelastic electron-proton scattering [55], i.e., scattering with large values of four-momentum transfer squared Q^2 and energy loss ν. The discovery that the deep inelastic scattering (DIS) structure function

$$F_2(Q^2,\nu) = F_2\left(\frac{Q^2}{\nu}\right) \tag{15}$$

"scales," or in other words, depends on the ratio

$$x = \frac{Q^2}{2M\nu} \tag{16}$$

independent of Q^2 as suggested by Bjorken [56], led to the concept of a proton being composed of pointlike "partons." Since the partons of DIS are charged, and hence must scatter electromagnetically from each other in $p+p$ collisions, a general formula for the cross section of the single-particle inclusive reaction

$$p + p \rightarrow C + X \tag{17}$$

was derived [57] using the principle of factorization of the reaction into parton distribution functions for the protons, fragmentation functions to particle C for the scattered partons, and a short-distance parton-parton hard scattering cross section.

The invariant cross section for the single-particle inclusive reaction [Eq. (17)], where particle C has transverse momentum p_T near midrapidity, was given by the general scaling form [58]

$$E\frac{d^3\sigma}{dp^3} = \frac{1}{p_T^n}F\left(\frac{2p_T}{\sqrt{s}}\right) \quad \text{where} \quad x_T = 2p_T/\sqrt{s}. \tag{18}$$

The cross section has two factors: a function F which depends only on the ratio of momenta, and a dimensioned factor p_T^{-n}, where n depends on the quantum exchanged in the hard-scattering. For QED or vector gluon exchange [57], $n=4$. For the case of quark-meson scattering by the exchange of a quark [58], $n=8$. The discovery of high-p_T pions in $p+p$ scattering at the CERN-ISR, in 1972 [59–61], at a rate much larger than predicted by electromagnetic scattering, but with the scaling form of Eq. (18), proved that the partons of DIS strongly interact with each other.

Inclusion of QCD [62] into the scaling form [Eq. (18)] led to the x_T-scaling law,

$$E\frac{d^3\sigma}{dp^3} = \frac{1}{\sqrt{s}^{n(x_T,\sqrt{s})}}\,G(x_T), \tag{19}$$

where the "x_T-scaling power" $n(x_T,\sqrt{s})$ should equal 4 in lowest order (LO) calculations, analogous to the $1/q^4$ form of Rutherford scattering in QED. The structure and fragmentation functions, which scale as the ratios of momenta are all in the $G(x_T)$ term. Due to higher order effects such as the running of the coupling constant, $\alpha_s(Q^2)$, the evolution of the structure and fragmentation functions, and the initial state k_T, measured values of $n(x_T,\sqrt{s})$ in $p+p$ collisions are in the range from 5 to 8.

The compilation of single particle inclusive transverse momentum spectra at midrapidity from $p+p$ and $p+\bar{p}$ collisions at center-of-mass (c.m.) energy $\sqrt{s}$ from 23 to 1800 GeV [31,50,63,64] is shown in Fig. 15(a) for $(h^+ + h^-)/2$, and in Fig. 16(a) for π^0 [16,65–68]. The spectra exhibit a characteristic shape: an exponential part at low $p_T \leqslant 1$ GeV/c which depends very little on $\sqrt{s}$ (soft physics), and a power-law tail for $p_T \geqslant 2$ GeV/c which depends very strongly on $\sqrt{s}$ (hard physics). The high-p_T part of the spectra shows a characteristic scaling behavior indicative of fragmentation of jets produced by hard scattering of the quark and gluon constituents of the proton as described by QCD [69–71].

The x_T scaling of the single particle inclusive data is nicely illustrated by a plot of

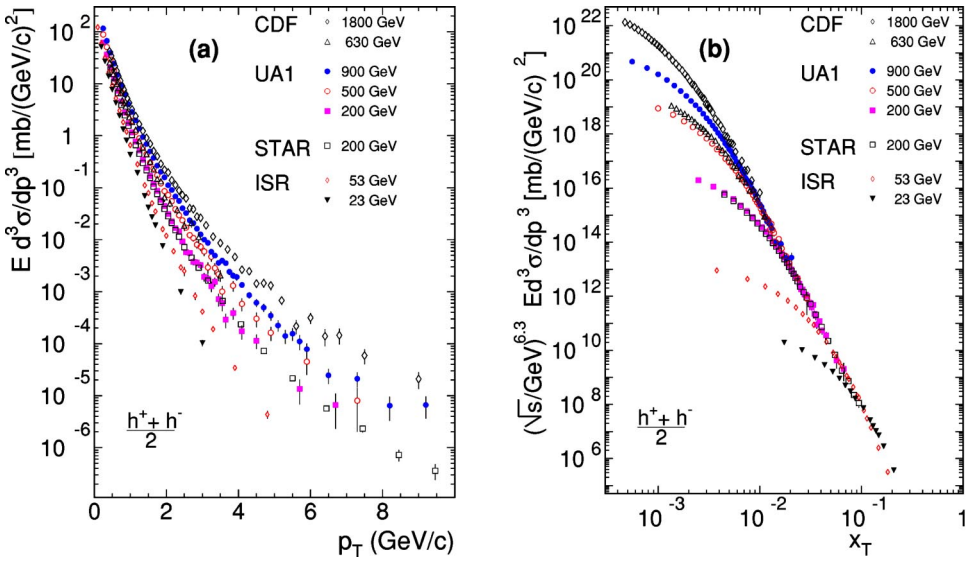

FIG. 15. (Color online) (a) Transverse momentum dependence of the invariant cross section at seven center-of-mass energies from different experiments [31,50,63,64]. (b) The same data multiplied by $\sqrt{s}^{6.3}$, plotted as a function of $x_T = 2p_T/\sqrt{s}$.

$$\sqrt{s}^{n(x_T,\sqrt{s})} \times E\frac{d^3\sigma}{dp^3} = G(x_T), \tag{20}$$

as a function of x_T, with $n(x_T,\sqrt{s})=6.3$. The $(h^+ + h^-)/2$ data [Fig. 15(b)] show an asymptotic power law with increasing x_T. Data at a given $\sqrt{s}$ fall below the asymptote at successively lower values of x_T with increasing $\sqrt{s}$, corresponding to the transition region from hard to soft physics in the p_T range of 1–2 GeV/c. The π^0 data [Fig. 16(b)] show a similar x_T scaling but without the deviation at low x_T, since all available data are for p_T larger than 1–2 GeV/c. For larger $x_T \geqslant 0.3$, a value of $n=5.1$ [66,72] improves the scaling for the three lower c.m. energies, $\sqrt{s}=38.7$, 52.7, and 62.4 GeV. It will be a challenge at RHIC to obtain data in this x_T range to see whether the value of $n\sim 5$ is the asymptotic limit for inclusive single particle production or whether n reaches the (LO) QCD value of 4. x_T scaling has also been studied in jet production at $\sqrt{s}=630$ and 1800 GeV [73], where $n=4.45$ is observed in the jet x_T range 0.15–0.3.

In Au+Au collisions, x_T scaling should work just as well as in $p+p$ collisions and should yield the same value of $n(x_T,\sqrt{s})$ if the high-p_T particles are the result of hard scattering according to QCD. This is because the structure and fragmentation functions in Au+Au collisions should scale, so that Eq. (19) applies, albeit with a different $G(x_T)$. Thus, if the suppression of high-p_T particles with respect to pointlike scaling from $p+p$ collisions is due to shadowing of the structure functions [47] or gluon saturation [26], which are basi-

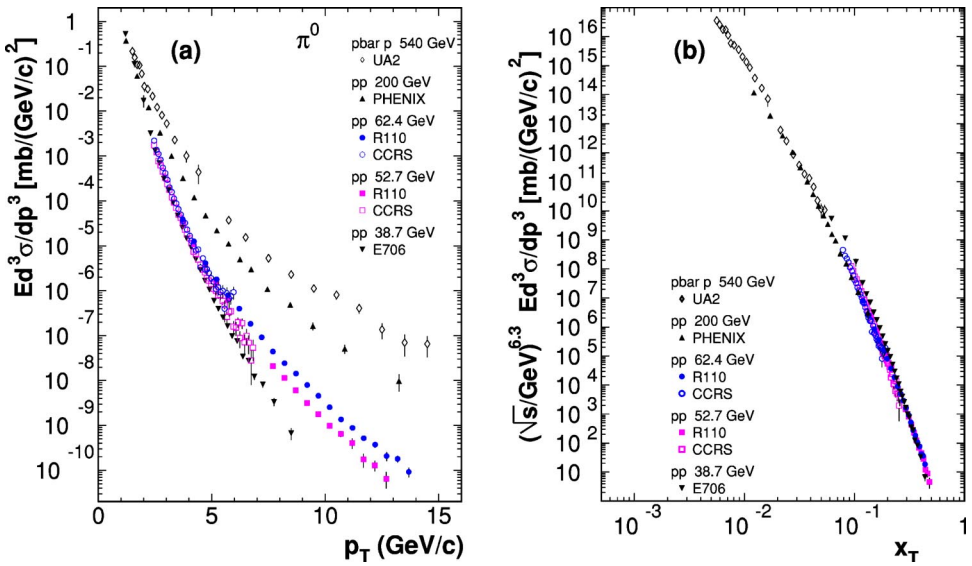

FIG. 16. (Color online) (a) Transverse momentum dependence of the invariant cross section for π^0 at five center-of-mass energies from different experiments [16,65–68]. (b) The same data multiplied by $\sqrt{s}^{6.3}$, plotted vs $x_T = 2p_T/\sqrt{s}$.

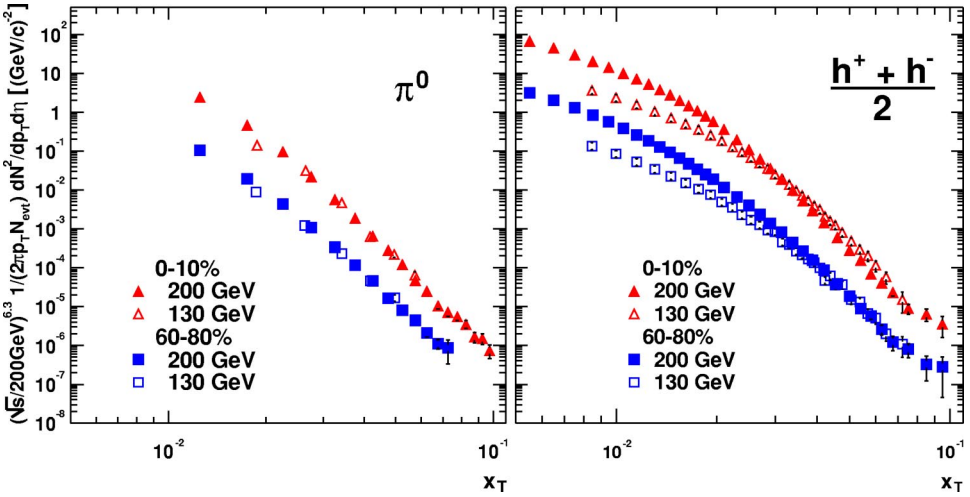

FIG. 17. (Color online) x_T scaled spectra for central collisions and peripheral collisions at $\sqrt{s_{NN}}=130$ and 200 GeV. The left figure shows the π^0 x_T spectra, and the right figure shows the $(h^++h^-)/2$ x_T spectra. The central (0–10%) x_T spectra are represented by triangular symbols, and the peripheral (60–80%) x_T spectra are represented by square symbols. The open symbols represent x_T spectra from $\sqrt{s_{NN}}=130$ GeV scaled by a factor of $(130/200)^{6.3}$. The solid symbols represent x_T spectra from $\sqrt{s_{NN}}=200$ GeV The error bars are statistical only.

cally scaling effects,[4] rather than due to a final state interaction with the dense medium, which may not scale, the cross sections [Eq. (19)] at a given x_T (and centrality) should all exhibit the same suppression. The initial state shadowing may cause $G(x_T)$ to change with centrality, but $n(x_T,\sqrt{s})$ should remain constant. In the case of the interaction with the dense medium, x_T scaling may or may not hold, depending on the details of the energy loss, for instance, whether or not the energy loss of the hard-scattered parton scales with its energy. It is also conceivable that the high-p_T particles observed in Au+Au collisions at RHIC have nothing to do with QCD hard scattering [27,33,52]. In this case, striking differences from Eq. (19) and the systematics observed in $p+p$ collisions should be expected.

To test x_T scaling in Au+Au collisions, we plot the quantities defined by Eq. (20) in Fig. 17 for charged hadron and π^0 data from $\sqrt{s_{NN}}=130$ GeV and 200 GeV for central (0–10%) and peripheral (60–80%) collisions. For the power n, we use the same value $n(x_T,\sqrt{s})=6.3$ that was used for the $p+p$ data shown in Fig. 15(b) and Fig. 16(b). The data are consistent with x_T scaling over the range $0.03\leqslant x_T\leqslant 0.06$ for π^0 and $0.04\leqslant x_T\leqslant 0.075$ for $(h^++h^-)/2$.

According to Eq. (19), the ratio of inclusive cross sections at fixed x_T equals $(200/130)^n$. Thus, the power $n(x_T,\sqrt{s})$ is related directly to the logarithm of the ratio of invariant hadron yield at fixed x_T as

$$n(x_T)=\frac{\log\left[\text{yield}(x_T,130\text{ GeV})/\text{yield}(x_T,200\text{ GeV})\right]}{\log(200/130)}. \tag{21}$$

The power n's for both neutral pions and charged hadrons for central and peripheral collisions are shown in Fig. 18.

While the π^0 data in central and peripheral collisions and charged hadron data in peripheral collisions seem to favor a similar power n, the charged hadron data from central collisions require a larger value of n.

For a more quantitative analysis, the Au+Au data for a given centrality and hadron selection are fitted simultaneously for $\sqrt{s_{NN}}=130$ and 200 GeV to the form

$$\left(\frac{A}{\sqrt{s}}\right)^n (x_T)^{-m}, \tag{22}$$

where we have approximated Eq. (19) by using a constant power $n(x_T,\sqrt{s})$ and a power law, x_T^{-m}, for $G(x_T)$ over a limited range in x_T. The fit results and errors are quoted in Table VI. The corresponding ratios of yields are presented by lines in Figure 18, where the fit ranges ($0.03\leqslant x_T\leqslant 0.06$ for π^0s and $0.04\leqslant x_T\leqslant 0.074$ for charged hadrons) are indicated by the length of the line.

For peripheral collisions the fitted values for the power are $n=6.33\pm0.54$ and $n=6.12\pm0.49$, for π^0 and charged hadrons respectively, which are in quantitative agreement with the expectation from $p+p$ collisions. Approximate x_T scaling in peripheral Au+Au collisions with the same power as observed in $p+p$ collisions indicates that hard scattering is the dominating production mechanism for high-p_T particles. In central collisions, neutral pions also exhibit x_T scaling with a similar power, $n=6.41\pm0.55$. Thus, it seems that high-p_T π^0 production is consistent with hard scattering, with scaling structure and fragmentation functions, for all centralities.

For charged hadrons, the power found for central collisions is $n=7.53\pm0.44$. Most of the systematic errors are common and cancel between central and peripheral collisions, thus the difference of the two powers found for charged hadrons, $\Delta n=n_{cent}-n_{periph}=1.41\pm0.43$ compared with that for neutral pion $\Delta n=0.09\pm0.47$, is significant.

This difference is consistent with the large proton and antiproton enhancement in central Au+Au collisions for in-

[4]There is a slight nonscaling effect of the structure functions [47] since for fixed x_T, Q^2 changes by a factor of 2.4 between the two $\sqrt{s_{NN}}$.

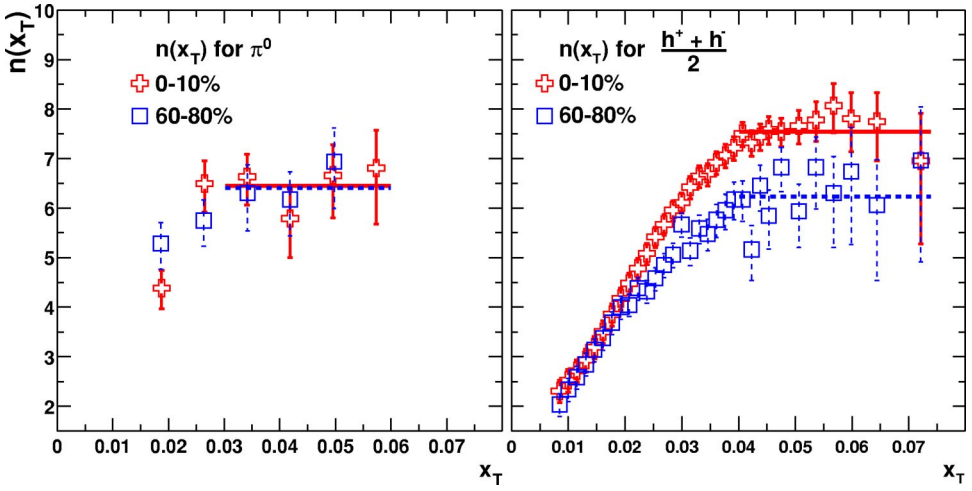

FIG. 18. (Color online) The x_T scaling power n [according to Eq. (21)] plotted as a function of x_T calculated for π^0 (left) and $(h^+ + h^-)/2$ (right) in central (0–10%) and peripheral (60–80%) collisions. The solid (and dashed) lines indicate a constant fit along with the fitting ranges to the central (and peripheral) $n(x_T)$ functions. The error bars at each data point include statistical and point-to-point systematic errors from $\sqrt{s_{NN}}$=130 and 200 GeV. The scale errors on x_T spectra are 20.7%(15.9%) for π^0 x_T spectra ratio in central (peripheral) collisions, and 18.6%(15.7%) for $(h^+ + h^-)/2$ x_T spectra ratio in central (peripheral) collisions. These type of errors propagate into the systematic errors on x_T scaling power n listed in Table VI.

termediate p_T seen at $\sqrt{s_{NN}}$=130 and 200 GeV, which appears to violate x_T scaling. The x_T range $0.04 \leqslant x_T \leqslant 0.074$ corresponds to $4 < p_T < 7.4$ GeV/c at $\sqrt{s_{NN}}$=200 GeV, but it corresponds to $2.6 < p_T < 4.8$ GeV/c at $\sqrt{s_{NN}}$=130 GeV. If protons are enhanced at $2 < p_T < 4.5$ GeV/c in central collisions at both $\sqrt{s_{NN}}$=130 GeV and 200 GeV, then n_{cent} will be larger than n_{periph} in the measured x_T range. Since $\sqrt{s_{NN}}$ =200 GeV data indicate that the proton enhancement is limited to the medium p_T range, based on the equality of R_{AA} for charged hadrons and π^0 at $p_T > 4.5$ GeV/c (Fig. 12), this difference should go away at larger x_T.

IV. SUMMARY

We have presented a systematic study of the p_T and centrality dependence of charged hadron production at $|\eta| < 0.18$ at $\sqrt{s_{NN}}$=200 GeV. The yields per nucleon-nucleon collision in central collisions are significantly suppressed compared to peripheral and nucleon-nucleon collisions. The suppression is approximately independent of p_T above 4.5 GeV/c for all centrality classes, suggesting a similar spectral shape between Au+Au and $p+p$ collisions. At $p_T > 4.5$, charged hadron suppression is the same as for neutral pions; the ratio h/π^0 is ~1.6 for all centralities, similar to the h/π value measured in $p+p$ and e^+e^- collisions. The similar spectral shape and particle composition at high p_T are consistent with jet fragmentation as the dominating mechanism of particle production in Au+Au collisions for $p_T > 4$–5 GeV/c. For both charged hadrons and neutral pions, the suppression sets in gradually from peripheral to central collisions, consistent with the expectation of partonic

TABLE VI. Results of the simultaneous fit to $\sqrt{s_{NN}}$=130 and 200 GeV data using Eq. (22). The fit ranges are $0.03 \leqslant x_T \leqslant 0.06$ for π^0 and $0.04 \leqslant x_T \leqslant 0.074$ for charged hadron. Only statistical and point-to-point systematic errors on the data points are included in the fit, which gives the statistical error on n. The normalization errors and other p_T correlated systematic errors are not included in the fit but are directly translated into a systematic error on n.

Fitting results for π^0 over $0.03 < x_T < 0.06$		
Parameters	0–10% centrality bin	60–80% centrality bin
A	0.973±0.232	0.843±0.3
m	8.48±0.17	7.78±0.22
n	6.41±0.25(stat) ±0.49(sys)	6.33±0.39(stat) ±0.37(sys)
Fitting results for $h^+ + h^-$ over $0.04 < x_T < 0.074$		
A	2.30±0.44	0.62±0.27
m	8.74±0.28	8.40±0.43

energy loss and surface emission of high-p_T hadrons. The x_T-scaled hadron yields are compared between $\sqrt{s_{NN}}$ = 130 GeV and $\sqrt{s_{NN}}$ = 200 GeV Au+Au collisions. We find that the x_T scaling power n calculated for neutral pions in central and peripheral collisions and charged hadron in peripheral collisions is 6.3 ± 0.6, similar to $p+p$ collisions. This again points towards similar production dynamics, i.e., hard scattering processes as described by QCD. However, n is 7.5 ± 0.5 for charged hadrons in central collisions, indicating a strong nonscaling modification of particle composition of charged hadron spectra from that of $p+p$ at intermediate p_T, 2–4.5 GeV/c. This is consistent with the large h/π^0 ratios observed over the same p_T range in central collisions.

(Received 28 July 2003; published 29 March 2004)

The centrality dependence of transverse momentum distributions and yields for $\pi^{\pm}, K^{\pm}, p$, and $\bar{p}$ in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV at midrapidity are measured by the PHENIX experiment at the Relativistic Heavy Ion Collider. We observe a clear particle mass dependence of the shapes of transverse momentum spectra in central collisions below ~ 2 GeV/c in p_T. Both mean transverse momenta and particle yields per participant pair increase from peripheral to midcentral and saturate at the most central collisions for all particle species. We also measure particle ratios of π^-/π^+, K^-/K^+, $\bar{p}/p$, K/π, p/π, and $\bar{p}/\pi$ as a function of p_T and collision centrality. The ratios of equal mass particle yields are independent of p_T and centrality within the experimental uncertainties. In central collisions at intermediate transverse momenta $\sim 1.5-4.5$ GeV/c, proton and antiproton yields constitute a significant fraction of the charged hadron production and show a scaling behavior different from that of pions.

I. INTRODUCTION

The motivation for ultrarelativistic heavy-ion experiments at the Relativistic Heavy Ion Collider (RHIC) at Brookhaven National Laboratory is the study of nuclear matter at extremely high temperature and energy density with the hope of creating and detecting deconfined matter consisting of quarks and gluons—the quark gluon plasma (QGP). Lattice QCD calculations [1] predict that the transition to a deconfined state occurs at a critical temperature $T_c \approx 170$ MeV and an energy density $\epsilon \approx 2$ GeV/fm^3. Based on the Bjorken estimation [2] and the measurement of transverse energy (E_T) in Au+Au collisions at $\sqrt{s_{NN}}=130$ GeV [3] and 200 GeV, the spatial energy density in central Au+Au collisions at RHIC is believed to be high enough to create such deconfined matter in a laboratory [3].

The hot and dense matter produced in relativistic heavy-ion collisions may evolve through the following scenario: preequilibrium, thermal (or chemical) equilibrium of partons, possible formation of QGP or a QGP-hadron gas mixed state, a gas of hot interacting hadrons, and finally, a freeze-out state when the produced hadrons no longer strongly interact with each other. Since produced hadrons carry information about the collision dynamics and the entire space-time evolution of the system from the initial to the final stage of collisions, a precise measure of the transverse momentum (p_T) distributions and yields of identified hadrons as a function of collision geometry is essential for the understanding of the dynamics and properties of the created matter.

In the low p_T region (<2 GeV/c), hydrodynamic models [4,5] that include radial flow successfully describe the measured p_T distributions in Au+Au collisions at $\sqrt{s_{NN}}=130$ GeV [6–8]. The p_T spectra of identified charged hadrons below $p_T \approx 2$ GeV/c in central collisions have been well reproduced by two simple parameters: transverse flow velocity β_T and freeze-out temperature T_{fo} [8] under the assumption of thermalization with longitudinal and transverse flow [4]. The particle production in this p_T region is considered to be dominated by secondary interactions among produced hadrons and participating nucleons in the reaction zone. Another model which successfully describes the particle abundances at low p_T is the statistical thermal model [9]. Particle ratios have been shown to be well reproduced by two parameters: a baryon chemical potential μ_B and a chemical freeze-out temperature T_{ch}. It is found that there is an overall good agreement between measured particle ratios at $\sqrt{s_{NN}}=130$ GeV Au+Au and the thermal model calculations [10,11].

On the other hand, at high p_T ($\geqslant 4$ GeV/c) the dominant particle production mechanism is the hard scattering described by perturbative quantum chromodynamics (pQCD), which produces particles from the fragmentation of energetic partons. One of the most interesting observations at RHIC is that the yield of high p_T neutral pions and nonidentified charged hadrons in central Au+Au collisions at RHIC are below the expectation of the scaling with the number of nucleon-nucleon binary collisions, N_{coll} [12–14]. This effect could be a consequence of the energy loss suffered by partons moving through deconfined matter [15,16]. It has also been observed that the yield of neutral pions is more strongly suppressed than that for nonidentified charged hadrons [12] in central Au+Au collisions at RHIC. Another interesting feature is that the proton and antiproton yields in central events are comparable to that of pions at $p_T \approx 2$ GeV/c [6], differing from the expectation of pQCD. These observations suggest that a detailed study of particle composition at intermediate $p_T (\approx 2-4$ GeV/$c)$ is very important to understand hadron production and collision dynamics at RHIC.

The PHENIX experiment [17] has a unique hadron identification capability in a broad momentum range. Pions and kaons are identified up to 3 GeV/c and 2 GeV/c in p_T, respectively, and protons and antiprotons can be identified up to 4.5 GeV/c by using a high resolution time-of-flight detector [18]. Neutral pions are reconstructed via $\pi^0 \rightarrow \gamma\gamma$ up to $p_T \approx 10$ GeV/c through an invariant mass analysis of γ pairs detected in an electromagnetic calorimeter [19] with wide azimuthal coverage. During the measurements of Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV in year 2001 at RHIC, the PHENIX experiment accumulated enough events to address the above issues at intermediate p_T as well as the particle production at low p_T with precise centrality dependences. In this paper, we present the centrality dependence of p_T spectra, $\langle p_T \rangle$, yields, and ratios for $\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$, in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV at midrapidity measured by the PHENIX experiment. We also present results on the scaling behavior of charged hadrons compared with results of π^0 measurements [14], which have been published separately.

The paper is organized as follows. Section II describes the PHENIX detector used in this analysis. In Sec. III the analysis details including event selection, track selection, particle identification, and corrections applied to the data are described. The systematic errors on the measurements are also discussed in this section. For the experimental results, centrality dependence of p_T spectra for identified charged particles is presented in Sec. IV A, and transverse mass spectra are given in Sec. IV B. Particle yields and mean transverse momenta as a function of centrality are presented in Sec. IV C. In Sec. IV D the systematic study of particle ratios as a function p_T and centrality is presented. Section IV E studies the scaling behavior of identified charged hadrons. A summary is given in Sec. V.

II. PHENIX DETECTOR

The PHENIX experiment is composed of two central arms, two forward muon arms, and three global detectors. The east and west central arms are placed at zero rapidity and designed to detect electrons, photons, and charged hadrons. The north and south forward muon arms have full azimuthal coverage and are designed to detect muons. The global detectors measure the start time, vertex, and multiplicity of the interactions. The following sections describe the parts of the detector that are used in the present analysis. A detailed description of the complete detector can be found elsewhere [17–22].

A. Global detectors

In order to characterize the centrality of Au+Au collisions, zero-degree calorimeters (ZDCs) [21] and beam-beam

counters (BBCs) [20] are employed. The zero-degree calorimeters are small hadronic calorimeters which measure the energy carried by spectator neutrons. They are placed 18 m upstream and downstream of the interaction point along the beam line. Each ZDC consists of three modules. Each module has a depth of two hadronic interaction lengths and is read out by a single photomultiplier tube (PMT). Both time and amplitude are digitized for each PMT along with the analog sum of the three PMT signals for each ZDC.

Two sets of beam-beam counters are placed 1.44 m from the nominal interaction point along the beam line (one on each side). Each counter consists of 64 Čerenkov telescopes, arranged radially around the beam line. The BBC measures the number of charged particles in the pseudorapidity region $3.0<|\eta|<3.9$. The correlation between BBC charge sum and ZDC total energy is used for centrality determination. The BBC also provides a collision vertex position and start time information for time-of-flight measurement.

B. Central arm detectors

Charged particles are tracked using the central arm spectrometers [22]. The spectrometer on the east side of the PHENIX detector (east arm) contains the following subsystems used in this analysis: drift chamber (DC), pad chamber (PC), and time-of-flight (TOF).

The drift chambers are the closest tracking detectors to the beam line—at a radial distance of 2.2 m. They measure charged particle trajectories in the azimuthal direction to determine the transverse momentum of each particle. By combining the polar angle information from the first layer of the PC with the transverse momentum, the total momentum p is determined. The momentum resolution is $\delta p/p \simeq 0.7\% \oplus 1.0\% \times p(\mathrm{GeV}/c)$, where the first term is due to the multiple scattering before the DC and the second term is the angular resolution of the DC. The momentum scale is known to 0.7%, from the reconstructed proton mass using the TOF.

The pad chambers are multiwire proportional chambers that form three separate layers of the central tracking system. The first pad chamber layer (PC1) is located at the radial outer edge of each drift chamber at a distance of 2.49 m, while the third layer (PC3) is 4.98 m from the interaction point. The second layer (PC2) is located at a radial distance of 4.19 m in the west arm only. PC1 and the DC, along with the vertex position measured by the BBC, are used in the global track reconstruction to determine the polar angle of each charged track.

The time-of-flight detector serves as the primary particle identification device for charged hadrons by measuring the stop time. The start time is given by the BBC. The TOF wall is located at a radial distance of 5.06 m from the interaction point in the east central arm. This contains 960 scintillator slats oriented along the azimuthal direction. It is designed to cover $|\eta|<0.35$ and $\Delta\phi=45°$ in azimuthal angle. The intrinsic timing resolution is $\sigma \simeq 115$ ps, which allows for a 3σ π/K separation up to $p_T \simeq 2.5$ GeV/c, and 3σ K/p separation up to $p_T \simeq 4$ GeV/c.

III. DATA ANALYSIS

In this section, we describe the event and track selection, charged particle identification and various corrections, including geometrical acceptance, particle decay, multiple scattering and absorption effects, detector occupancy corrections, and weak decay contributions from Λ and $\bar{\Lambda}$ to proton and antiproton spectra. The estimations of systematic uncertainties on the measurements are addressed at the end of this section.

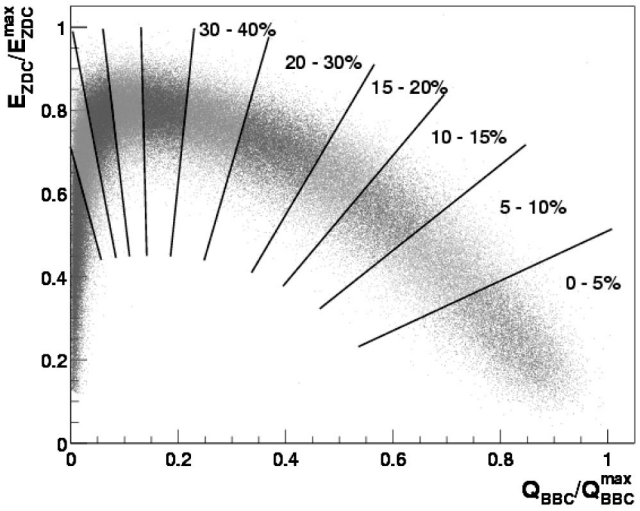

FIG. 1. BBC vs ZDC analog response. The lines represent the centrality cut boundaries.

A. Event selection

For the present analysis, we use the PHENIX minimum bias trigger events, which are determined by a coincidence between north and south BBC signals. We also require a collision vertex within ±30 cm from the center of the spectrometer. The collision vertex resolution determined by the BBC is about 6 mm in Au+Au collisions in minimum bias events [20]. The PHENIX minimum bias trigger events include $92.2^{+2.5}_{-3.0}$% of the 6.9 b Au+Au total inelastic cross section [14]. Figure 1 shows the correlation between the BBC charge sum and ZDC total energy for Au+Au at $\sqrt{s_{NN}}$ =200 GeV. The lines on the plot indicate the centrality definition in the analysis. For the centrality determination, these events are subdivided into 11 bins using the BBC and ZDC correlation: 0–5%, 5–10%, 10–15%, 15–20%, 20–30%, …, 70–80%, and 80–92%. Due to the statistical limitations in the peripheral events, we also use the 60–92% centrality bin as the most peripheral bin. After event selection, we analyze 2.02×10^7 minimum bias events, which represents ~140 times more events than used in our published Au+Au data at 130 GeV [6,8]. Based on a Glauber model calculation [8,14] we use two global quantities to characterize the event centrality: the average number of participants $\langle N_{part}\rangle$ and the average number of collisions $\langle N_{coll}\rangle$ associated with each centrality bin (Table I).

B. Track selection

Charged particle tracks are reconstructed by the DC based on a combinatorial Hough transform [25]—which gives the angle of the track in the main bend plane. The main bend

TABLE I. The average nuclear overlap function ($\langle T_{\mathrm{AuAu}}\rangle$), the number of nucleon-nucleon binary collisions ($\langle N_{coll}\rangle$), and the number of participant nucleons ($\langle N_{part}\rangle$) obtained from a Glauber Monte Carlo [8,14] correlated with the BBC and ZDC response for Au+Au at $\sqrt{s_{NN}}=200$ GeV as a function of centrality. Centrality is expressed as percentiles of $\sigma_{\mathrm{AuAu}}=6.9$ b with 0% representing the most central collisions. The last line refers to minimum bias collisions.

plane is perpendicular to the beam axis (azimuthal direction). PC1 is used to measure the position of the hit in the longitudinal direction (along the beam axis). When combined with the location of the collision vertex along the beam axis (from the BBC), the PC1 hit gives the polar angle of the track. Only tracks with valid information from both the DC and PC1 are used in the analysis. In order to associate a track with a hit on the TOF, the track is projected to its expected hit location on the TOF. Tracks are required to have a hit on the TOF within $\pm 2\sigma$ of the expected hit location in both the azimuthal and beam directions. Finally, a cut on the energy loss in the TOF scintillator is applied to each track. This β-dependent energy loss cut is based on a parametrization of the Bethe-Bloch formula, i.e., $dE/dx \approx \beta^{-5/3}$, where $\beta = L/(ct_{\mathrm{TOF}})$, L is the path length of the track trajectory from the collision vertex to the hit position of the TOF wall, t_{TOF} is the time of flight, and c is the speed of light. The flight path length is calculated from a fit to the reconstructed track trajectory. The background due to random association of DC/PC1 tracks with TOF hits is reduced to a negligible level when the mass cut used for particle identification is applied (described in the following) section.

C. Particle identification

The charged particle identification (PID) is performed by using the combination of three measurements: time of flight from the BBC and TOF, momentum from the DC, and flight path length from the collision vertex point to the hit position on the TOF wall. The square of the mass is derived from the following formula:

$$m^2 = \frac{p^2}{c^2}\left[\left(\frac{t_{\mathrm{TOF}}}{L/c}\right)^2 - 1\right], \tag{1}$$

where p is the momentum, t_{TOF} is the time of flight, L is a flight path length, and c is the speed of light. The charged particle identification is performed using cuts in m^2 and momentum space.

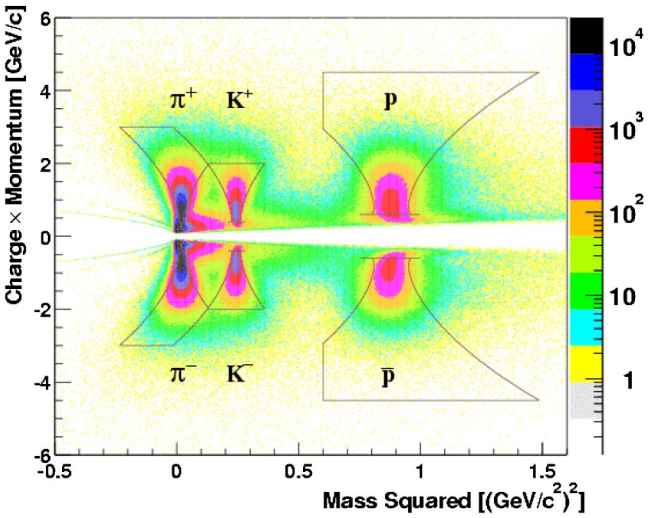

FIG. 2. (Color online) Mass-squared vs momentum multiplied by charge distribution in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The lines indicate the PID cut boundaries for pions, kaons, and protons (antiprotons) from left to right, respectively.

In Fig. 2, a plot of m^2 versus momentum multiplied by charge is shown together with applied PID cuts as solid curves. We use 2σ standard deviation PID cuts in m^2 and momentum space for each particle species. The PID cut is based on a parametrization of the measured m^2 width as a function of momentum,

$$\sigma_{m^2}^2 = \frac{\sigma_\alpha^2}{K_1^2}(4m^4p^2) + \frac{\sigma_{ms}^2}{K_1^2}\left[4m^4\left(1+\frac{m^2}{p^2}\right)\right] + \frac{\sigma_t^2 c^2}{L^2}[4p^2(m^2+p^2)], \tag{2}$$

where σ_α is the angular resolution, σ_{ms} is the multiple scattering term, σ_t is the overall time-of-flight resolution, m is the centroid of m^2 distribution for each particle species, and K_1 is a magnetic field integral constant term of 87.0 mrad GeV. The parameters for PID are $\sigma_\alpha = 0.835$ mrad, $\sigma_{ms}=0.86$ mrad GeV, and $\sigma_t=120$ ps. Through improvements in alignment and calibrations, the momentum resolution is improved over the 130 GeV data [8]. The centrality dependence of the width and the mean position of the m^2 distribution has also been checked. There is no clear difference seen between central and peripheral collisions. For pion identification above 2 GeV/c, we apply an asymmetric PID cut to reduce kaon contami-

nation of the pions. As shown by the lines in Fig. 2, the overlap region which is within the 2σ cuts for both pions and kaons is excluded. For kaons, the upper momentum cutoff is 2 GeV/c since the pion contamination level for kaons is ≈10% at that momentum. The upper momentum cutoff on the pions is p_T=3 GeV/c—where the kaon contamination reaches ≈10%. The contamination of protons by kaons reaches about 5% at 4 GeV/c. Electron (positron) and decay muon background at very low p_T (<0.3 GeV/c) are well separated from the pion mass-squared peak. The contamination background on each particle species is not subtracted in the analysis. For protons, the upper momentum cutoff is set at 4.5 GeV/c due to statistical limitations and background at high p_T. An additional cut on m^2 for protons and antiprotons, $m^2 > 0.6$ (GeV/c^2)^2, is introduced to reduce background. The lower momentum cutoffs are 0.2 GeV/c for pions, 0.4 GeV/c for kaons, and 0.6 GeV/c for p and $\bar{p}$. This cutoff value for p and $\bar{p}$ is larger than those for pions and kaons due to the large energy loss effect.

D. Acceptance, decay, and multiple scattering corrections

In order to correct for (1) the geometrical acceptance, (2) in-flight decay for pions and kaons, (3) the effect of multiple scattering, and (4) nuclear interactions with materials in the detector (including antiproton absorption), we use PISA (PHENIX Integrated Simulation Application), a GEANT [26] based Monte Carlo (MC) simulation program of the PHENIX detector. The single-particle tracks are passed from GEANT through the PHENIX event reconstruction software [25]. In this simulation, the BBC, TOF, and DC detector responses are tuned to match the real data. For example, dead areas of DC and TOF are included, and momentum and time-of-flight resolution are tuned. The track association to TOF in both azimuth (ϕ) and along the beam axis (z) as a function of momentum and the PID cut boundaries are parametrized to match the real data. A fiducial cut is applied to choose identical active areas on the TOF in both the simulation and data. We generate 1×10^7 single-particle events for each particle species ($\pi^{\pm}$, $K^{\pm}$, p, and $\bar{p}$) with low p_T enhanced (<2 GeV/c)+flat p_T distributions for high p_T (2–4 GeV/c for pions and kaons, 2–8 GeV/c for p and $\bar{p}$). [1] The efficiencies are determined in each p_T bin by dividing the reconstructed output by the generated input as expressed as follows:

$$\epsilon_{\rm acc}(j,p_T) = \frac{\text{No. of reconstructed MC tracks}}{\text{No. of generated MC tracks}}, \qquad (3)$$

where j is the particle species. The resulting correction factors ($1/\epsilon_{\rm acc}$) are applied to the data in each p_T bin and for each individual particle species.

[1]Due to the good momentum resolution at the high p_T region, the momentum smearing effect for a steeply falling spectrum is <1% at p_T=5 GeV/c. The flat p_T distribution up to 5 GeV/c can be used to obtain the correction factors.

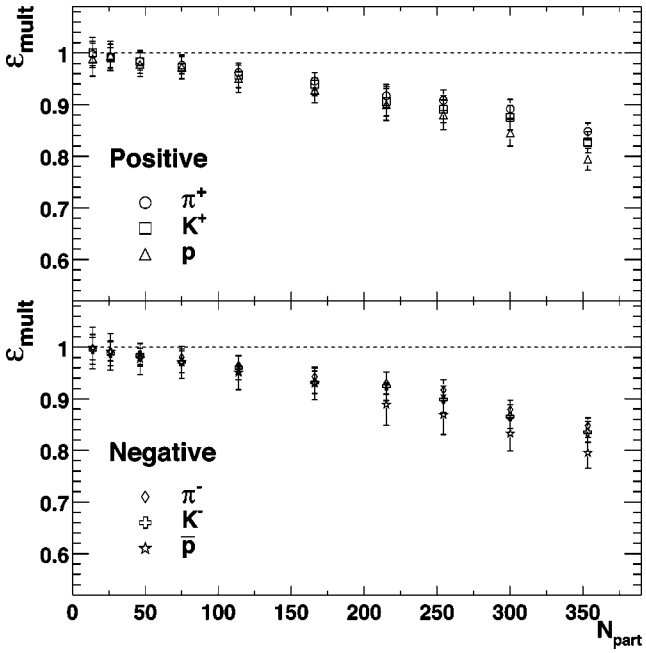

FIG. 3. Track reconstruction efficiency ($\epsilon_{\rm mult}$) as a function of centrality. The error bars on the plot represent the systematic errors.

E. Detector occupancy correction

Due to the high multiplicity environment in heavy ion collisions, which causes high occupancy and multiple hits on a detector cell such as scintillator slats of the TOF, it is expected that the track reconstruction efficiency in central events is lower than that in peripheral events. The typical occupancy at TOF is less than 10% in the most central Au+Au collisions. To correct for this effect, we merge single particle simulated events with real events and calculate the track reconstruction efficiency for each simulated track as follows:

$$\epsilon_{\rm mult}(i,j) = \frac{\text{No. of reconstructed embedded tracks}}{\text{No. of embedded tracks}}, \qquad (4)$$

where i is the centrality bins and j is the particle species. This study has been performed for each particle species and each centrality bin. The track reconstruction efficiencies are factorized (into independent terms depending on centrality and p_T) for $p_T > 0.4$ GeV/c, since there is no p_T dependence in the efficiencies above that p_T. Figure 3 shows the dependence of track reconstruction efficiency for $\pi^{\pm}$, $K^{\pm}$, p, and $\bar{p}$ as a function of centrality expressed as N_{part}. The efficiency in the most central 0–5% events is about 80% for protons ($\bar{p}$), 83% for kaons, and 85% for pions. Slower particles are more likely lost due to high occupancy in the TOF because the system responds to the earliest hit. For the most peripheral 80–92% events, the efficiency for detector occupancy effect is ≈99% for all particle species. The factors are applied to the spectra for each particle species and centrality bin. Systematic uncertainties on detector occupancy corrections ($1/\epsilon_{\rm mult}$) are less than 3%.

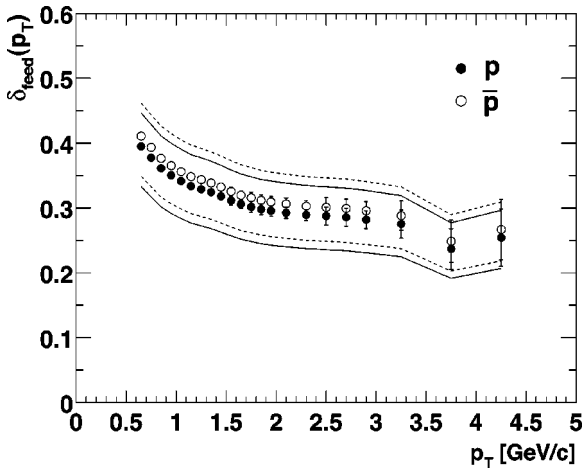

FIG. 4. The fractional contribution of protons ($\bar{p}$) from Λ ($\bar{\Lambda}$) decays in all measured protons ($\bar{p}$), $\delta_{\text{feed}}(p_T)$, as a function of p_T. The solid (dashed) lines represent the systematic errors for protons ($\bar{p}$). The error bars are statistical errors.

F. Weak decay correction

Protons and antiprotons from weak decays (e.g., from Λ and $\bar{\Lambda}$) can be reconstructed as tracks in the PHENIX spectrometer. The proton and antiproton spectra are corrected to remove the feed-down contribution from weak decays using a HIJING [27] simulation. HIJING output has been tuned to reproduce the measured particle ratios of Λ/p and $\bar{\Lambda}/\bar{p}$ along with their p_T dependencies in $\sqrt{s_{NN}}=130$ GeV Au+Au collisions [28] which include contribution from Ξ and Σ^0. Corrections for feed-down from $\Sigma^{\pm}$ are not applied, as these yields were not measured. About 2×10^6 central HIJING events (impact parameter $b=0-3$ fm) covering the TOF acceptance have been generated and processed through the PHENIX reconstruction software. To calculate the feed-down corrections, the $\bar{p}/p$ and $\bar{\Lambda}/\Lambda$ yield ratios were assumed to be independent of p_T and centrality. The systematic error due to the feed-down correction is estimated at 6% by varying the Λ/p and $\bar{\Lambda}/\bar{p}$ ratios within the systematic errors of the $\sqrt{s_{NN}}=130$ GeV Au+Au measurement [28] (±24%) and assuming m_T scaling at high p_T. This uncertainty could be larger if the Λ/p and $\bar{\Lambda}/\bar{p}$ ratios change significantly with p_T and beam energy. The fractional contribution to the p ($\bar{p}$) yield from Λ ($\bar{\Lambda}$), $\delta_{\text{feed}}(p_T)$, is shown in Fig. 4. The solid (dashed) lines represent the systematic errors for protons ($\bar{p}$). The obtained factor is about 40% below 1 GeV/c and 30% at 4 GeV/c. We multiply the proton and antiproton spectra by the factor C_{feed} for all centrality bins as a function of p_T:

$$C_{\text{feed}}(j,p_T) = 1 - \delta_{\text{feed}}(j,p_T), \tag{5}$$

where $j=p,\bar{p}$.

G. Invariant yield

Applying the data cuts and corrections discussed above, the final invariant yield for each particle species and centrality bin are derived using the following equation:

$$\frac{1}{2\pi p_T}\frac{d^2N}{dp_T dy} = \frac{1}{2\pi p_T}\frac{1}{N_{evt}(i)}C_{ij}(p_T)\frac{N_j(i,p_T)}{\Delta p_T \Delta y}, \tag{6}$$

where y is rapidity, $N_{evt}(i)$ is the number of events in each centrality bin i, $C_{ij}(p_T)$ is the total correction factor, and $N_j(i,p_T)$ is the number of counts in each centrality bin i, particle species j, and p_T. The total correction factor is composed of

$$C_{ij}(p_T) = \frac{1}{\epsilon_{\text{acc}}(j,p_T)}\frac{1}{\epsilon_{\text{mult}}(i,j)}C_{\text{feed}}(j,p_T). \tag{7}$$

H. Systematic uncertainties

To estimate systematic uncertainties on the p_T distribution and particle ratios, various sets of p_T spectra and particle ratios were made by changing the cut parameters including the fiducial cut, PID cut, and track association windows slightly from what was used in the analysis. For each of these spectra and ratios using modified cuts, the same changes in the cuts were made in the Monte Carlo analysis. The absolutely normalized spectra with different cut conditions are divided by the spectra with the baseline cut conditions, resulting in uncertainties associated with each cut condition as a function of p_T. The various uncertainties are added in quadrature. Three different centrality bins (minimum bias, central 0–5%, and peripheral 60–92%) are used to study the centrality dependence of systematic errors. The same procedure has been applied for the following particle ratios: π^-/π^+, K^-/K^+, $\bar{p}/p$, K/π, p/π^+, and $\bar{p}/\pi^-$.

TABLE II. Systematic errors on the p_T spectra for central events. All errors are given in percent.

	π^+	π^-	K^+	K^-	p		$\bar{p}$	
p_T range (GeV/c)	0.2–3.0	0.2–3.0	0.4–2.0	0.4–2.0	0.6–3.0	3.0–4.5	0.6–3.0	3.0–4.5
Cuts	6.2	6.2	11.2	9.5	6.6	11.6	6.6	11.6
Momentum scale	3	3	3	3	3	3	3	3
Occupancy correction	2	2	3	3	3	3	3	3
Feed-down correction					6.0	6.0	6.0	6.0
Total	7.2	7.2	12.0	10.4	9.9	13.7	9.9	9.9

TABLE III. Systematic errors on central-to-peripheral ratio (R_{CP}). All errors are given in percent.

Source	$(\pi^+ + \pi^-)/2$	$(K^+ + K^-)/2$	$(p+\bar{p})/2$
Occupancy correction (central)	2	3	3
Occupancy correction (peripheral)	2	3	3
$\langle T_{\mathrm{AuAu}} \rangle$ (0–10%)	6.9	6.9	6.9
$\langle T_{\mathrm{AuAu}} \rangle$ (60–92%)	28.6	28.6	28.6
Total	29.5	29.7	29.7

Table II shows the systematic errors of the p_T spectra for central collisions. The systematic uncertainty on the absolute value of momentum (momentum scale) is estimated as 3% in the measured p_T range by comparing the known proton mass to the value measured as protons in real data. It is found that the total systematic error on the p_T spectra is 8–14% in both central and peripheral collisions. For the particle ratios, the typical systematic error is about 6% for all particle species. The dominant source of uncertainties on the central-to-peripheral ratio scaled by N_{coll} (R_{CP}) are the systematic errors on the nuclear overlap function, T_{AuAu} (see Table III). The systematic errors on dN/dy and $\langle p_T \rangle$ are discussed in Sec. IV C together with the procedure for the determination of these quantities.

IV. RESULTS

In this section, the p_T and transverse mass spectra and yields of identified charged hadrons as a function of centrality are shown. Also a systematic study of particle ratios in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV at midrapidity is presented.

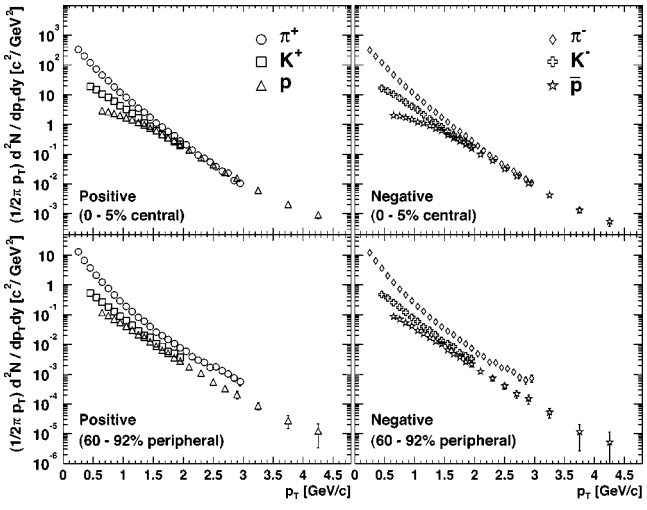

FIG. 5. Transverse momentum distributions for pions, kaons, protons, and antiprotons in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The top two figures show p_T spectra for the most central 0–5% collisions. The bottom two are for the most peripheral 60–92% collisions. The error bars are statistical only. The Λ ($\bar{\Lambda}$) feed-down corrections for protons (antiprotons) have been applied.

A. Transverse momentum distributions

Figure 5 shows the p_T distributions for pions, kaons, protons, and antiprotons. The top two plots are for the most central 0–5% collisions, and the bottom two are for the most peripheral 60–92% collisions. The spectra for positive particles are presented on the left, and those for negative particles on the right. For $p_T < 1.5$ GeV/c in central events, the data show a clear mass dependence in the shapes of the spectra. The p and $\bar{p}$ spectra have a shoulder-arm shape, the pion spectra have a concave shape, and the kaons fall exponentially. On the other hand, in the peripheral events, the mass dependences of the p_T spectra are less pronounced and the p_T spectra are more nearly parallel to each other. Another notable observation is that at p_T above $\approx$2.0 GeV/c in central events, the p and $\bar{p}$ yields become comparable to the pion yields, which is also observed in 130 GeV Au+Au collisions [6]. This observation shows that a significant fraction of the total particle yield at $p_T \approx 2.0$–4.5 GeV/c in Au+Au central collisions consists of p and $\bar{p}$.

These high statistics Au+Au data at $\sqrt{s_{NN}}=200$ GeV allow us to perform a detailed study of the centrality dependence of the p_T spectra. In this analysis, we use the 11 centrality bins described in Sec. III A as well as the combined peripheral bin (60–92%) for each particle species. Figure 6 shows the centrality dependence of the p_T spectrum for π^+ (left) and π^- (right). For clarity, the data points are scaled

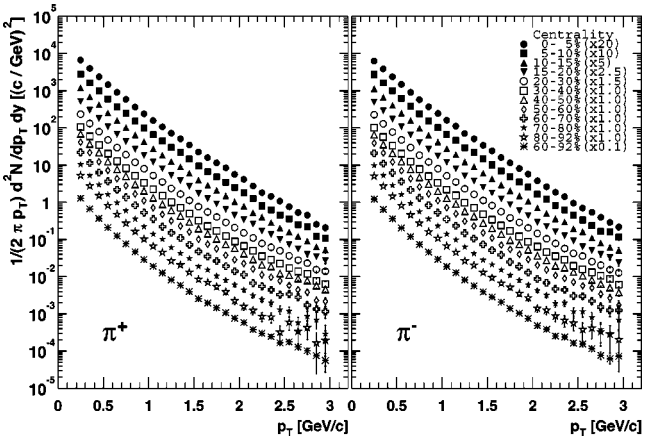

FIG. 6. Centrality dependence of the p_T distribution for π^+ (left) and π^- (right) in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The different symbols correspond to different centrality bins. The error bars are statistical only. For clarity, the data points are scaled vertically as quoted in the figure.

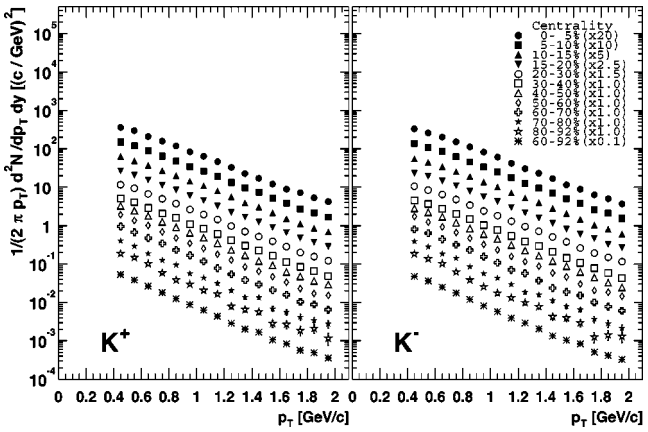

FIG. 7. Centrality dependence of the p_T distribution for K^+ (left) and K^- (right) in Au+Au collisions at $\sqrt{s_{NN}}$=200 GeV. The different symbols correspond to different centrality bins. The error bars are statistical only. For clarity, the data points are scaled vertically as quoted in the figure.

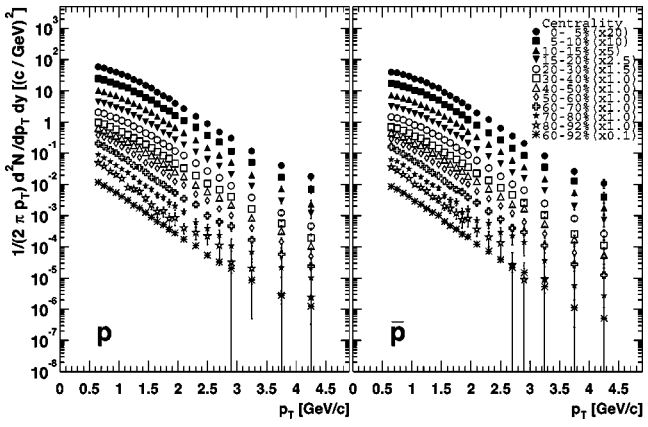

FIG. 8. Centrality dependence of the p_T distribution for protons (left) and antiprotons (right) in Au+Au collisions at $\sqrt{s_{NN}}$ =200 GeV. The different symbols correspond to different centrality bins. The error bars are statistical only. Feed-down corrections for Λ ($\bar{\Lambda}$) decaying into proton ($\bar{p}$) have been applied. For clarity, the data points are scaled vertically as quoted in the figure.

vertically as quoted in the figures. The error bars are statistical only. The pion spectra show an approximately power-law shape for all centrality bins. The spectra become steeper (fall faster with increasing p_T) for more peripheral collisions.

Figure 7 shows similar plots for kaons. The data can be well approximated by an exponential function in p_T for all centralities. Finally, the centrality dependence of the p_T spectra for protons (left) and antiprotons (right) is shown in Fig. 8. As in Fig. 5, both p and $\bar{p}$ spectra show a strong centrality dependence below 1.5 GeV/c, i.e., they develop a shoulder at low p_T and the spectra flatten (fall more slowly with increasing p_T) with increasing collision centrality.

Up to p_T=1.5–2 GeV/c, it has been found that hydrodynamic models can reproduce the data well for $\pi^{\pm}$, $K^{\pm}$, p, and $\bar{p}$ spectra at 130 GeV [8], and also the preliminary data at 200 GeV in Au+Au collisions (e.g., Refs. [5,29]). These models assume thermal equilibrium and that the created particles are affected by a common transverse flow velocity β_T and freeze-out (stop interacting) at a temperature T_{fo} with a fixed initial condition governed by the equation of state (EOS) of matter. There are several types of hydrodynamic calculations, e.g., (1) a conventional hydrodynamic fit to the experimental data with two free parameters, β_T and T_{fo} [30], (2) a combination of hydrodynamics and a hadronic cascade model [5], (3) transverse and longitudinal flow with simultaneous chemical and thermal freeze-outs within the statistical thermal model [31], (4) requiring the early thermalization with a QGP type EOS [32]. Despite the differences between the hydrodynamic models, all models are in qualitative agreement with the identified single-particle spectra in central collisions at low p_T as seen in Ref. [8]. However, they fail to reproduce the peripheral spectra above $p_T \simeq 1$ GeV/c and their applicability in the high p_T region (>2 GeV/c) is limited. Comparison with the detailed centrality dependence of hadron spectra presented here would shed light on further understanding of the EOS, chemical properties in the model, and the freeze-out conditions at RHIC.

B. Transverse mass distributions

In order to quantify the observed particle mass dependence of the p_T spectra shape and their centrality dependence, the transverse mass spectra for identified charged hadrons are presented here. From former studies at lower beam energies, it is known that the invariant differential cross sections in $p+p$, $p+A$, and $A+A$ collisions generally show a shape of an exponential in m_T-m_0, where m_0 is particle mass, and $m_T=\sqrt{p_T^2+m_0^2}$ is transverse mass. For an m_T spectrum with an exponential shape, one can parametrize it as follows:

$$\frac{d^2N}{2\pi m_T dm_T dy} = \frac{1}{2\pi T(T+m_0)} A \exp\left(-\frac{m_T-m_0}{T}\right), \quad (8)$$

where T is referred to as the inverse slope parameter, and A is a normalization parameter which contains information on dN/dy. In Fig. 9, m_T distributions for $\pi^{\pm}$, $K^{\pm}$, p, and $\bar{p}$ for central 0–5% (top panels), midcentral 40–50% (middle panels), and peripheral 60–92% (bottom panels) collisions are shown. The spectra for positive particles are on the left and for negative particles are on the right. The solid lines overlaid on each spectra are the fit results using Eq. (8). The error bars are statistical only. As seen in Fig. 9, all the m_T spectra display an exponential shape in the low m_T region. However, at higher m_T, the spectra become less steep, which corresponds to a power-law behavior in p_T. Thus, the inverse slope parameter in Eq. (8) depends on the fitting range. In this analysis, the fits cover the range 0.2–1.0 GeV/c^2 for pions and 0.1–1.0 GeV/c^2 for kaons, protons, and antiprotons in m_T-m_0. The low m_T region ($m_T-m_0<0.2$ GeV/c^2) for pions is excluded from the fit to eliminate the contributions from resonance decays. The inverse slope parameters for each particle species in the three centrality bins are summarized in Fig. 10 and in Table IV. The inverse slope parameters increase with increasing particle mass in all centrality bins. This

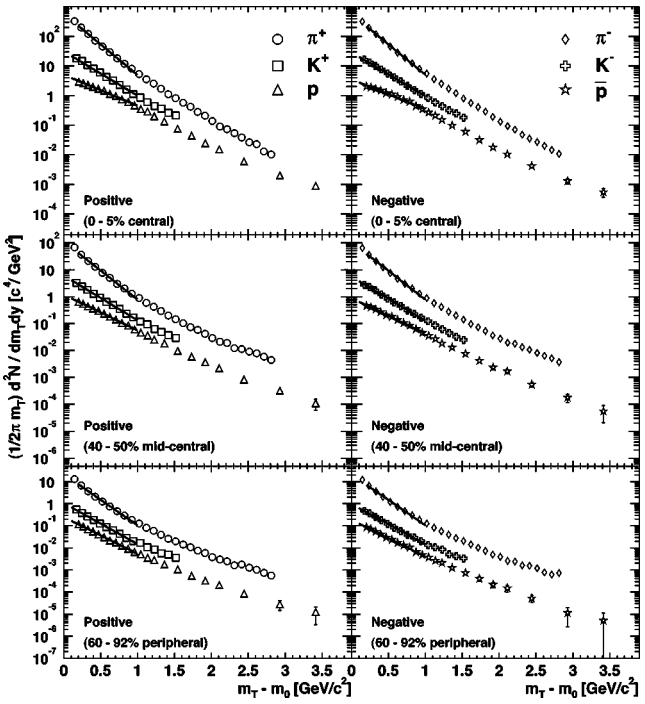

FIG. 9. Transverse mass distributions for $\pi^{\pm}$, $K^{\pm}$, protons, and antiprotons for central 0–5% (top panels), midcentral 40–50% (middle panels), and peripheral 60–92% (bottom panels) in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The lines on each spectra are the fitted results using m_T exponential function. The fit ranges are 0.2–1.0 GeV/c^2 for pions and 0.1–1.0 GeV/c^2 for kaons, protons, and antiprotons in m_T-m_0. The error bars are statistical errors only.

increase for central collisions is more rapid for heavier particles.

Such a behavior was derived, under certain conditions, by Schnedermann *et al.* [33] for central collisions and by Csörgő *et al.* [34] for noncentral heavy-ion collisions:

$$T = T_0 + m\langle u_t\rangle^2. \tag{9}$$

Here T_0 is a freeze-out temperature and $\langle u_t\rangle$ is a measure of the strength of the (average radial) transverse flow. The dotted lines in Fig. 10 represent a linear fit of the results from each centrality bin as a function of mass using Eq. (9). The fit parameters for positive and negative particles are shown in Table IV. It indicates, that the linear extrapolation of the slope parameter $T(m)$ to zero mass has the same intercept parameters T_0 in all the centrality classes, indicating that the freeze-out temperature is approximately independent of the centrality. On the other hand, $\langle u_t\rangle$, the strength of the average transverse flow is increasing with increasing centrality, supporting the hydrodynamic picture.

Motivated by the idea of a color glass condensate, the authors of Ref. [35] argued that the m_T spectra (not m_T-m_0) of identified hadrons at RHIC energy follow a generalized scaling law for all centrality classes when the proton (kaon) spectrum is multiplied by a factor of 0.5 (2.0). The 200 GeV Au+Au pion and kaon spectra seem to follow this m_T scaling, but proton and antiproton spectra are below it by a factor of $\sim$2 for all centralities. Since p and $\bar{p}$ spectra presented here are corrected for weak decays from Λ and $\bar{\Lambda}$, the model also needs to study the feed-down effect to conclude that a universal m_T scaling law is seen at RHIC.

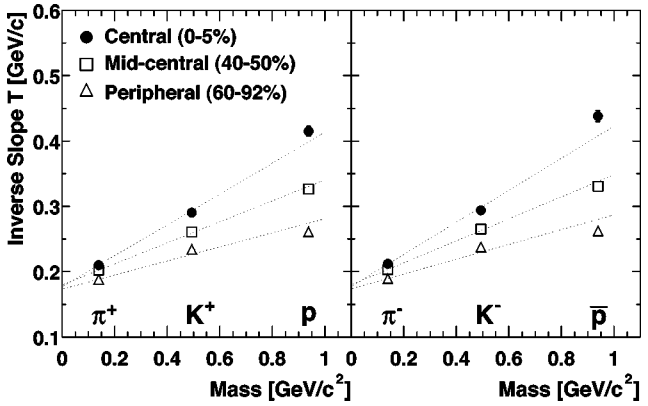

FIG. 10. Mass and centrality dependence of inverse slope parameters T in m_T spectra for positive (left) and negative (right) particles in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The fit ranges are 0.2–1.0 GeV/c^2 for pions and 0.1–1.0 GeV/c^2 for kaons, protons, and antiprotons in m_T-m_0. The dotted lines represent a linear fit of the results from each centrality bin as a function of mass using Eq. (9).

C. Mean transverse momentum and particle yields versus N_{part}

By integrating a measured p_T spectrum over p_T, one can determine the mean transverse momentum $\langle p_T\rangle$ and particle yield per unit rapidity, dN/dy, for each particle species. The procedure to determine the mean p_T and dN/dy is described below.

TABLE IV. (Top) Inverse slope parameters for π, K, p, and $\bar{p}$ for the 0–5%, 40–50%, and 60–92% centrality bins, in units of MeV/c^2. The errors are statistical only. (Bottom) The extracted fit parameters of the freeze-out temperature T_0 in units of MeV/c^2 and the measure of the strength of the average radial transverse flow ($\langle u_t\rangle$) using Eq. (9). The fit results shown here are for positive and negative particles, as denoted in the superscripts, and for three different centrality bins.

Particle	0–5%	40–50%	60–92%

$\langle u_t\rangle^{(+)}$	0.48±0.07	0.40±0.07	0.32±0.07
$\langle u_t\rangle^{(-)}$	0.49±0.07	0.41±0.07	0.33±0.07

TABLE V. Systematic errors on dN/dy for central 0–5% (top) and peripheral 60–92% (bottom) collisions. All errors are given in percent.

Source	π^+	π^-	K^+	K^-	p	$\bar{p}$
			Central 0–5%			
Cuts + occupancy	6.5	6.5	11.6	10.0	7.2	7.2
Extrapolation	5.4	4.8	5.7	5.6	9.6	9.2
Contamination background	<1	<1	<1	<1	<1	<1
Feed-down					8.0	8.0
Total	8.4	8.0	12.9	11.4	14.4	14.4
			Peripheral 60–92%			
Cuts + occupancy	6.5	6.5	8.3	7.2	8.3	8.3
Extrapolation	8.4	8.0	7.4	7.5	13.6	13.6
Contamination background	<1	<1	<1	<1	<1	<1
Feed-down					8.0	8.0
Total	10.6	10.3	11.1	10.3	17.8	17.8

(1) Determine dN/dy and $\langle p_T \rangle$ by integrating over the measured p_T range from the data.

(2) Fit several appropriate functional forms (detailed below) to the p_T spectra. Note that all of the fits are reasonable approximations to the data. Integrate from zero to the first data point and from the last data point to infinity.

(3) Sum the data yield and the two functional yield pieces together to get dN/dy and $\langle p_T \rangle$ in each functional form.

(4) Take the average between the upper and lower bounds from the different functional forms to obtain the final dN/dy and $\langle p_T \rangle$. The statistical uncertainties are determined from the data. The systematic errors from the extrapolation of yield are defined as half of the difference between the upper and lower bounds.

(5) Determine the final systematic errors on dN/dy and $\langle p_T \rangle$ for each centrality bin by taking the quadrature sum of the extrapolation errors, errors associated with cuts, detector occupancy corrections (for dN/dy), and feed-down corrections (for p and $\bar{p}$).

For the extrapolation of dN/dy and $\langle p_T \rangle$, the following functional forms are used for different particle species: a power-law function and a p_T exponential for pions, a p_T exponential and an m_T exponential for kaons, and a Boltzmann function, p_T exponential, and m_T exponential for protons and antiprotons. The effects of contamination background at high-p_T region for both dN/dy and $\langle p_T \rangle$ are estimated as less than 1% for all particle species. The overall systematic uncertainties on both dN/dy and $\langle p_T \rangle$ are about 10–15%. See Table V for the systematic errors of dN/dy and Table VI for those of $\langle p_T \rangle$.

In Fig. 11, the centrality dependence of $\langle p_T \rangle$ for $\pi^{\pm}$, $K^{\pm}$, p, and $\bar{p}$ is shown. The error bars in the figure represent the

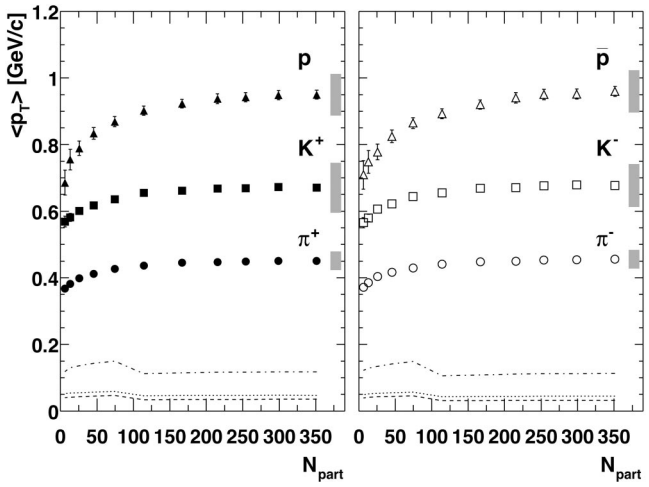

FIG. 11. Mean transverse momentum as a function of N_{part} for pions, kaons, protons, and antiprotons in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The left (right) panel shows the $\langle p_T \rangle$ for positive (negative) particles. The error bars are statistical errors. The systematic errors from cut conditions are shown as shaded boxes on the right for each particle species. The systematic errors from extrapolations, which are scaled by a factor of 2 for clarity, are shown in the bottom for protons and antiprotons (dashed-dot lines), kaons (dotted lines), and pions (dashed lines).

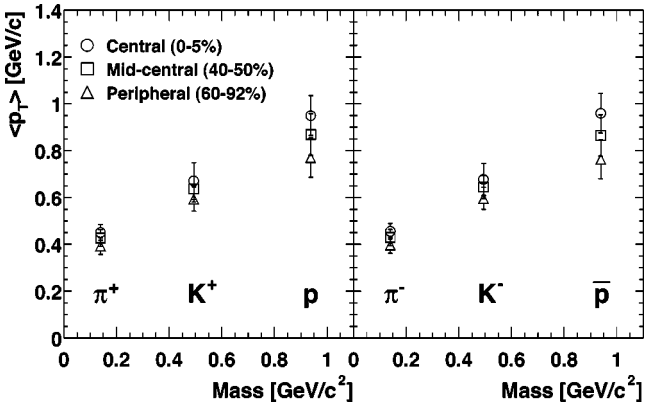

FIG. 12. Mean transverse momentum versus particle mass for central 0–5%, midcentral 40–50%, and peripheral 60–92% in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The left (right) panel shows the $\langle p_T \rangle$ for positive (negative) particles. The error bars represent the total systematic errors. The statistical errors are negligible.

statistical errors. The systematic errors from cut conditions are shown as shaded boxes on the right for each particle species. The systematic errors from extrapolations, which are scaled by a factor of 2 for clarity, are shown in the bottom for each particle species. The data are also summarized in Table VII. It is found that $\langle p_T \rangle$ for all particle species increases from the most peripheral to midcentral collisions, and appears to saturate from the midcentral to central collisions (although the $\langle p_T \rangle$ values for p and $\bar{p}$ may continue to rise). It should be noted that while the total systematic errors on $\langle p_T \rangle$ listed in Table VI is large, the trend shown in the figure is significant. One of the main sources of the uncertainty is the yield extrapolation in unmeasured p_T range (e.g., $p_T < 0.6$ GeV/c for protons and antiprotons). These systematic errors are correlated, and therefore move the curve up and down simultaneously. In Fig. 12, the particle mass and centrality dependence of $\langle p_T \rangle$ are shown. The data presented here are the $\langle p_T \rangle$ for the 0–5%, 40–50% and 60–92% centrality bins. Figure 12 is similar to Fig. 10, which shows the inverse slope parameters, in that the $\langle p_T \rangle$ increases with particle mass and with centrality. This is qualitatively consistent with the hydrodynamic expansion picture [29,33,34].

Figure 13 shows the centrality dependence of dN/dy per participant pair (0.5 N_{part}). The data are summarized in Table VIII. The error bars on each point represent the quadratic sum of the statistical errors and systematic errors from cut conditions. The statistical errors are negligible. The lines represent the effect of the systematic error on N_{part} which affects all curves in the same way. The data indicate that dN/dy per participant pair increases for all particle species with N_{part} up to $\approx$100, and saturates from the midcentral to the most central collisions. From dN/dy for protons and antiprotons, we obtain the net proton number at midrapidity for the most central 0–5% collisions, $dN/dy|_p - dN/dy|_{\bar{p}} = 18.47-13.52$

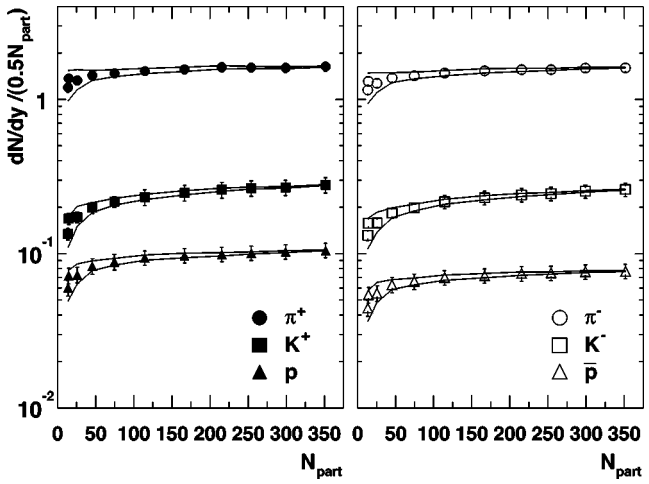

FIG. 13. Particle yield per unit rapidity (dN/dy) per participant pair ($0.5N_{part}$) as a function of N_{part} for pions, kaons, protons, and antiprotons in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The left (right) panel shows the dN/dy for positive (negative) particles. The error bars represent the quadratic sum of statistical errors and systematic errors from cut conditions. The lines represent the effect of the systematic error on N_{part} which affects all curves in the same way.

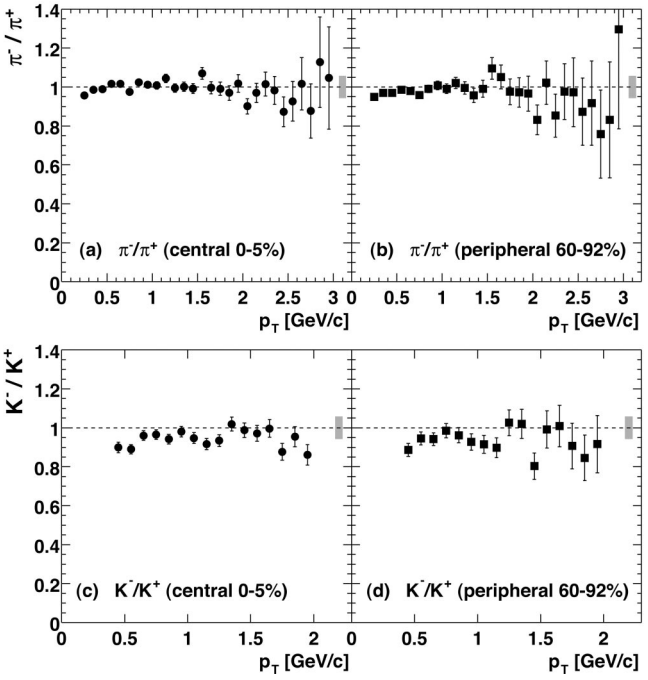

FIG. 14. Particle ratios of (a) π^-/π^+ for central 0–5%, (b) π^-/π^+ for peripheral 60–92%, (c) K^-/K^+ for central 0–5%, and (d) K^-/K^+ for peripheral 60–92% in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The error bars indicate the statistical errors and shaded boxes around unity on each panel indicate the systematic errors.

$=4.95\pm2.74$, which is consistent with the preliminary result at 200 GeV Au+Au (midrapidity) reported by the BRAHMS Collaboration [36].

D. Particle ratios

The ratios of π^-/π^+, K^-/K^+, $p/\bar{p}$, K/π, p/π, and $\bar{p}/\pi$ measured as a function of p_T and centrality at $\sqrt{s_{NN}}=200$ GeV in Au+Au collisions are presented here.

1. Particle Ratios versus p_T

Figure 14 shows the particle ratios of (a) π^-/π^+ for central 0–5%, (b) π^-/π^+ for peripheral 60–92%, (c) K^-/K^+ for central 0–5%, and (d) K^-/K^+ for peripheral 60–92%. Similar plots for the $\bar{p}/p$ ratios are shown in Fig. 15. The error bars represent statistical errors and the shaded boxes on each panel represent the systematic errors. For each of these particle species and centralities, the particle ratios are constant within the experimental errors over the measured p_T range. Similar centrality and p_T dependences are observed in 130 GeV Au+Au data [8,37–42] and previously published 200 GeV Au+Au data [43,44].

To investigate the p_T dependence of the $\bar{p}/p$ ratio in detail, it is shown in Fig. 16 for minimum bias events with two theoretical calculations: a pQCD calculation (dashed line) and a baryon junction model with jet-quenching [46] (solid line). The baryon junction calculation agrees well with the measured $\bar{p}/p$ ratio over the measured p_T range within the experimental uncertainties, while the pQCD calculation does not explain the constant $\bar{p}/p$ ratio over the wide p_T range.

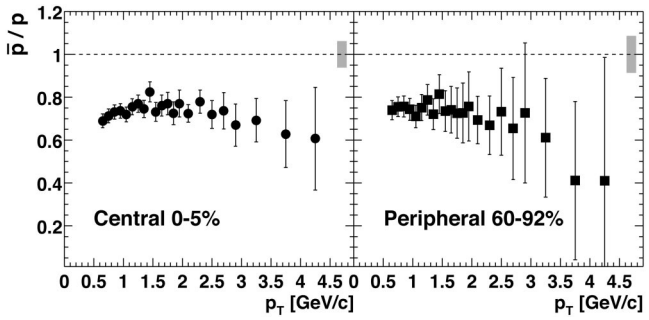

FIG. 15. Ratio of $\overline{p}/p$ as a function of p_T for central 0–5% (left) and peripheral 60–92% (right) in Au+Au collisions at $\sqrt{s_{NN}}$ =200 GeV. The error bars indicate the statistical errors and shaded boxes around unity on each panel indicate the systematic errors.

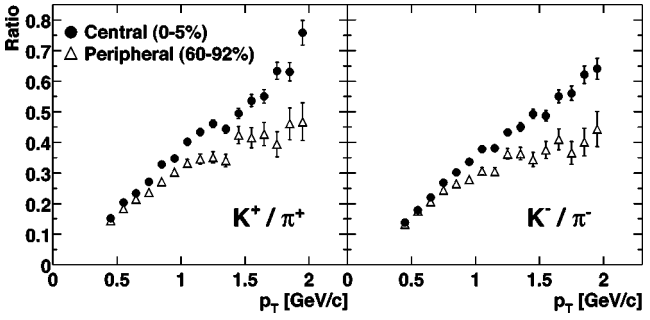

FIG. 17. K/π ratios as a function of p_T for central 0–5% and peripheral 60–92% in Au+Au collisions at $\sqrt{s_{NN}}$=200 GeV. The left is for K^+/π^+ and the right is for K^-/π^-. The error bars indicate the statistical errors.

The statistical thermal model (discussed in more detail later in this section) predicted [10] a baryon chemical potential of μ_B=29 MeV and a freeze-out temperature of T_{ch} =177 MeV for central Au+Au collisions at 200 GeV. From these, the expected $\overline{p}/p$ ratio is $e^{-2\mu_B/T_{ch}}$=0.72, which agrees with our data (0.73). The parton recombination model [45] also reproduces the $\overline{p}/p$ ratio and its flat p_T dependence. The $\overline{p}/p$ ratio in this model is 0.72 since the statistical thermal model is used.

In Fig. 17, the p_T dependence of the K/π ratio is shown for the most central 0–5% and the most peripheral 60–92% centrality bins. The K^+/π^+ (K^-/π^-) ratios are shown on the left (right). Both ratios increase with p_T and the increase is faster in central collisions than in peripheral ones.

In Fig. 18, the p/π and $\overline{p}/\pi$ ratios are shown as a function of p_T for the 0–10%, 20–30% and 60–92% centrality bins. In this figure, the results of p/π^0 and $\overline{p}/\pi^0$ [14] are presented above 1.5 GeV/c and overlaid on the results of p/π^+ and $\overline{p}/\pi^-$, respectively. The absolutely normalized p_T spectra of

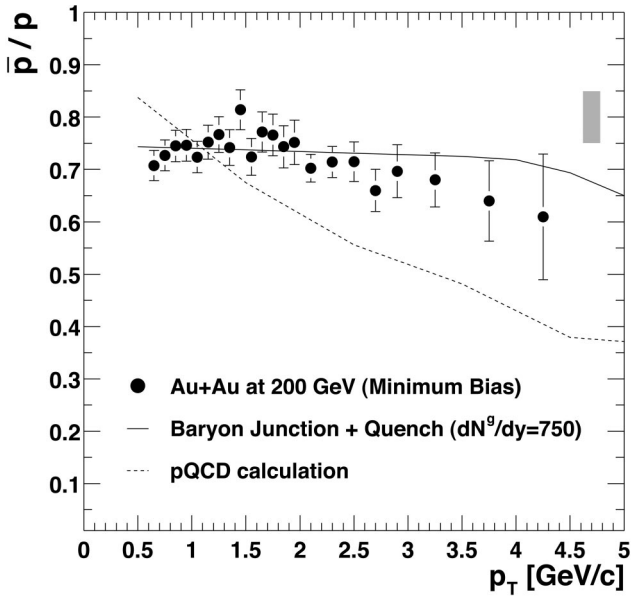

FIG. 16. $\overline{p}/p$ ratios as a function of p_T for minimum bias events in Au+Au at $\sqrt{s_{NN}}$=200 GeV. The error bars indicate the statistical errors and shaded box on the right indicates the systematic errors. Two theoretical calculations are shown: baryon junction model (solid line) and pQCD calculation (dashed line) taken from Ref. [46].

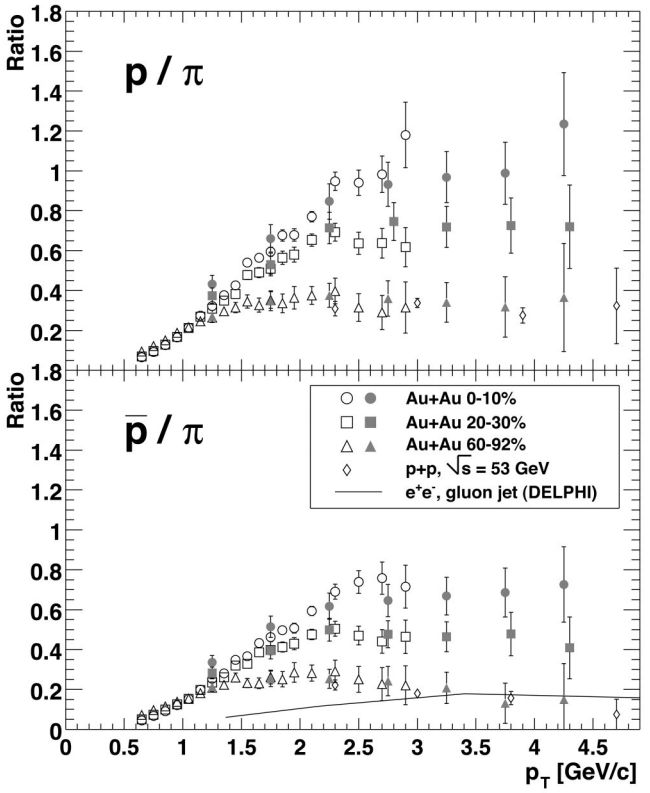

FIG. 18. Proton/pion (top) and antiproton/pion (bottom) ratios for central 0–10%, midcentral 20–30%, and peripheral 60–92% in Au+Au collisions at $\sqrt{s_{NN}}$=200 GeV. Open (filled) points are for charged (neutral) pions. The data at $\sqrt{s}$=53 GeV $p+p$ collisions [47] are also shown. The solid line is the $(\overline{p}+p)/(\pi^+ + \pi^-)$ ratio measured in gluon jets [48].

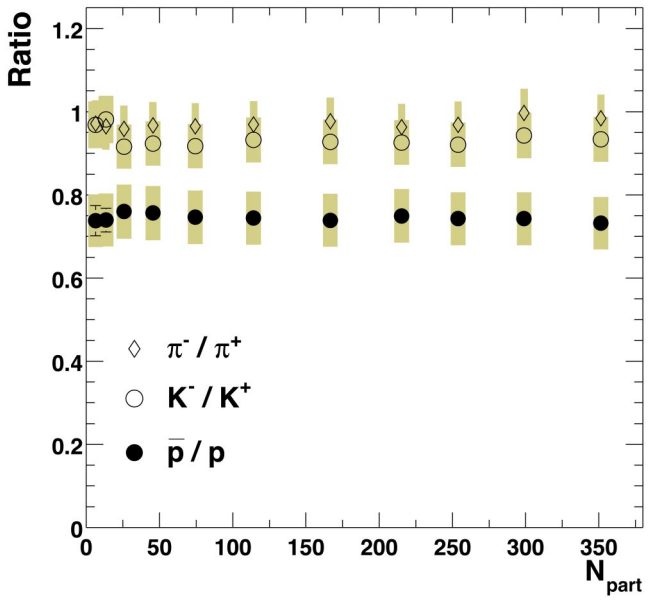

FIG. 19. (Color online) Centrality dependence of particle ratios for π^-/π^+, K^-/K^+, and $\bar{p}/p$ in Au+Au collisions at $\sqrt{s_{NN}}$ =200 GeV. The error bars indicate the statistical errors. The shaded boxes on each data point are the systematic errors.

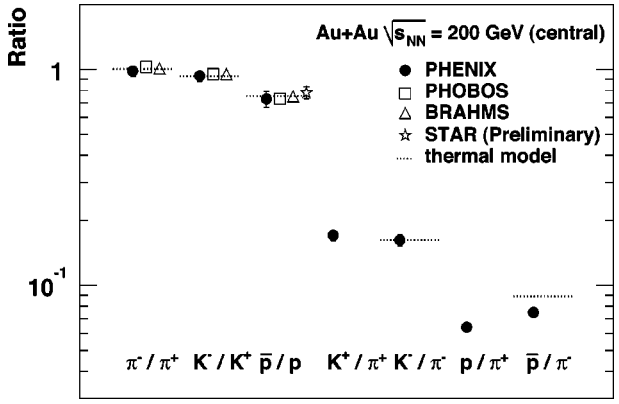

FIG. 20. Comparison of PHENIX particle ratios with those of PHOBOS [44], BRAHMS [43], and STAR (preliminary) [51] results in Au+Au central collisions at $\sqrt{s_{NN}}$=200 GeV at midrapidity. The thermal model prediction [10] for 200 GeV Au+Au central collisions are also shown as dotted lines. The error bars on data indicate the systematic errors.

charged and neutral pions agree within 5–15%. The error bars on the PHENIX data points in the figure show the quadratic sum of the statistical errors and the point-to-point systematic errors. There is an additional normalization uncertainty of 8% for p/π^+, $\bar{p}/\pi^-$ and 12% for p/π^0, $\bar{p}/\pi^0$ [the quadratic sum of the systematic errors on p (or $\bar{p}$) normalization and p_T independent systematic errors from π^0 [23]], which may shift the data up or down for all three centrality bins together, but does not affect their shape. The ratios increase rapidly at low p_T, but saturate at different values of p_T which increase from peripheral to central collisions. In central collisions, the yields of both protons and antiprotons are comparable to that of pions for $p_T>2$ GeV/c. For comparison, the corresponding ratios for $p_T>2$ GeV/c observed in $p+p$ collisions at lower energies [47], and in gluon jets produced in e^++e^- collisions [48], are also shown. Within the uncertainties those ratios are compatible with the peripheral Au+Au results. In hard-scattering processes described by pQCD, the p/π and $\bar{p}/\pi$ ratios at high p_T are determined by the fragmentation of energetic partons, independent of the initial colliding system, which is seen as agreement between $p+p$ and e^++e^- collisions. Thus, the clear increase in the p/π ($\bar{p}/\pi$) ratios at high p_T from $p+p$ and peripheral to the midcentral and to the central Au+Au collisions requires ingredients other than pQCD.

The first observation of the enhancement of protons and antiprotons compared to pions in the intermediate p_T region was in the 130 GeV Au+Au data [6]. The data inspired several new theoretical interpretations and models. Hydrodynamics calculations [32] predict that the $\bar{p}/\pi$ ratio at high p_T exceeds unity for central collisions. The expected $\bar{p}/\pi$ ratio in the thermal model at fixed and sufficiently large p_T is determined by $2e^{-\mu_B/T_{ch}}\approx 1.7$ using T_{ch}=1.77 MeV and μ_B =29 MeV [10] for 200 GeV Au+Au central collisions. Due to the strong radial flow effect at RHIC at relativistic transverse momenta ($p_T \gg m$), all hadron spectra have a similar shape. The hydrodynamic model thus explains the excess of $\bar{p}/\pi$ in central collisions at intermediate p_T. However, the hydrodynamic model [49] predicts no or very little dependence on the centrality, which clearly disagrees with the present data. This model predicts, within 10%, the same p_T dependence of p/π ($\bar{p}/\pi$) for all centrality bins.

Recently, two new models have been proposed to explain the experimental results on the p_T dependence of p/π and $\bar{p}/\pi$ ratios. One model is the parton recombination and fragmentation model [45] and the other model is the baryon junction model [50]. Both models explain qualitatively the observed feature of p/π enhancement in central collisions, and their centrality dependencies. Furthermore, both theoretical models predict that this baryon enhancement is limited to $p_T<5-6$ GeV/c. This will be discussed in Sec. IV E in detail.

2. Particle ratio versus N_{part}

Figure 19 shows the centrality dependence of particle ratios for π^-/π^+, K^-/K^+, and $\bar{p}/p$. The ratios presented here are derived from the integrated yields over p_T (i.e., dN/dy). The shaded boxes on each data point indicate the systematic errors. Within uncertainties, the ratios are all independent of N_{part} over the measured range. Figure 20 shows a comparison of the PHENIX particle ratios with those from PHOBOS [44], BRAHMS [43], and STAR (preliminary) [51] in Au+Au central collisions at $\sqrt{s_{NN}}$=200 GeV at midrapidity. The PHENIX antiparticle-to-particle ratios are consistent with other experimental results within the systematic uncertainties.

Figure 21 shows the centrality dependence of K/π and p/π ratios. Both K^+/π^+ and K^-/π^- ratios increase rapidly

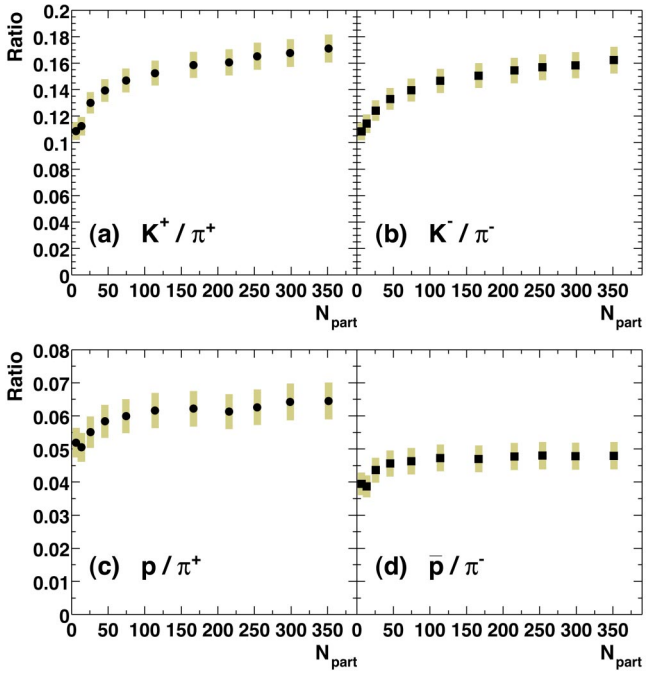

FIG. 21. (Color online) Centrality dependence of particle ratios for (a) K^+/π^+, (b) K^-/π^-, (c) p/π^+, and (d) $\bar{p}/\pi^-$ in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The error bars indicate the statistical errors. The shaded boxes on each data point are the systematic errors.

for peripheral collisions ($N_{part}<100$), and then saturate or rise slowly from the midcentral to the most central collisions. The p/π^+ and $\bar{p}/\pi^-$ ratios increase for peripheral collisions ($N_{part}<50$) and saturate from midcentral to central collisions—similar to the centrality dependence of K/π ratio (but possibly flatter).

Within the framework of the statistical thermal model [9] in a grand canonical ensemble with baryon number, strangeness, and charge conservation [10], particle ratios measured at $\sqrt{s_{NN}}=130$ GeV at midrapidity have been analyzed with the extracted chemical freeze-out temperature $T_{ch}=174\pm7$ MeV and baryon chemical potential $\mu_B=46\pm5$ MeV. A set of chemical parameters at $\sqrt{s_{NN}}=200$ GeV in Au+Au were also predicted by using a phenomenological parametrization of the energy dependence of μ_B. The predictions were $\mu_B=29\pm8$ MeV and $T_{ch}=177\pm7$ MeV at $\sqrt{s_{NN}}=200$ GeV. The comparison between the PHENIX data at 200 GeV for 0–5% central and the thermal model prediction is shown in Table IX and Fig. 20. There is a good agreement between data and the model. The thermal model calculation was performed by assuming a 50% reconstruction efficiency of all weakly decaying baryons in Ref. [10]. However, our results have been corrected to remove these contributions. Therefore, Table IX includes $\bar{p}/p$ and $\bar{p}/\pi^-$ ratios with and without Λ ($\bar{\Lambda}$) feed-down corrections to the proton and antiproton spectra. The ratios without the Λ ($\bar{\Lambda}$) feed-down correction are labeled "inclusive." The small μ_B is qualitatively consistent with our measurement of the number of net protons (≈5) in central Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV at midrapidity.

TABLE IX. Comparison between the data for the 0–5% central collisions and the thermal model prediction at $\sqrt{s_{NN}}=200$ GeV with $T_{ch}=177$ MeV and $\mu_B=29$ MeV [10].

E. Binary collision scaling of p_T spectra

One of the most striking features in Au+Au collisions at RHIC is that π^0 and nonidentified hadron yields at $p_T>2$ GeV/c in central collisions are suppressed with respect to the number of nucleon-nucleon binary collisions (N_{coll}) scaled by $p+p$ and peripheral Au+Au results [12–14]. Moreover, the suppression of π^0 is stronger than that for nonidentified charged hadrons [12], and the yields of protons and antiprotons in central collisions are comparable to that of pions around $p_T=2$ GeV/c [6]. The enhancement of the p/π ($\bar{p}/\pi$) ratio in central collisions at intermediate p_T (2.0–4.5 GeV/c), which was presented in the preceding section, is consistent with the above observations. These results show the significant contributions of proton and antiproton yields to the total particle composition at this intermediate p_T region. We present here the N_{coll} scaling behavior for charged pions, kaons, and protons (antiprotons) in order to quantify the particle composition at intermediate p_T.

Figure 22 shows the p_T spectra scaled by the averaged number of binary collisions, $\langle N_{coll}\rangle$, for $(\pi^++\pi^-)/2$, $(K^++K^-)/2$, and $(p+\bar{p})/2$ in three centrality bins: central 0–10%, midcentral 40–50%, and peripheral 60–92%. For $(p+\bar{p})/2$ in the range of $p_T=1.5$–4.5 GeV/c, it is clearly seen that the spectra are on top of each other. This indicates that proton and antiproton production at high p_T scales with the number of binary collisions. On the other hand, at p_T below 1.5 GeV/c, different shapes for different centrality bins are observed, which indicates a strong contribution from radial flow. The scaling behavior of the kaons seems to be similar to protons, but this is not conclusive due to our PID limitations. For pions, the N_{coll} scaled yield in central events is suppressed compared to that for peripheral events at $p_T>2$ GeV/c, which is consistent with the results in the π^0 spectra [12,14].

Figure 23 shows the central (0–10%) to peripheral (60–92%) ratio for N_{coll} scaled p_T spectra ($R_{\rm CP}$: the nuclear modification factor) of $(\bar{p}+p)/2$, kaons, charged pions, and π^0. In this paper we define $R_{\rm CP}$ as

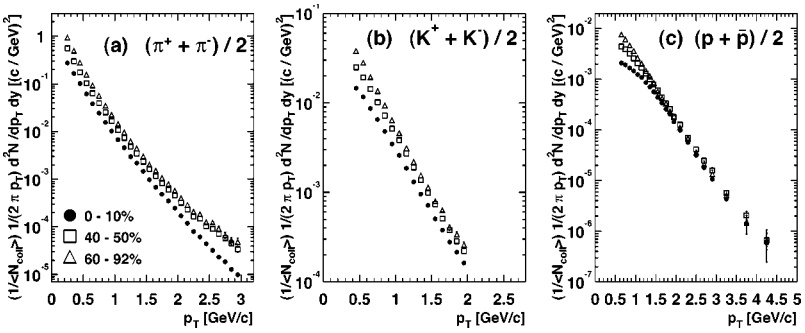

FIG. 22. p_T spectra scaled by the averaged number of binary collisions for averaged charged (a) pions, (b) kaons, and (c) $(p+\bar{p})/2$ in three different centrality bins: central 0–10%, midcentral 40–50%, and peripheral 60–92% in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The error bars are statistical only. Note the different horizontal and vertical scales on the three plots.

$$R_{\mathrm{CP}} = \frac{\mathrm{Yield}^{0-10\%}/\langle {N_{coll}}^{0-10\%}\rangle}{\mathrm{Yield}^{60-92\%}/\langle {N_{coll}}^{60-92\%}\rangle}. \tag{10}$$

The peripheral 60–92 % Au+Au spectrum is used as an approximation of the yields in $p+p$ collisions, based on the experimental fact that the peripheral spectra scale with N_{coll} by using the yields in $p+p$ collisions measured by PHENIX [14,24]. Thus the meaning of the R_{CP} is expected to be the same as R_{AA} used in our previous publications [12–14]. The lines in Fig. 23 indicate the expectations of N_{part} (dotted) and N_{coll} (dashed) scaling. The shaded bars at the end of each line represent the systematic error associated with the determination of these quantities for central and peripheral events. The error bars on charged particles are statistical errors only, and those for π^0 are the quadratic sum of the statistical errors and the point-to-point systematic errors. The data show that $(\bar{p}+p)/2$ reaches unity for $p_T \gtrsim 1.5$ GeV/c, consistent with N_{coll} scaling. The data for kaons also show the N_{coll} scaling behavior around 1.5–2.0 GeV/c, but the behavior is weaker than for protons. As with neutral pions [14], charged pions are also suppressed at 2–3 GeV/c with respect to peripheral Au+Au collisions.

Motivated by the observation that the $(\bar{p}+p)/2$ spectra scale with N_{coll} above $p_T=1.5$ GeV/c, the ratio of the integrated yield between central and peripheral events (scaled by the corresponding N_{coll}) above $p_T=1.5$ GeV/c are shown in Fig. 24 as a function of N_{part}. The p_T ranges for the integration are 1.5–4.5 GeV/c for $(\bar{p}+p)/2$, 1.5–2.0 GeV/c for kaons, and 1.5–3.0 GeV/c for charged pions. The data points are normalized to the most peripheral data point. The shaded boxes in the figure indicate the systematic errors, which include the normalization errors on the p_T spectra, the errors on the detector occupancy corrections, and the uncertainties of the $\langle T_{\mathrm{AuAu}}\rangle$ determination for the numerator only. Only at the most peripheral data point, the uncertainty on the denominator $\langle T_{\mathrm{AuAu}}^{60-92\%}\rangle$ is also added. The figure shows that $(\bar{p}+p)/2$ scales with N_{coll} for all centrality bins, while the data for charged pions show a decrease with N_{part}. The kaon data points are between the charged pions and the $(\bar{p}+p)/2$ spectra.

The standard picture of hadron production at high momentum is the fragmentation of energetic partons. While the observed suppression of the π^0 yield at high p_T in central collisions may be attributed to the energy loss of partons during their propagation through the hot and dense matter

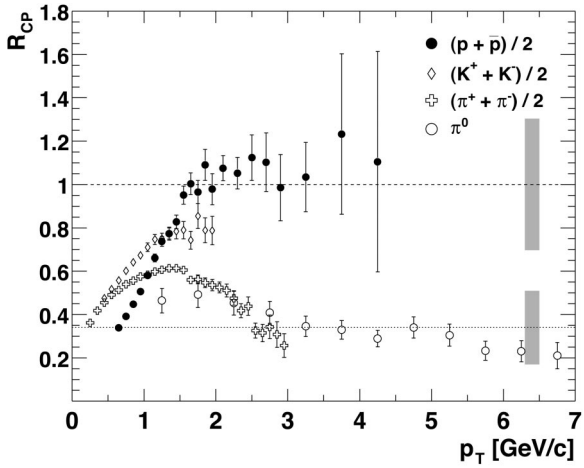

FIG. 23. Central (0–10%) to peripheral (60–92%) ratios of binary-collision-scaled p_T spectra, R_{CP}, as a function of p_T for $(\bar{p}+p)/2$, charged kaons, charged pions, and π^0 [14] in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The lines indicate the expectations of N_{part} (dotted) and N_{coll} (dashed) scaling, the shaded bars represent the systematic errors on these quantities.

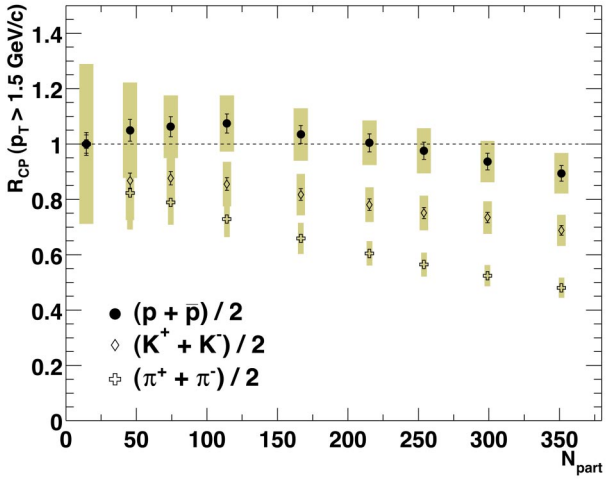

FIG. 24. (Color online) Centrality dependence of integrated R_{CP} above 1.5 GeV/c normalized to the most peripheral 60–92% value. The data show R_{CP} for $(\bar{p}+p)/2$, charged kaons, and charged pions in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV. The error bars are statistical only. The shaded boxes represent the systematic errors (see text for details).

created in the collisions, i.e., jet quenching [15,16], it is a theoretical challenge to explain the absence of suppression for baryons up to 4.5 GeV/c for all centralities along with the enhancement of the p/π ratio at $p_T=2-4$ GeV/c for central collisions.

It has been recently proposed that such observations can be explained by the dominance of parton recombination at intermediate p_T, rather than by fragmentation [45]. The competition between recombination and fragmentation of partons may explain the observed features. The model predicts that the effect is limited to $p_T<5$ GeV/c, beyond which fragmentation becomes the dominant production mechanism for all particle species.

Another possible explanation is the baryon junction model [50]. It invokes a topological gluon configuration with jet quenching. With pion production above 2 GeV/c suppressed by jet quenching, gluon junctions produce copious baryons at intermediate p_T, thus leading to the enhancement of baryons in this p_T region. The model reproduces the baryon-to-meson ratio and its centrality dependence qualitatively [52].

Both theoretical models predict that baryon enhancement is limited to $p_T<5-6$ GeV/c, which is unfortunately beyond our current PID capability. However, it is possible to test the two predictions indirectly by using the nonidentified charged hadrons to neutral pion ratio (h/π^0) as a measure of the baryon content at high p_T, as published in Ref. [23]. The results support the limited behavior of baryon enhancement up to 5 GeV/c in p_T. Similar trends are observed in Λ, K^0_S, and $K^{\pm}$ measurements by the STAR Collaboration [53].

On the other hand, it is also possible that nuclear effects, such as the "Cronin effect" [54,55], attributed to initial state multiple scattering (p_T broadening) [56], contribute to the observed species dependence. At center-of-mass energies up to $\sqrt{s}=38.8$ GeV, a nuclear enhancement beyond N_{coll} scaling has been observed for π, K, p, and their antiparticles in $p+A$ collisions. The effect is stronger for protons and antiprotons than for pions, which leads to an enhancement of the p/π and $\bar{p}/\pi$ ratios compared to $p+p$ collisions. In proton-tungsten reactions, the increase is a factor of ~ 2 in the range $3<p_T<6$ GeV. For pions, theoretical calculations at RHIC energies [57] predict a reduced strength of the Cronin effect compared to lower energies, although no prediction exists for protons. New data from d+Au collisions at $\sqrt{s_{NN}}=200$ GeV will help to clarify this issue.

V. SUMMARY AND CONCLUSION

In summary, we present the centrality dependence of identified charged hadron spectra and yields for $\pi^{\pm}$, $K^{\pm}$, p and $\bar{p}$ in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV at midrapidity. In central events, the low p_T region ($\leqslant 2.0$ GeV/c) of the p_T spectra show a clear particle mass dependence in their shapes, namely, p and $\bar{p}$ spectra have a shoulder-arm shape while the pion spectra have a concave shape. The spectra can be well fit with an exponential function in m_T at the region below 1.0 GeV/c^2 in m_T-m_0. The resulting inverse slope parameters show clear particle mass and centrality dependences that increase with particle mass and centrality. These observations are consistent with the hydrodynamic radial flow picture. Moreover, at around $p_T=2.0$ GeV/c in central events, the p and $\bar{p}$ yields are comparable to the pion yields. Here, baryons comprise a significant fraction of the hadron yield in this intermediate p_T range. The $\langle p_T\rangle$ and dN/dy per participant pair increase from peripheral to midcentral collisions and saturate for the most central collisions for all particle species. The net proton number in Au+Au central collisions at $\sqrt{s_{NN}}=200$ GeV is ~ 5 at midrapidity.

The particle ratios of π^-/π^+, K^-/K^+, $p/\bar{p}$, K/π, p/π, and $\bar{p}/\pi$ as a function of p_T and centrality have been measured. Particle ratios in central Au+Au collisions are well reproduced by the statistical thermal model with a baryon chemical potential of $\mu_B=29$ MeV and a chemical freeze-out temperature of $T_{ch}=177$ MeV. Regardless of the particle species and centrality, it is found that ratios for equal mass particles are constant as a function of p_T, within the systematic uncertainties in the measured p_T range. On the other hand, both K/π and p/π ($\bar{p}/\pi$) ratios increase as a function of p_T. This increase with p_T is stronger for central than for peripheral events. The p/π and $\bar{p}/\pi$ ratios in central events both increase with p_T up to 3 GeV/c and approach unity at $p_T\approx 2$ GeV/c. However, in peripheral collisions these ratios saturate at the value of 0.3–0.4 around $p_T=1.5$ GeV/c. The observed centrality dependence of p/π and $\bar{p}/\pi$ ratios in intermediate p_T region is not explained by the hydrodynamic model alone, but both the parton recombination model and the baryon junction model qualitatively agree with data.

The scaling behavior of identified charged hadrons is compared with results for neutral pions. In the N_{coll} scaled p_T spectra for $(p+\bar{p})/2$, the spectra scale with N_{coll} from $p_T=1.5$ to 4.5 GeV/c. The central-to-peripheral ratio R_{CP} approaches unity for $(\bar{p}+p)/2$ from $p_T=1.5$ up to 4.5 GeV/c. Meanwhile, charged and neutral pions are suppressed. The ratio of integrated R_{CP} from $p_T=1.5$ to 4.5 GeV/c exhibits an N_{coll} scaling behavior for all centrality bins in the $(\bar{p}+p)/2$ data, which is in contrast to the stronger pion suppression that increases with centrality.

APPENDIX: TABLE OF INVARIANT YIELDS

The invariant yields for $\pi^{\pm}$, $K^{\pm}$, p, and $\bar{p}$ in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV at midrapidity are tabulated in Tables X–XXIX. The data presented here are for the minimum bias events and each centrality bin (0–5%, 5–10%, 10–15%, 15–20%, 20–30%,…, 70–80%, 80–92%, and 60–92%). Errors are statistical only.

TABLE X. Invariant yields for π^{+} at midrapidity in the minimum bias, 0–5%, 5–10%, and 10–15% centrality bins, normalized to unit rapidity. Errors are statistical only.

p_T (GeV/c)	Minimum bias	0–5%	5–10%	10–15%
0.25	$1.07\times10^{2}\pm8.8\times10^{-1}$	$3.29\times10^{2}\pm2.7\times10^{0}$	$2.76\times10^{2}\pm2.3\times10^{0}$	$2.39\times10^{2}\pm2.0\times10^{0}$

Transverse momentum spectra and yields of hadrons are measured by the PHENIX collaboration in Au + Au collisions at $\sqrt{s_{NN}}$=130 GeV at the Relativistic Heavy Ion Collider. The time-of-flight resolution allows identification of pions to transverse momenta of 2 GeV/c and protons and antiprotons to 4 GeV/c. The yield of pions rises approximately linearly with the number of nucleons participating in the collision, while the number of kaons, protons, and antiprotons increases more rapidly. The shape of the momentum distribution changes between peripheral and central collisions. Simultaneous analysis of all the p_T spectra indicates radial collective expansion, consistent with predictions of hydrodynamic models. Hydrodynamic analysis of the spectra shows that the expansion velocity increases with collision centrality and collision energy. This expansion boosts the particle momenta, causing the yield from soft processes to exceed that for hard to large transverse momentum, perhaps as large as 3 GeV/c.

I. INTRODUCTION

Heavy ion reactions at ultrarelativistic energies provide information on strongly interacting matter under extreme conditions. Lattice QCD and phenomenological predictions indicate that at high enough energy density a deconfined state of quarks and gluons, the quark-gluon plasma, is formed. It is expected that conditions in ultrarelativistic heavy ion reactions may produce this new state of matter, the study of which is the major goal of the experiments at the Relativistic Heavy Ion Collider (RHIC).

The high energy density state thus created will cool down and expand, undergoing a phase transition to "ordinary" hadronic matter. While the tools of choice to study the earliest phase of the reactions, and thereby the new state, are probes that do not interact via the strong force, such as photons, electrons, or muons, the global properties and dynamics of later stages in the system are best studied via hadronic observables. Hadron momentum spectra in proton-proton reactions are often separated into two parts, a soft part at low transverse momentum p_T, where the shape is roughly exponential in transverse mass $m_T=\sqrt{p_T^2+m_0^2}$, and a high p_T region where the shape more closely resembles a power law. Soft production (low p_T) is attributed to fragmentation of a string [1,2] between components of the struck nucleons, while hard (high p_T) hadrons are expected to originate predominantly

*Deceased.
†Spokesperson. Email address: zajc@nevis.columbia.edu

from fragmentation of hard-scattered partons. The transition between these two regimes is not sharply defined, but is commonly believed to be near $p_T \approx 2$ GeV/c [3].

In proton-nucleus ($p+A$) scattering, these two regimes depend on the colliding system size in different ways. The soft production depends on the number of nucleons struck or participating in the collision ($N_{\rm part}$). The number of hard scatterings should increase proportionally to the number of binary nucleon-nucleon encounters ($N_{\rm coll}$) since these processes have a small elementary cross section and may be considered as incoherent. Hard scattering also produces color strings which fragment and produce some low-p_T particles, though these are much fewer in number than those from the much more frequent soft scatterings. In $p+A$ these $N_{\rm part}$ and $N_{\rm coll}$ are connected by a very simple relation, namely, $N_{\rm part} = N_{\rm coll} + 1$.

In nucleus-nucleus collisions, the number of participant nucleons does not scale simply with A, so it is more useful to study scaling with $N_{\rm coll}$ or $N_{\rm part}$. Collisions are sorted according to centrality, allowing control of the geometry and determination of $N_{\rm coll}$ or $N_{\rm part}$.

In heavy ion collisions, one expects secondary collisions of particles (rescattering) to take place, especially among particles with low and intermediate transverse momentum. Rescattering may occur among partons early in the collision, and also among hadrons later in the collision. Both kinds of rescattering can lead to collective behavior among the particles, and the presence of elliptic flow [4–9] indicates that partonic rescattering is important at RHIC. In the extreme, rescattering can lead to thermalization. Rescattering has observable consequences on the final hadron momentum spectra, causing them to be broadened as shown in this paper. This relates to some of the key questions regarding the evolution of the collision: Are the size and lifetime sufficient to attain local equilibrium? Are the momentum distributions thermal, and, if so, what are the chemical and kinetic freeze-out temperatures? Can expansion be described by hydrodynamic models? Momentum distributions of hadrons as a function of centrality provide a means to investigate these questions and permit extraction of thermodynamic quantities which govern the predicted phase transition.

This paper reports semi-inclusive momentum spectra and yields of π, K, and p from Au-Au collisions at $\sqrt{s_{NN}} = 130$ GeV. The data are measured and analyzed by the PHENIX Collaboration in the first year of the physics program at RHIC (Run-1).

The paper is organized as follows. In Sec. II the PHENIX detectors used in the analysis are described. The data reduction techniques using the time-of-flight and drift chamber detectors, along with the corrections applied to the spectra, are described in Sec. III. Functions that describe the shape of the spectra are used to extrapolate the unmeasured portion in order to determine the total average momentum and particle yield for each particle. The overall systematic uncertainties in the spectra are discussed. The resulting minimum bias and centrality-selected particle spectra are presented in Sec. IV. In Sec. V a description of the particle production within a hydrodynamic picture is investigated. For each centrality selection, a hydrodynamic parametrization of the m_T distribution is fit simultaneously to the spectra of different species.

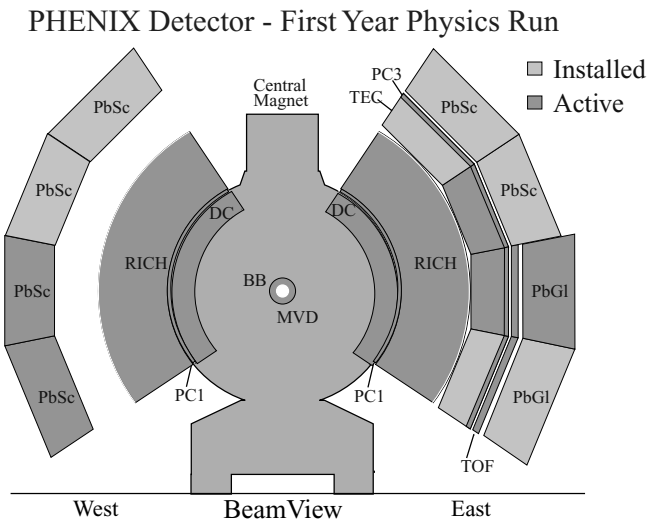

FIG. 1. A cross-sectional view of the PHENIX detector transverse to the beamline. Within the two central arm spectrometers the detectors that were instrumented and operational during the $\sqrt{s_{NN}} = 130$ GeV run are shown.

The data are compared to full hydrodynamic calculations. The transition region in p_T between hard (perturbative QCD) and soft (hydrodynamic behavior) physics is investigated by comparison of extrapolated soft spectra to the data. Finally, we study the dependence of the particle yields on the number of nucleons participating in the collision.

II. EXPERIMENT

The PHENIX [10,11] experiment at RHIC identifies hadrons over a large momentum range, by the addition of excellent time-of-flight capability to the detector suite optimized for photons, electrons, and muons. PHENIX has four spectrometer arms: two that are positioned about midrapidity (the central arms) and two at more forward rapidities (the muon arms). A cross-sectional view of the PHENIX detector, transverse to the beam line is shown in Fig. 1. Within the two central arm spectrometers, the detectors that were instrumented and operational during the $\sqrt{s_{NN}} = 130$ GeV run (Run-1) are shown. The detector systems in PHENIX are discussed in detail elsewhere [12]. The detector systems used for the measurements reported in this paper are described in detail in the following sections.

A. Central arm detectors

The central arm spectrometers use a central magnet that produces an approximately axially symmetric field that focuses charged particles into the detector acceptance. The two central arms are labeled as east and west arms. The east arm contains the following subsystems used in this analysis: drift chamber (DC), pad chamber (PC), and a time-of-flight (TOF) wall. The PHENIX hadron acceptance using the TOF system in the east arm is illustrated in Fig. 2 where the transverse momentum is plotted as a function of the particle rapidity (the phase space) within the central arm acceptance subtend-

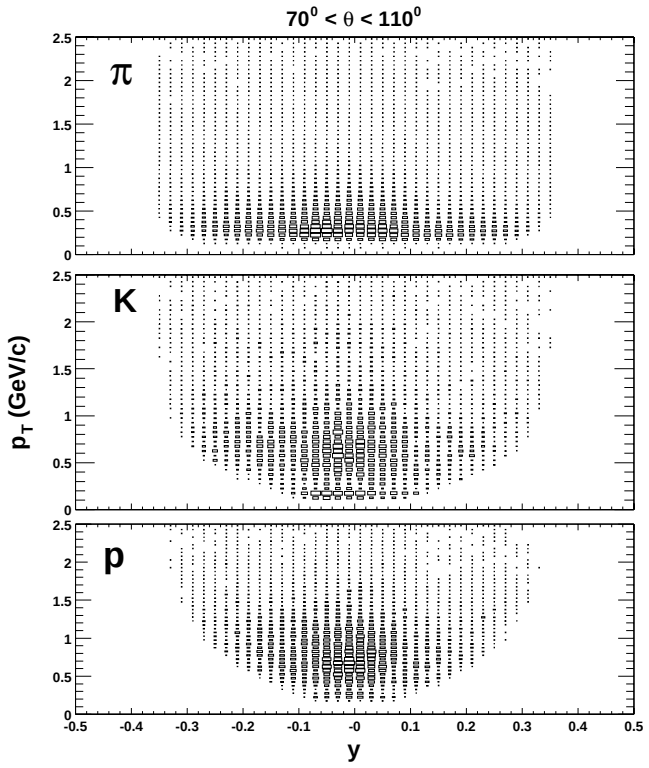

FIG. 2. The central arm spectrometer acceptance in rapidity and transverse momentum for pions (top), kaons (middle), and protons (bottom).

ing the polar angle θ from 70° to 110° for pions, kaons, and protons. The vertical lines are the equivalent pseudorapidity edges, corresponding to $|\eta|<0.35$. More details are discussed elsewhere [13].

1. Tracking chambers

The charged particle tracking chambers include three layers of pad chambers and two drift chambers. The chambers are designed to operate in a high particle multiplicity environment.

The drift chambers are the first tracking detectors that charged particles encounter as they travel from the collision vertex through the central arms. Each is 1.8 m in width in the beam direction, subtends 90° in azimuthal angle ϕ, centered at a radius $R_{\mathrm{DC}}=2.2$ m, and is filled with a 50-50 argon-ethane gas mixture. It consists of 40 planes of sense wires arranged in 80 drift cells placed cylindrically symmetric about the beam line. The wire planes are placed in an *X*-*U*-*V* configuration in the following order (moving outward radially): 12 *X* planes (*X*1)), four *U* planes (*U*1), four *V* planes (*V*1), 12 *X* planes (*X*2), four *U* planes (*U*2), and four *V* planes (*V*2). The *U* and *V* planes are tilted by a small ±5° stereo angle to allow for full three-dimensional track reconstruction. The field wire design is such that the electron drift to each sense wire is only from one side, thus removing most left-right ambiguities everywhere except within 2 mm of the sense wire. The wires are divided electrically in the middle at the beam-line center. The occupancy for a central RHIC Au+Au collision is about two hits per wire.

At the drift chamber location, the field of the central magnet is nearly zero, so the DC determines (nearly) straight-line track segments in the r-ϕ plane. Each track segment is intersected with a circle at R_{DC}, where it is characterized by two angles: the angular deflection in the main bend plane and the azimuthal position in ϕ. A combinatorial Hough transform technique is used to identify track segments by searching for location maxima in this angular space [14]. The DCs are calibrated with respect to the event collision time measurement (see Sec. II B). With this calibration, the single-wire resolution in the r-ϕ plane is 160 μm. The single-track wire efficiency is 99% and the two-track resolution is better than 1.5 mm.

The drift chambers are used to measure the momentum of charged particles and the direction vector for charged particles traversing the spectrometer. The angular deflection is inversely proportional to the component of momentum in the bend plane only. Both the bend angle and the measured track points are used in the momentum reconstruction and track model, which uses a look-up table of the measured central magnet field grid. For this dataset, the drift chamber momentum resolution is $\sigma_p/p=0.6\% \oplus 3.6\% p$, where the first term is multiple scattering up to the drift chambers and the second is the angular resolution of the detector.

In run-1, there were three pad chambers in PHENIX. Each pad chamber measures a three-dimensional space point of a charged track. The pad chambers are pixel-based detectors with effective readout sizes of 8.45 mm along the beam line by 8.40 mm in the plane transverse to the beam line. The first pad chamber layer (PC1) is fixed to the outer edge radially of each drift chamber at a radial distance of 2.49 m, while the third layer (PC3) is positioned at 4.98 m from the beam line. Both arms include PC1 chambers, while only the east arm is instrumented with PC3. The second layer (PC2) is located at an inner inscribed radius of 4.19 m in the west arm and was not installed for run-1.

The position resolution of PC1 is 1.6 mm along the beam axis and 2.3 mm in the plane transverse to the beam axis. The position resolutions of PC3 are 3.2 mm and 4.8 mm, respectively. The PC3 is used to reject background from albedo and nonvertex decay particles; however, only the PC1 is used for the results presented here. The PC1 is used in the global track reconstruction with the measured vertex position using the beam-line detectors (see Sec. II B) to determine the polar angle of each charged track. Both PC1 and the beam-line detectors provide z-coordinate information with a 1.89 mm resolution.

2. Time of flight

The TOF detector serves as the primary particle identification device for charged hadrons by the measurement of their arrival time at the TOF wall 5.1 m from the collision vertex. The TOF wall spans 30° in azimuth in the east arm. It consists of 10 panels of 96 scintillator slats each with an intrinsic timing resolution better than 100 ps. Each slat is oriented along the r-ϕ direction and provides timing as well as beam-axis position information for each particle hit recorded. The slats are viewed by two photomultiplier tubes (PMTs), attached to either end of the scintillator.

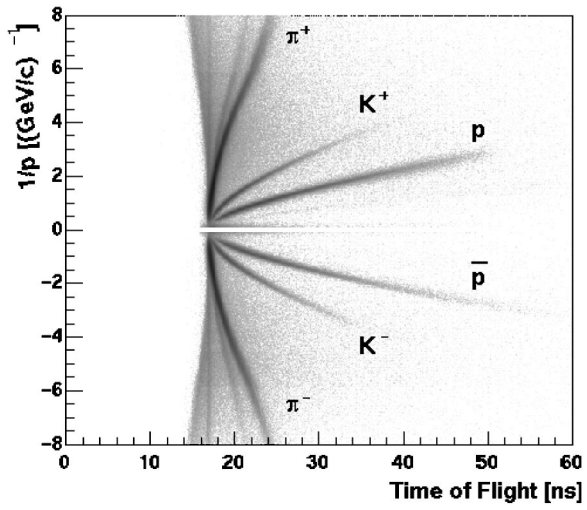

FIG. 3. Scaled time-of-flight vs reciprocal momentum in minimum-bias Au+Au collisions at $\sqrt{s_{NN}}=130$ GeV. The distribution demonstrates the particle identification capability using the TOF for the run-1 data taking period.

A $\pm 2\sigma$ π/K separation at momenta up to 2 GeV/c, and a $\pm 2\sigma$ $(\pi+K)$/proton separation up to 4 GeV/c can be achieved.

For each particle, the time, energy loss in the scintillator, and geometrical position are determined. The total time offset is calibrated slat by slat. A particle hit in the scintillator is defined by a measured pulse height which is also used to correct the time recorded at each end of the slat (slewing correction). After calibration, the average of the times at either end of the slat is the measured time for a particle. The azimuthal position is proportional to the time difference across the slat and the known velocity of light propagation in the scintillator (for Bicron BC404, this is 14 cm/ns). The slat position along the beam line determines the longitudinal coordinate position of the particle. The total time of flight is measured relative to the beam-beam counter (BBC) initial time (see Sec. II B), the measured time in the time-of-flight detector, and a global time offset from the RHIC clock. Positive pions in the momentum range $1.4<p_T<1.8$ GeV/c are used to determine the TOF resolution. The timing calibration in this analysis results in a resolution of $\sigma=115$ ps.[1]

Particle identification for charged hadrons is performed by combining the information from the tracking system with the timing information from the BBC and the TOF. Tracks at 1 GeV/c in momentum point to the TOF with a projected resolution σ_{proj} of 5 mrad in azimuthal angle and 2 cm along the beam axis. Tracks that point to the TOF with less than 2.0 σ_{proj} were selected. Figure 3 shows the resulting time of flight as a function of the reciprocal momentum in minimum-bias Au+Au collisions.

B. Beam-line detectors

The beam-line detectors determine the collision vertex position along the beam direction, and the trigger and timing information for each event. These detectors include the zero degree calorimeters (ZDCs), the BBCs, and the multiplicity vertex detector (MVD) and are positioned in PHENIX as shown in Fig. 4.

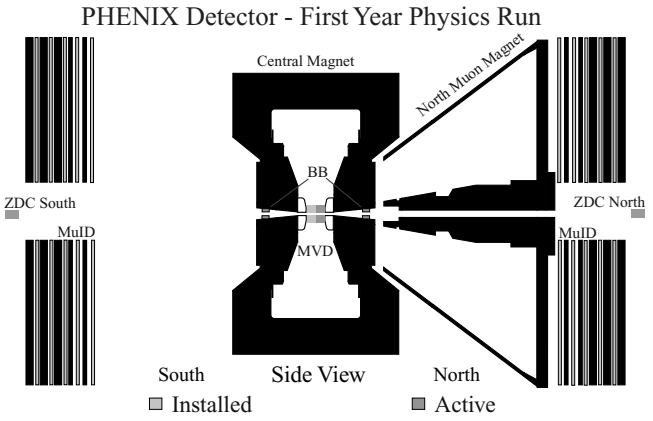

FIG. 4. A side view of the PHENIX detector parallel to the beam line. The beam line detectors determine the collision vertex position along the beam direction, and the trigger and timing information for each event.

The zero-degree calorimeters are small transverse area hadron calorimeters that are installed at each of the four RHIC experiments. They measure the fraction of the energy deposited by spectator neutrons from the collisions and serve as an event trigger for each RHIC experiment. The ZDCs measure the unbound neutrons in small forward cones ($\theta<2$ mrad) around each beam axis. Each ZDC is positioned 18 m upstream and downstream from the interaction point along the beam axis. A single ZDC consists of three modules each with a depth of two hadronic interaction lengths and read out by a single PMT. Both time and amplitude are digitized for each of the three PMTs as well as an analog sum of the PMTs for each ZDC [15].

There are two beam-beam counters each positioned 1.4 m from the interaction point, just behind the central magnet poles along the beam axis (see Fig. 4). The BBC consists of two identical sets of counters installed on both sides of the interaction point along the beam. Each counter consists of 64 Cherenkov telescopes, arranged radially about the collision axis and situated north and south of the MVD. The BBCs measure the fast secondary particles produced in each collision at forward angles, with $3.0\leqslant\eta\leqslant 3.9$, and full azimuthal coverage.

For both the ZDC and the BBC, the time and vertex position are determined using the measured time difference between the north and the south detector and the known distance between the two detectors. The start time T_0 and the vertex position along the beam axis (Z_{vertex}) are calculated as $T_0=(T_1+T_2)/2$ and $Z_{\text{vertex}}=(T_1-T_2)/2c$, where T_1 and T_2 are the average timing of particles in each counter and c is the speed of light. With an intrinsic timing resolution of 150 ps, the ZDC vertex is measured to within 3 cm. In run-1, the BBC timing resolution of 70 ps results in a vertex position resolution of 1.5 cm.

Event centrality is determined using a correlation measurement between neutral energy deposited in the ZDCs and

[1]Ultimately, 96 ps results after further calibration, as reported in Ref. [12].

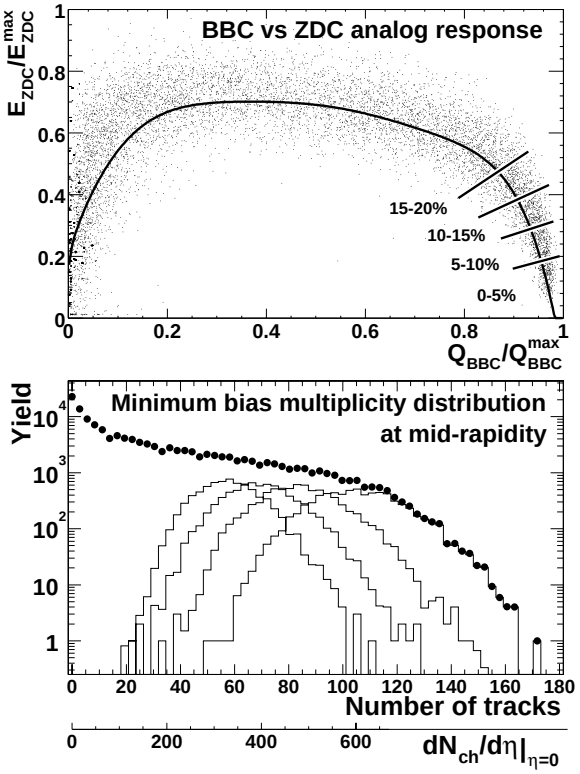

FIG. 5. The event centrality (upper plot) is determined using a correlation measurement of the fraction of neutron energy recorded in the ZDCs (vertical scale) and the fractional charge measured in the BBCs (horizontal scale). The equivalent track multiplicity in each centrality selection is shown in the lower plot.

fast particles recorded in the BBCs as shown in Fig. 5. The spectator nucleons are unaffected by the interaction and travel at their initial momentum from each respective ion. The number of neutrons measured by the ZDC is proportional to the number of spectators, while the BBC signal increases with the number of participants.

III. DATA REDUCTION AND ANALYSIS

A. Data reduction

The PHENIX Level-1 trigger selected events with hits coincident in both the ZDC and BBC detectors, and in time with the RHIC clock. A total of 5 million events were recorded at $\sqrt{s_{NN}}=130$ GeV in the ZDCs [11]. The collision position along the beam direction was required to be within ±30 cm of the center of PHENIX, using the collision vertex reconstructed by the BBC.

The trigger on both BBC and ZDC counters includes $92\pm4\%$ of the total inelastic cross section (6.8 ± 0.4 b). A Monte Carlo Glauber model [16] is used with a simulation of the BBC and ZDC responses to determine the number of nucleons participating in the collisions for the minimum-bias events. The Woods-Saxon parameters determined from electron scattering experiments are radius $R=6.38\pm0.06$ fm, diffusivity $d=0.54\pm0.01$ fm [17], and the nucleon-nucleon inelastic cross section, $\sigma^{inel}_{N+N}=40\pm3$ mb. An additional systematic uncertainty enters the radius parameter since the radial distribution of neutrons in large nuclei should be larger than for protons and is not well determined [18].

The centrality selections used in this paper are 0–5 %, 5–15 %, 15–30 %, 30–60 %, and 60–92 % of the total geometrical cross section, where 0–5 % corresponds to the most central collisions.

Only tracks that are reconstructed in all three dimensions are included in the spectra. These tracks are then matched within $2\sigma_{\rm proj}$ to the measured positions in the TOF detector. For each TOF hit, the time, position, and energy loss are measured in the TOF detector. The widths of residual distance distributions between projected tracks and TOF hit positions, $\sigma_{\rm proj}$, increase at lower momentum due to multiple scattering. Therefore, a momentum-dependent hit association criterion was defined.

Finally, a requirement on energy loss in the TOF is applied to each track to exclude false hits by requiring the energy deposit of at least minimum ionizing particle energy. A β-dependent energy loss cut whose form is a parametrization of the Bethe-Bloch formula [19] is used, where

$$dE/dx \approx \beta^{-5/3} \tag{1}$$

and $\beta=L/ct$, where L is the pathlength of the particle's trajectory from the BBC vertex to the TOF detector, t is the particle's time of flight, and c is the speed of light. The approximate Bethe-Bloch formula is scaled by a factor to fall below the data and thereby serve as a cut. The resulting equation is $\Delta E=A\beta^{-5/3}$, where A is a scaling factor equal to 1.6 MeV. The energy loss cut reduces low momentum background under the kaon and proton mass peaks. The fraction of tracks excluded after the energy loss cut is less than 5.5%.

The measured momentum p, pathlength L, and time of flight t in the spectrometer are used to calculate the particle mass, which is used for particle identification:

$$m^2 = \frac{p^2}{c^2}\left[\left(\frac{1}{\beta}\right)^2 - 1\right]. \tag{2}$$

The widths of the peaks in the mass-squared distribution depend on both momentum and time-of-flight resolutions. An analytic form for the width of m^2 as a function of momentum resolution σ_p and time-of-flight resolution is determined using Eq. (2). The error in the particle's pathlength L results in an effective time width that is included with the TOF resolution, σ_T,

$$\sigma^2_{m^2} = 4m^4\left(\frac{\sigma_p}{p}\right)^2 + 4p^4\left(\frac{\sigma_T}{\beta t}\right)^2. \tag{3}$$

The momentum resolution of the drift chambers is expressed in the following form:

$$\sigma^2_p = \left(C_1 p\frac{1}{\beta}\right)^2 + (C_2 p^2)^2, \tag{4}$$

$$C_1 = \frac{\delta\phi_{\rm ms}}{K_1}, \tag{5}$$

$$C_2 = \frac{\delta\phi_\alpha}{K_1}, \tag{6}$$

where C_1 and C_2 are the multiple scattering and angular resolution terms, respectively. The units of $\delta\phi_{\rm ms}$ are mrad GeV/c. The constant K_1 is the momentum kick on the particle from the magnetic field and is equal to 87.3 mrad GeV/c. The constant C_1 is the width in ϕ due to the multiple scattering (ms) of a charged particle with materials of the spectrometer up to the drift chambers. The C_2 term is the angular resolution of the bend angle α, which is the angular deflection in ϕ of the track segment relative to the radius to the collision vertex.

Equation (4) is used in Eq. (3) with $\beta = p/\sqrt{p^2+m^2}$, where m is the mass centroid of the particle's mass-squared distribution. The mass centroid is close to the rest mass of the particle; however due to residual misalignments and timing calibration, the centroid of the distribution is a fit parameter in order to avoid cutting into the distribution. The m^2 width for each particle is written as follows:

$$\sigma^2_{m^2} = C_1^2 4m^4\left(1+\frac{m^2}{p^2}\right) + C_2^2 4m^4p^2 + C_3^2[4p^2(m^2+p^2)], \tag{7}$$

where the coefficient C_3 is related to the combined TOF,

$$C_3 = \frac{\sigma_T c}{L}, \tag{8}$$

and pathlength contributions to the time width, σ_T in Eq. (8). From the measured drift chamber momentum resolution, $C_1 = 0.006$ and $C_2 = 0.036$ c/GeV. While the TOF resolution is 115 ± 15 ps, the pathlength uncertainty introduces a width of $\approx 20-40$ ps, so 145 ps is used for σ_T in C_3.

The pions, kaons, and protons are identified using the measured peak centroids of the m^2 distribution and selecting 2σ bands; shown as shaded regions in Fig. 6 for two different momentum slices. The 2σ bands for pions and kaons do not overlap up to $p_T = 2$ GeV/c. The protons are identified up to $p_T = 4$ GeV/c. By studying variations in the m^2 centroid and width before the particle identification cut is applied, the uncertainty in the particle identification is estimated to be 5% for all particles.

Kaons are depleted by decays in flight and geometrical acceptance. For the low momentum protons, energy loss and geometrical acceptance cause a drop in the raw yield for $p_T < 0.5$ GeV/c, as seen in Fig. 2.

The remaining background contribution was determined by reflecting the track about the midpoint of PHENIX along the beam line and repeating the association and particle identification cuts used in the TOF detector. This random background was evaluated separately for each particle type. The background contribution is $\approx 30\%$ for the kaon spectra at $0.2 < p_T < 0.4$ GeV/c and defines the low p_T limit in the spectra. The background is less than 5% in all other cases, and negligible above 0.8 GeV/c in the measured momentum range in this analysis. The background was not subtracted but is instead treated as a systematic uncertainty. This uncertainty is 2%, 5%, and 3% for pions, kaons, and protons, respectively, at $p_T < 0.6$ GeV/c and is negligible at higher momenta.

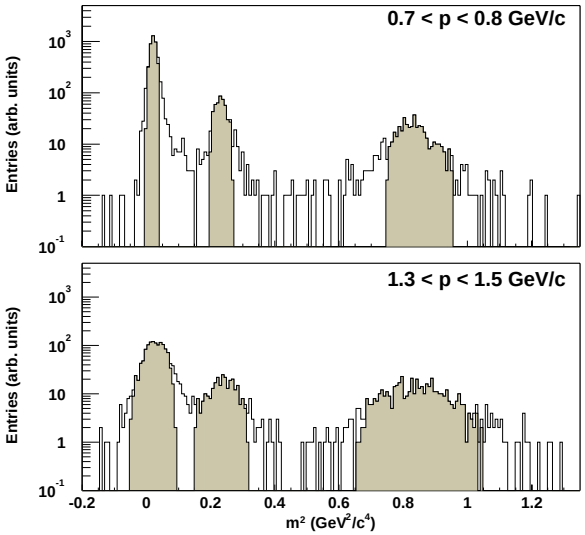

FIG. 6. (Color online) The mass-squared distributions of positive pions, kaons, and protons for two different momentum slices. The momentum slice $0.7 < p < 0.8$ GeV/c is the upper panel and $1.3 < p < 1.5$ GeV/c is the lower panel. The shaded regions correspond to the 2σ particle identification bands based on the calculated mass-squared width, the measured mass-squared centroids, and the known detector resolutions.

B. Analysis

The raw spectra include inefficiencies from detector acceptance, resolution, particle decays in flight and track reconstruction. The base-line efficiencies are determined by simulating and reconstructing single hadrons. Multiplicity dependent effects are then evaluated by embedding simulated single hadrons into real events and calculating the degradation of the reconstruction efficiency.

1. Corrections: Acceptance, decays in flight, and detector response

The corrections for the finite detector aperture, pion and kaon decays in flight, and the detector response are determined using single particles in the the GEANT [20] simulation of the detector. All details of each detector are modeled, including dead channels in the drift chambers, pad chambers, and time-of-flight detector. All physics processes are automatically taken into account, resulting in corrections for multiple scattering, antiproton annihilation, pion and kaon decays in flight, finite geometrical acceptance of the detector, and momentum resolution, which affects the spectral shape above 2.5 GeV/c.

The drift chamber simulated response is tuned to describe the response of the real drift chambers on the single-wire level. This is done using a simple geometrical model of the drift chamber and the straight-line trajectories of particles from the zero-field data. This simple model of the drift cell in the drift chamber is sufficient to describe the observed drift

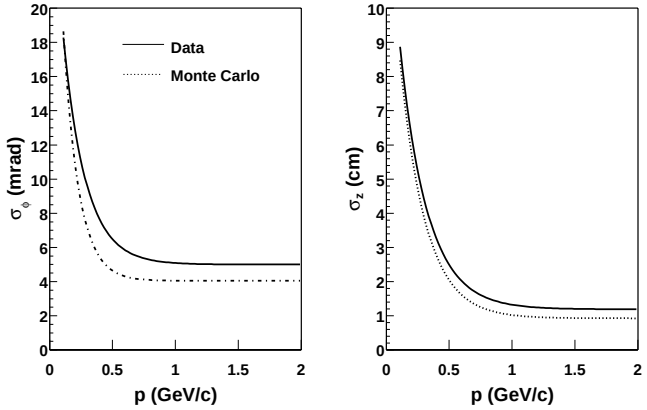

FIG. 7. Comparison of the momentum-dependent residuals of DC tracks matched to TOF hits in azimuthal angle ϕ (left) and z (right) between data (solid) and simulation (dashed).

distance distribution, the pulse width, the single-wire efficiency, and the detector resolution. The TOF response is simulated by smearing the true time of flight using a Gaussian distribution with a width as measured in the data.

Figure 7 shows the momentum dependence of the residual distance between projected tracks and TOF hits for the real (solid line) and simulated (dashed) events. These residuals are parametrized in the azimuthal angle ϕ and the beam-line direction z, separately for data and simulation. For each case, tracks that fall outside 2σ of the parametrized width are rejected, thus allowing use of the Monte Carlo to evaluate the correction for the 2σ match requirement for real tracks.

A fiducial cut is made in both the simulation and the data to ensure the same fiducial volume. The systematic uncertainty in the acceptance correction is $\approx 5\%$.

The simulated distributions are generated uniformly in p_T, ϕ, and y. For each hadron, sufficient Monte Carlo events are generated to obtain the correction factor for every measured p_T bin. The statistical errors from the correction factors were smaller than those in the data and both are added in quadrature.

The distribution of the number of particles generated in each p_T slice, dN/dp_T, is the "ideal" input distribution without detector and reconstruction effects. This distribution is normalized to 2π and 1 unit of rapidity. After detector response and track reconstruction, the output distribution is the number of particles found in each p_T slice. The final corrections are determined after an iterative weighting procedure. First, the flat input and output distributions are weighted by exponential functions for all particles using an inverse slope of 300 MeV. The ratio of input to output distributions is determined as a function of momentum. In each p_T slice, the corresponding ratio is applied to the data. The corrected data are next fitted with exponentials for kaons and protons [see Eq. (11)], and a power law for the pions [see Eq. (9)]. The original flat input and output distributions are weighted by these resulting functions. The procedure is repeated until the functions remain constant in their parameters. The weighted input and output distributions are divided to produce acceptance correction factors. The corrections are larger for kaons due to the decays in flight. The statistical error in determination of the correction factor is added in quadrature to the statistical error in the data.

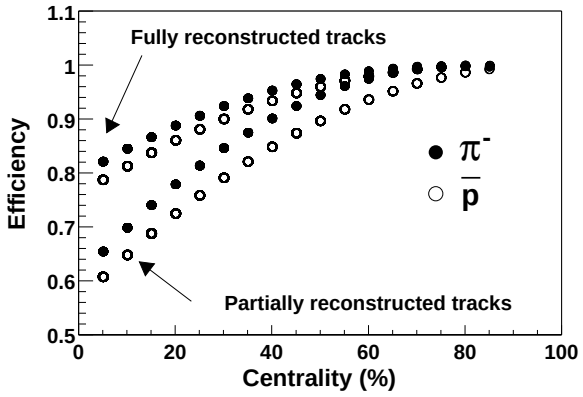

FIG. 8. The multiplicity dependent efficiency correction for pions (solid) and (anti)protons (open) for two types of tracks. The upper set of points correspond to fully reconstructed tracks in the drift chambers, while the lower set of points correspond to partially reconstructed tracks in the drift chambers.

2. High track-density efficiency correction

A final multiplicity dependent correction is determined using simulated single-particles embedded into real events. This correction depends on both the quality of the track reconstruction in a high multiplicity environment and the type of particle measured.

Depending on the centrality of the event, the correction factor is determined for each particle in the raw transverse momentum distribution and is applied as a weight. The final efficiency corrections are shown in Fig. 8, where the correction for pions is shown as solid circles and for (anti)protons as open circles. The horizontal axis ranges from the most central to the most peripheral events in increments of 5%. The systematic uncertainty in the multiplicity efficiency correction is 9%.

The difference between pions (solid) and (anti)protons (open) is due to the different TOF efficiencies for each particle (protons are slower than pions). In a small fraction of cases two particles may hit the same TOF slat at different times, and the slower particle is assigned an incorrect time. The particle will then fall outside the particle identification cuts. This effect depends on the type of particle.

For each particle, two curves are shown, representing the DC tracking inefficiency for two types of tracks: fully reconstructed and partially reconstructed tracks. Fully reconstructed tracks include $X1$ and $X2$ sections. In a high track-density environment, tracks may be partially reconstructed or hits may be incorrectly associated. There are two cases when this incorrect hit association occurs. In the first case, the direction vector in the azimuth prevents the track from pointing properly to the PC1 detector, and the correct hit cannot be associated. In the second case, the track is reconstructed properly, but there are two possible PC1 points. If no UV hits are found, then the wrong PC1 point can be associated with the track and the track's beam-line coordinate is misreconstructed. In both of these cases, the track fails the matching criteria in the TOF detector and is lost.

3. Determining the yield and mean p_T

The dN/dy and $\langle p_T \rangle$ are determined using the data in the measured region and an extrapolation to the unmeasured re-

TABLE I. The sources of systematic uncertainties in $\langle p_T \rangle$ and dN/dy.

	π(%)	K(%)	(anti)p(%)
Extrapolation	6	8	7.5
Background ($p_T < 0.6$ GeV/c)	2	5	3
$\langle p_T \rangle$ total	7	10	8
Corrections and cuts	11	11	11

gion after integrating a functional form fit to the data. A function describing the spectral shape is fit to the data, with varying p_T ranges to control systematic uncertainties in the fit parameters. The fitted shape is extrapolated, integrated over the unmeasured range, and then combined with the measured data to get the full yield. Two different functions are used to estimate upper and lower bounds for each spectrum. The average between the upper and lower bounds is used for dN/dy and $\langle p_T \rangle$. The statistical error is determined from the data, and the systematic uncertainty is taken as half the difference between the upper and lower bounds.

For pions, a power law in p_T [Eq. (9)] and an exponential in $m_T (=\sqrt{p_T^2 + m_0^2})$ [Eq. (10)] are fit to the data. For kaons and (anti)protons, two exponentials—one in p_T [Eq. (11)] and the other in m_T—are used. The p_T exponential provides an upper limit for the extrapolated yield, which is most important for the (anti)protons. The power-law function has three parameters labeled A, p_0, and n in Eq. (9). The exponentials have two parameters, A and T.

$$\frac{d^2N}{2\pi p_T dp_T dy} = A\left(\frac{p_0}{p_0 + p_T}\right)^n, \tag{9}$$

$$\frac{d^2N}{2\pi m_T dm_T dy} = Ae^{-m_T/T}, \tag{10}$$

$$\frac{d^2N}{2\pi p_T dp_T dy} = Ae^{-p_T/T}. \tag{11}$$

C. Systematic uncertainties

In Table I, the sources of systematic uncertainties in both $\langle p_T \rangle$ and dN/dy are tabulated. The sources of uncertainty include the extrapolation in p_T, the background, and the Monte Carlo corrections, and cuts. The uncertainty in the Monte Carlo corrections is 11% and includes the multiplicity efficiency correction of 9%, the particle identification cut of 5%, and the fiducial cuts of 5%. The uncertainties in the correction functions are added in quadrature to the statistical error in the data. Background is only relevant for $p_T < 0.6$ GeV/c in the spectra.

The total systematic uncertainty in the $\langle p_T \rangle$ depends on the extrapolation and background uncertainties; the uncertainties are 7%, 10%, and 8% for pions, kaons, and protons, respectively. The overall uncertainty on dN/dy includes the uncertainties on $\langle p_T \rangle$ in addition to the uncertainties from the corrections and cuts; the uncertainties are 13%, 15%, and 14% for pions, kaons, and protons, respectively [21].

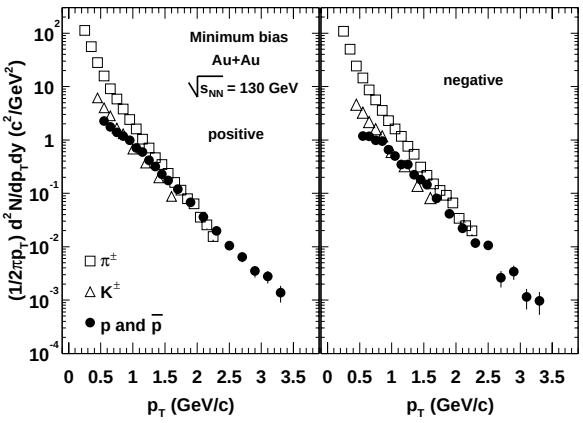

FIG. 9. The spectra of positive particles (left) and negative (right) in minimum-bias collisions from Au+Au collisions at $\sqrt{s_{NN}} = 130$ GeV. The errors include both statistical and systematic errors from the corrections.

The hadron yields and $\langle p_T \rangle$ values include an additional uncertainty arising from the fitting function used for extrapolation to the unmeasured region at low and high p_T. The magnitude of the extrapolation is $30 \pm 6\%$ of the spectrum for pions, $40 \pm 8\%$ for kaons, and $25 \pm 7.5\%$ for protons [21]. The systematic uncertainty quoted here is taken as half the difference between the results from the two different functional forms.

The momentum scale is known to better than 2%, and the momentum resolution affects the spectra shape, primarily for protons, above 2.5 GeV/c. The momentum resolution is corrected by the Monte Carlo. As other sources of uncertainty on the number of particles at any given momentum are much larger, momentum resolution effects are neglected in determining the overall systematic uncertainty from the data reduction.

IV. RESULTS

A. Transverse momentum distributions

The invariant yields as a function of p_T for identified hadrons are shown in Fig. 9, while Fig. 10 provides the centrality dependence of the spectra. The spectra are tabulated in Appendix B. The $\pi^{\pm}$, $K^{\pm}$, p, and $\bar{p}$ invariant yields for the most central, midcentral, and the most peripheral collisions, were reported previously [22]. Pion and (anti)proton invariant yields are comparable for $p_T > 1$ GeV in the most central collisions.

As can be seen already from Fig. 10 all the spectra seem to be exponential; however, upon closer inspection, small deviations from an exponential form are apparent for the more peripheral collisions. The spectrum in the most peripheral collisions is noticeably power-law-like when compared to the more exponential-like spectrum in central collisions. This is especially apparent for the pions. The effect can be seen more clearly in the ratio of the spectra for a given particle species in two different centrality classes. Such ratios

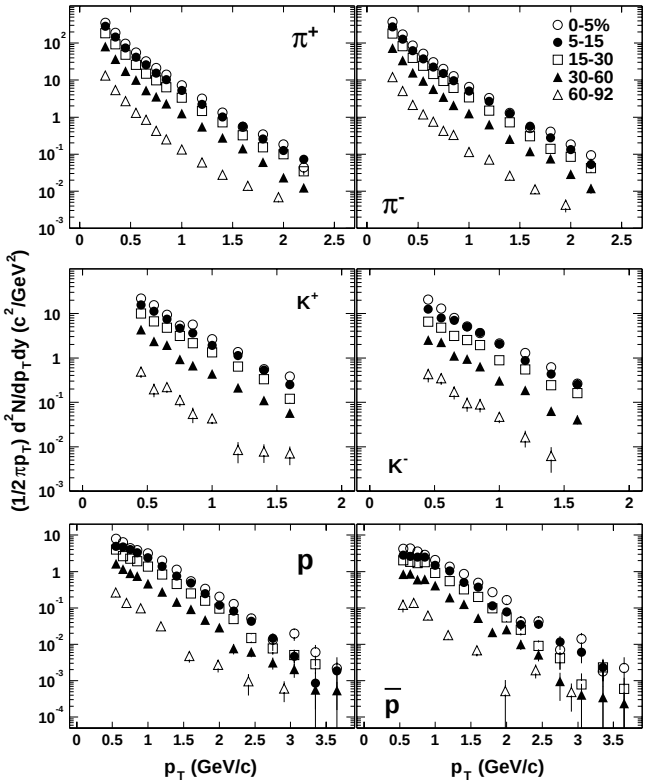

FIG. 10. The hadron spectra for five centralities from the most central 0–5 % to the most peripheral 60–92 % at $\sqrt{s_{NN}}=130$ GeV. Errors include both the statistical and point-by-point error in the corrections added in quadrature.

are shown in Fig. 11 for the 5% central and the most peripheral positive spectra (60–92 % centrality). The ratios for protons and antiprotons as well as for π^+ have a maximum at intermediate p_T and are lower at both low and high p_T. The kaon shape change is not very significant, given the current statistics.

The change in slope at low p_T in central collisions compared to peripheral is consistent with a more substantial hydrodynamic, pressure-driven transverse flow existing in central collisions, since the increased boost would tend to deplete particles at the lowest p_T (see Sec. IV C). This is observed at lower energies at the CERN SPS [23,24]. It is in contrast to results obtained at the ISR [25] for $p+p$ collisions at $\sqrt{s}=63$ GeV, where a shallow maximum or minimum exists at low p_T (in the range 0.3–0.6 GeV/c).

Feed-down contribution to p and $\bar{p}$ from inclusive Λ and $\bar{\Lambda}$

Inclusive Λ and $\bar{\Lambda}$ transverse momentum distributions have been measured in the west arm of the PHENIX spectrometer using the tracking detectors (DC, PC1) and a lead-scintillator electromagnetic calorimeter (EMCal) [26]. The invariant mass is reconstructed from the weak decays $\Lambda \rightarrow p+\pi^-$ and $\bar{\Lambda}\rightarrow \bar{p}+\pi^+$.

The tracks from the tracking detectors are required to fall within 3σ of EMCal measured space points. The EMCal timing resolution of the daughter particles is $\approx$700 ps. Using the DC momentum and the EMCal time of flight, the particle mass is calculated, and protons, antiprotons, and pions are

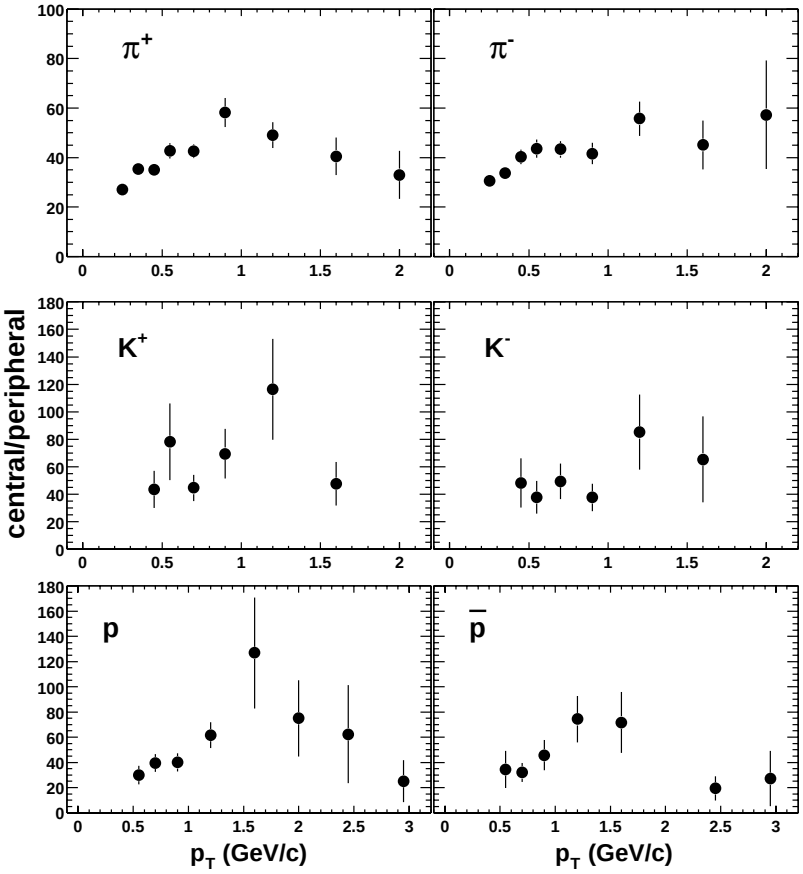

FIG. 11. The ratio of the most central to the most peripheral yields as a function of p_T for pions (top), kaons (middle), and (anti)protons (bottom).

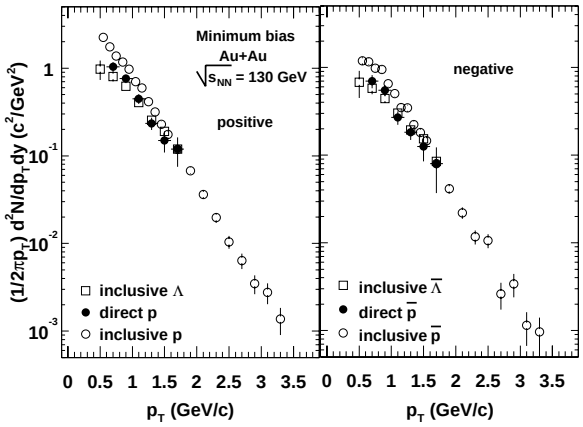

FIG. 12. For minimum-bias collisions, the inclusive Λ, inclusive p, and direct p transverse momentum distributions are plotted together in the left panel. The equivalent comparison for inclusive $\bar{\Lambda}$, $\bar{p}$, and direct $\bar{p}$ transverse momentum distributions is in the right panel.

identified using 2σ momentum-dependent mass-squared cuts. A clean particle separation is obtained using an upper momentum cut of 0.6 GeV/c and 1.4 GeV/c for pions and protons, respectively. The momentum is determined assuming the primary decay vertex is positioned at the event vertex and results in a momentum shift of 1–2% based on a Monte Carlo study.

Using all combinations of pions and protons, the invariant mass is determined. The mass distribution shows a Λ peak on top of a random combinatorial background, which is determined by combining protons and pions from different collisions with the same centrality. A signal-to-background ratio of 1/2 is obtained after applying a decay kinematic cut on the daughter particles. Fitting a Gaussian function to the mass distribution in the range $1.05 < m_{p\pi} < 1.20$ GeV/c^2, 12000 Λ and 9000 $\bar{\Lambda}$ are observed, with mass resolution $\delta m/m \approx 2\%$. The reconstructed Λ and $\bar{\Lambda}$ spectra are corrected for the acceptance, pion decay-in-flight, momentum resolution, and reconstruction efficiency [26]. The systematic uncertainty on the p_T spectra is 13% from the corrections and 3% from the combinatorial background subtraction. The feed-down contributions from heavier hyperons Σ^0 and Ω are not measured but are estimated to be $<5\%$.

Figure 12 shows the transverse momentum spectra of inclusive protons (left) and antiprotons (right) with the inclusive Λ and $\bar{\Lambda}$ transverse momentum distributions. The solid points are the (anti)proton spectra after the feed-down correction from Λ and $\bar{\Lambda}$ weak decays. From here forward, the data that are presented and discussed are not corrected for this feed-down effect; inclusive p and $\bar{p}$ yields are given. More details on the Λ and $\bar{\Lambda}$ measurement are included in Ref. [26].

TABLE III. The $\langle p_T \rangle$ in MeV/c for hadrons produced at midrapidity in each centrally class. The errors are statistical only. The systematic uncertainities are 7%, 10%, and 8% for pions, kaons, and (anti)protons, respectively.

B. Yield and $\langle p_T \rangle$

The yield dN/dy and the average transverse momentum $\langle p_T \rangle$ are determined for each particle as described in the preceding section and have been previously published in Ref. [22]. For each centrality, the rapidity density dN/dy and average transverse momentum $\langle p_T \rangle$ are tabulated in Tables II and III, respectively.

The $N_{\rm part}$ and $N_{\rm coll}$ in each centrality selection are determined using a Glauber-model calculation in Ref. [27]. The resulting values of $N_{\rm part}$ and $N_{\rm coll}$ are also tabulated in Table II. (See Appendix A for more detail.) The errors on $N_{\rm part}$ and $N_{\rm coll}$ include the uncertainties in the model parameters as

TABLE II. The dN/dy at midrapidity for hadrons produced at midrapidity in each centrality class. The errors are statistical only. The systematic errors are 13%, 15%, and 14% for pions, kaons, and (anti)protons, respectively. The $N_{\rm part}$ and $N_{\rm coll}$ in each centrality selection are from a Glauber-model calculation in Ref. [27], also shown with systematic errors based on a 92±4% coverage.

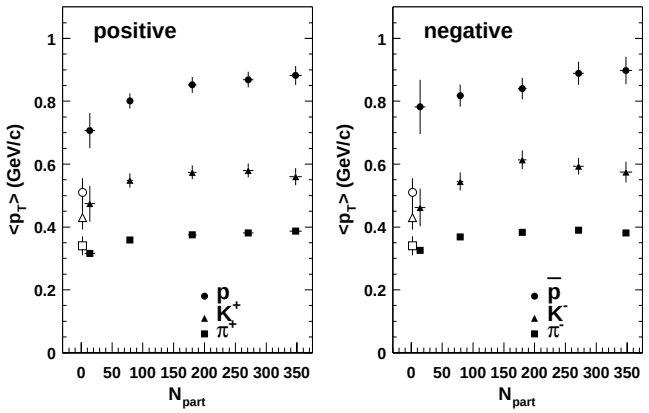

FIG. 13. The integrated mean p_T for pions, kaons, and (anti)protons produced in the five different classes of event centrality [22]. The error bars are statistical only. The systematic uncertainties are 7%, 10%, and 8% for pions, kaons, and (anti)protons, respectively. The open points are equivalent average transverse momenta from pp and $p\bar{p}$ data, interpolated to $\sqrt{s}=130$ GeV.

well as in the fraction of the total geometrical cross section $(92\% \pm 4\%)$ seen by the interaction trigger. The error due to model uncertainties is 2% [27]. An additional 3.5% error results from time dependencies in the centrality selection over the large data sample.

Pions dominate the charged particle multiplicity, but a large number of kaons and (anti)protons are produced. The inclusive yield of antiprotons is nearly comparable to that of protons. In the most central Au+Au collisions, the particle density at midrapidity (dN/dy) is ≈ 20 for antiprotons and 28 for protons, not corrected for feed-down from strange baryons.

The average transverse momenta increase with particle mass and with decreasing impact parameter. The mean transverse momentum increases with the number of participant nucleons by $20 \pm 5\%$ for pions and protons, as shown in Fig. 13. The $\langle p_T \rangle$ of particles produced in $p+p$ and $p\bar{p}$ collisions, extrapolated to RHIC energies, are consistent with the most peripheral pion and kaon data; however, the $\langle p_T \rangle$ of protons produced in Au+Au collisions is significantly higher. This dependence on the number of participant nucleons may be due to radial expansion. It should be noted that the feeding of protons and antiprotons from Λ decays affects $\langle p_T \rangle$. If the spectra are corrected for feed-down, $\langle p_T \rangle$ increases by approximately 15%.

C. Transverse mass distributions

Production of hadrons from a thermal source would make transverse mass the natural variable for analysis. Therefore we extract inverse slopes from the transverse mass distributions by separately fitting a thermal distribution to each particle species. The Boltzmann distribution is given in Eq. (12),

$$\frac{d^2N}{2\pi m_T dm_T dy} = A m_T e^{-m_T/T_{eff}}. \tag{12}$$

We use a simple exponential, however, with no powers of m_T in the prefactor, as shown in Eq. (10). This simplification is acceptable as the difference in the inverse slope is found to be less than 2%. The simple m_T exponential was also used in an equivalent analysis in Ref. [28]. The inverse slope T_{eff} can be compared to other experiments, provided the same momentum range of the spectrum is used for fitting.

If the system develops collective motion, particles experience a velocity boost from this motion, resulting in an additional transverse kinetic energy component. This motivates use of the transverse kinetic energy, i.e., transverse mass minus the particle rest mass, for plotting data. Figure 14 shows the transverse kinetic energy distributions (i.e., transverse mass minus the particle rest mass) for all positive particles (left) and negative particles (right). Pions are in the top panel, kaons in the middle panel, and (anti)protons in the bottom panel, with different symbols indicating different centrality bins. The solid lines are m_T exponential fits in the range $(m_T - m_0) < 1$ GeV for all particle species while the dashed lines are the extrapolated fits. The pion spectra follow an exponential for $0.38 < (m_T - m_0) < 1.0$ GeV while the kaons and protons appear exponential over the entire measured m_T range. The same is true for the negative particles in the right panel; however, the antiprotons have more curvature for $(m_T - m_0) < 0.5$ GeV. We extract T_{eff} by fitting exponentials of form (10) to the transverse mass spectra in the range $(m_T - m_0) < 1$ GeV.

This range is chosen common for all particle species and minimizes contributions from hard processes. Caution must be taken when comparing T_{eff} values as the local slope of the transverse mass spectra varies somewhat over m_T for pions and antiprotons even within this fit range. The resulting values of T_{eff} for all particles and centralities are tabulated in Table IV in units of MeV. The inverse slopes increase and then saturate for more central collisions for all particles except antiprotons. The fact that the inverse slope is different for mesons and baryons and for central and peripheral events is consistent with the mean p_T trends discussed above.

We compare to published inverse slopes of transverse mass distributions at midrapidity from m_T exponential fits in the region $(m_T - m_0) < 1.2$ GeV, listed in Table V. The comparison includes NA44 [28–31] and WA97 [32,33] at the SPS at $\sqrt{s_{NN}} = 17-29$ GeV; and, at $\sqrt{s_{NN}} = 23$ GeV at the ISR, Alper *et al.* [34] and Guettler *et al.* [35]. These data are chosen as they match the $m_T - m_0$ range used in fitting our data. For pions, the low-p_T region of $(m_T - m_0) < 0.3$ GeV, populated by decay of baryonic resonances, is systematically excluded from the fits. The effective temperatures are given in Table V with the references noted accordingly.

Radial flow imparts a radial velocity boost on top of the thermal distribution. Heavy particles are boosted to higher p_T, depleting the cross section at lower p_T and yielding a higher inverse slope. Therefore, the observed inverse slope dependence on both centrality and particle mass implies more radial expansion in more central collisions. At CERN SPS, the T_{eff} depends on both mass and system size (the number of participating nucleons in the collision), indicating collective expansion. The T_{eff} values at RHIC shown in Table IV are somewhat larger.

In p-p collisions at similar $\sqrt{s}$ at the ISR, hadron spectra were analyzed in transverse mass, m_T, rather than transverse

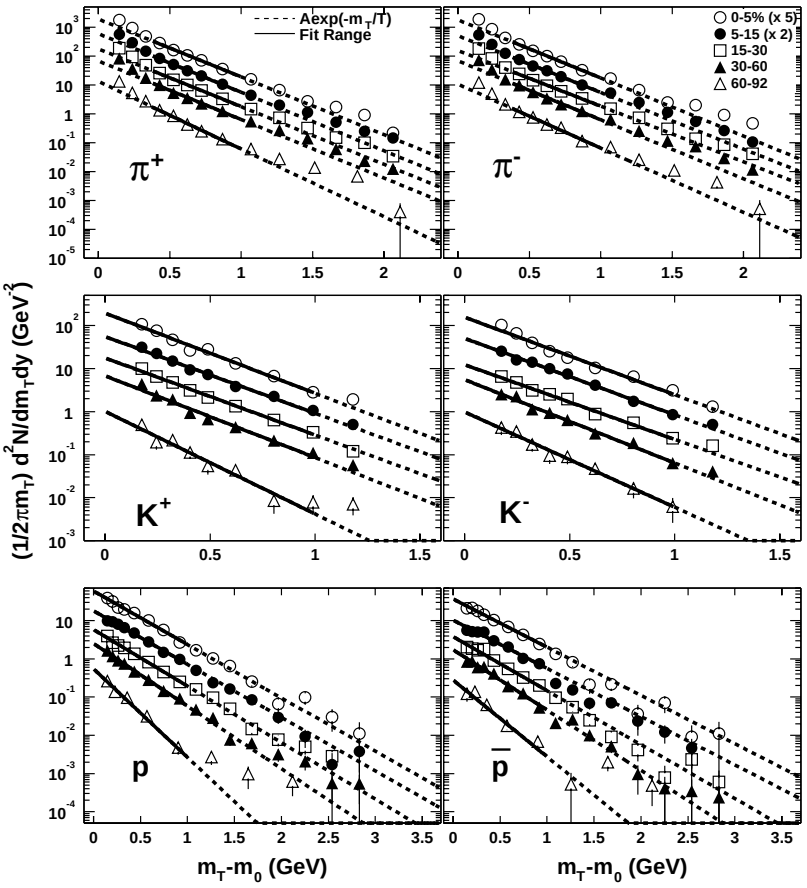

FIG. 14. Transverse mass distributions of pions (top), kaons (middle), and (anti)protons (bottom) in events with different centralities. Positive particle distributions are on the left and negative particle distributions are on the right. The solid lines are m_T exponential fits in the range $(m_T - m_0) < 1$ GeV for all particle species while the dashed lines are the extrapolated fits.

kinetic energy $m_T - m_0$ [36,37]. To facilitate a direct comparison, Fig. 15 shows the PHENIX hadron spectra, including π^0 from the 10% most central Au+Au collisions. The spectra approach one another, but do not fall upon a universal curve, and thereby fail the usual definition of scaling.

It has been suggested that at transverse mass significantly larger than the rest mass of the particle, thermal emission and radial flow may not be the only physics affecting the particle spectra. If heavy ion collisions can be described as collisions of two sheets of colored glass in which the gluon occupation number is sufficiently large to saturate, scaling of different hadron spectra with transverse mass is also predicted [38]. For Au+Au collisions at different impact parameters, the saturation scale differs, and some differences in the spectra may be expected. Nevertheless, the authors observe that the level of m_T scaling in our data is in qualitative agreement with expectations from gluon saturation [38]. Single-particle spectra alone, however, are not sufficient to disentangle saturation from flow effects.

It is often stated that m_T scaling holds in pp collisions at similar $\sqrt{s}$ to RHIC (see data, for example, in Refs. [36] and [37]). Scaling in m_T, i.e., spectra following a universal curve in m_T, might be expected if the hadrons are emitted from a source in thermal equilibrium. It is instructive to note that Ref. [36] states: "Although the curves for different particles do come together, there is no real evidence for any universal behavior in this variable." Thus, scaling at the ISR was never claimed by the original authors. In central Au+Au collisions, the slopes and yields of π, K, and p approach each other as well, but Figs. 15–17 also do not support a truly universal

TABLE IV. The resulting inverse slopes in MeV after fitting an m_T exponential to the spectra in the range $m_T - m_0 < 1$ GeV in each event centrality classes. The pion resonance is excluded in the fits. The equivalent p_T fit range for each particle is shown accordingly. The errors are statistical only.

behavior in m_T. Therefore the apparent puzzle of how the data could exhibit both m_T scaling and the mass-dependent p_T boost characteristic of radial flow is no puzzle at all, as any "m_T scaling" is only very approximate.

D. Summed charged particle multiplicity

As a consistency check we compare the measured rapidity densities as given in Sec. IV B to previously published pseudorapidity densities of charged particles. The measured dN/dy for each hadron species is converted to $dN/d\eta$, and the total $dN/d\eta$ is calculated by summation. Figure 18 shows $dN/d\eta$ per participant nucleon pair, compared to the measurement made by PHENIX using the pad chambers alone [27] as well as to PHOBOS and STAR yields in central collisions [40,41]. We note that the lines correspond to the fit of a linear parametrization of $N_{\rm part}$ and $N_{\rm coll}$ to the PHENIX measurement (open circles) with $a=0.88\pm0.28$ and $b=0.34\pm0.12$ as described in Ref. [42]. For the 5% central collisions, we measure 598 ± 30, and is comparable to the STAR result of 567 ± 38 [41], the PHOBOS result of 555 ± 37 [43], and the PHENIX pad chamber result of 622 ± 41 [27]. The agreement is excellent, allowing the results of this analysis to be used to decompose the particle-type dependence of the charge particle multiplicity increase with centrality.

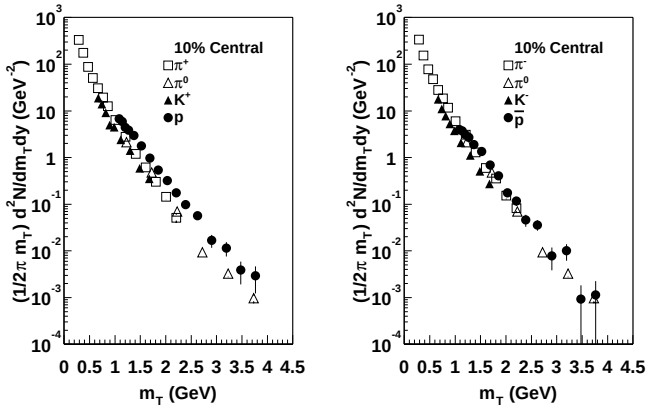

FIG. 15. The transverse mass distributions of inclusive identified hadrons produced in 10% central events, including the π^0 as measured in the electromagnetic calorimeter in PHENIX and published in Ref. [39].

V. COMPARISON WITH MODELS

A. Hydrodynamic-inspired fit

The charged particle pseudorapdity distributions are incompatible with a static thermal source, but the flat distribution observed in Ref. [43] reflects the strong longitudinal motion in the initial state. Consequently, the longitudinal momentum distribution is not an unambiguous sign of collective motion. Transverse momentum is, however, generated in the collision, so collective expansion may be more easily inferred from transverse momentum distributions.

Following the arguments of the preceding section, we analyze the particle m_T spectra. A parametrization of the m_T distribution of particles emitted from a hydrodynamic ex-

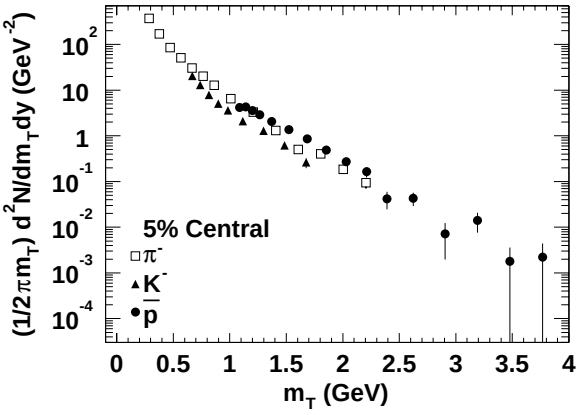

FIG. 16. The transverse mass distributions of the inclusive identified hadrons produced in the 5% central events.

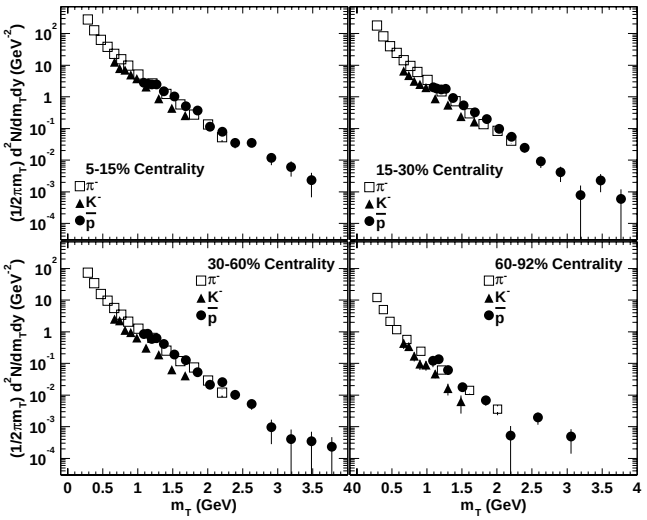

FIG. 17. The transverse mass distributions of the inclusive identified hadrons produced in events with different centralities.

panding hadron source is used. In order to determine the freeze-out temperature and collective flow without confusion from hard scattering processes, a limited p_T range is used in the fits. We include only particles with $(m_T-m_0)<1$ GeV in the fit. Pions with $(m_T-m_0)<0.38$ GeV are excluded to avoid resonance decays. All particles are assumed to decouple from the expanding hadron source [44] at the same freeze-out temperature $T_{\rm fo}$. This procedure allows us to extract $T_{\rm fo}$ and the magnitude of the collective boost in the transverse direction.

The inverse slope includes the local temperature of a section of the hadronic matter along with its collective velocity. The simple exponential fit of Eq. (10) treats each particle spectrum as a static thermal source, and a collective expansion velocity cannot be extracted reliably from a single-particle spectrum. However, the relative sensitivity to the

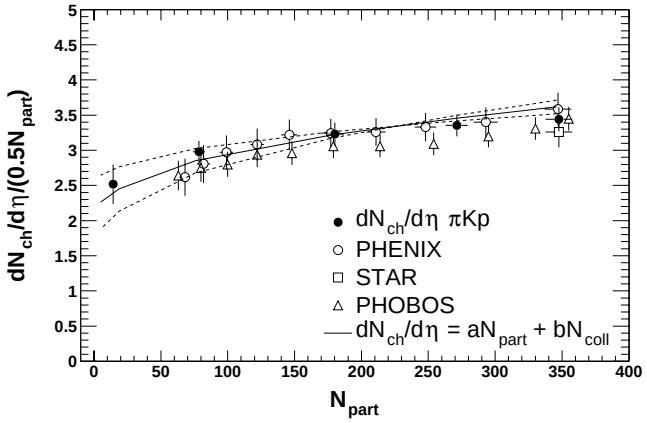

FIG. 18. Both the total charged multiplicity (open) in Refs. [40–42] and the total identified charged multiplicity (closed) scaled by the number of participant pairs are plotted together as a function of the number of participants. The lines correspond to the fit of a linear parametrization of $N_{\rm part}$ and $N_{\rm coll}$ to the PHENIX charged multiplicity measurement (open circles) with $a=0.88\pm0.28$ and $b=0.34\pm0.12$ as described in Ref. [42].

temperature and collective radial flow velocity differs for different particles. By using the information from all the particles, the expansion velocity can be inferred. We fit all particle species simultaneously with a functional form for a boosted thermal source based on relativistic hydrodynamics [44].

Use of this form assumes that (1) all particles decouple kinematically on a freeze-out hypersurface at the same freeze-out temperature $T_{\rm fo}$; (2) the particles collectively expand with a velocity profile increasing linearly with the radial position in the source (i.e., Hubble expansion where fluid elements do not pass through one another); and (3) the particle density distribution is independent of the radial position. Longitudinally boost-invariant expansion of the particle source is also assumed.

The transverse velocity profile is parametrized as:

$$\beta_T(\xi)=\beta_T^{\rm max}\xi^n, \tag{13}$$

where $\xi=r/R$, and R is the maximum radius of the expanding source at freeze-out $(0<\xi<1)$ [45]. The maximum surface velocity is given by $\beta_T^{\rm max}$, and for a linear velocity profile, $n=1$. The average of the transverse velocity is equal to

$$\langle\beta_T\rangle=\frac{\int\beta_T^{\rm max}\xi^n\xi d\xi}{\int\xi d\xi}=\frac{2}{2+n}\beta_T^{\rm max}. \tag{14}$$

Each fluid element is locally thermalized and receives a transverse boost ρ that depends on the radial position as

$$\rho=\tanh^{-1}(\beta_T(\xi)). \tag{15}$$

The m_T dependence of the invariant yield $dN/m_T dm_T$ is determined by integrating over the rapidity, azimuthal angle, and radial distribution of fluid elements in the source. This procedure, discussed in Appendix C, yields

$$\frac{d^2N}{m_T dm_T dy}=A\int_0^1 m_T f(\xi)K_1\left(\frac{m_T\cosh(\rho)}{T_{\rm fo}}\right)I_0\left(\frac{p_T\sinh(\rho)}{T_{\rm fo}}\right)\xi d\xi. \tag{16}$$

The parameters determined by fitting Eq. (16) to the data are the freeze-out temperature $T_{\rm fo}$, the normalization A, and the maximum surface velocity $\beta_T^{\rm max}$ using a flat particle density distribution [i.e., $f(\xi)=1$].

To study the parameter correlations, we make a grid of combinations of temperature and velocity, and perform a χ^2 minimization to extract the normalization A for each particle type. The fit is done simultaneously for all particles in the range $(m_T-m_0)<1$ GeV. In addition to this upper limit in the fit, the pion fit range includes a lower limit of $(m_T-m_0)>0.38$ GeV to avoid the resonance contribution to the low-p_T region (see Sec. V A 2).

The radial flow velocity and freeze-out temperature for all centralities are determined in the same way. The results are plotted together with the spectra in Fig. 19. The hydrody-

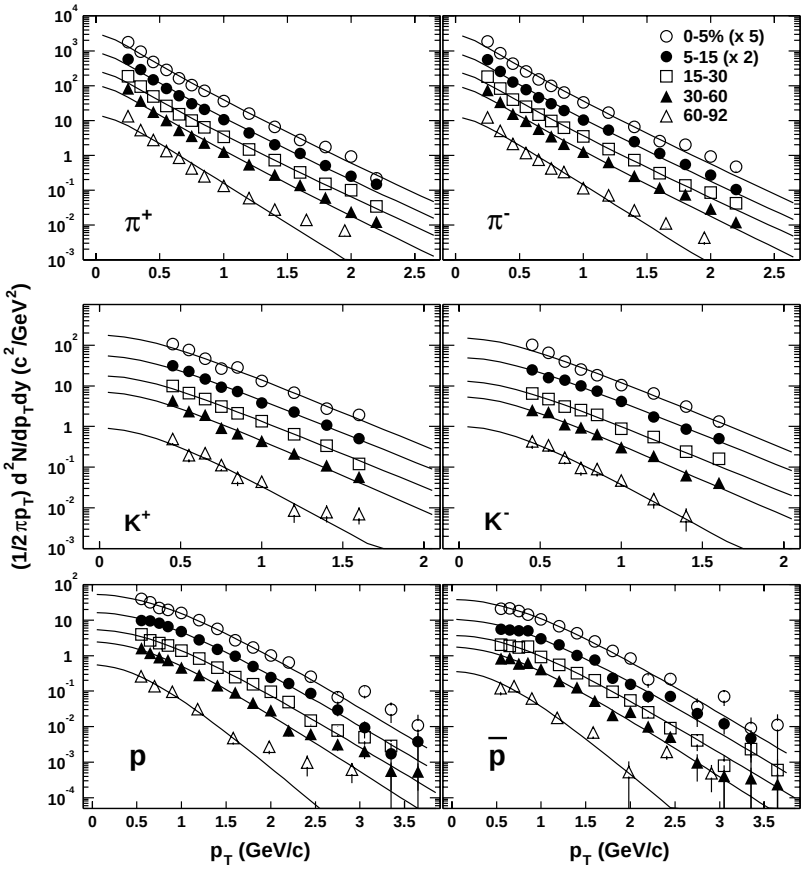

FIG. 19. The parametrization and the p_T hadron spectra for all five centrality selections.

namic form clearly describes the spectra better than the simple exponential in Fig. 14. The values for $T_{\rm fo}$ and $\beta_T^{\rm max}$ are tabulated in Table VI.

Figure 20 shows χ^2 contours for the temperature and velocity parameters for the 5% most central collisions. The n-sigma contours are labeled up to 8σ. The χ^2 contours indicate strong anticorrelation of the two parameters. If the freeze-out temperature decreases, the flow velocity increases. The minimum χ^2 is 34 and the total number of degrees of freedom (DOF) is 40. The parameters that correspond to this minimum are $T_{\rm fo}=121\pm4$ MeV and $\beta_T^{\rm max}=0.70\pm0.01$. The quoted errors are the 1σ contour widths of $\Delta\beta_T^{\rm max}$ and $\Delta T_{\rm fo}$. Within 3σ, the $T_{\rm fo}$ range is 106–141 MeV and the $\beta_T^{\rm max}$ range is 0.75–0.64.

TABLE VI. The minimum χ^2 and the parameters $T_{\rm fo}$ and $\beta_T^{\rm max}$ for each of the five centrality selections. The best fit parameters are determined by averaging all parameter pairs within the 1σ contour. The errors correspond to the standard deviation of the parameter pairs within the 1σ χ^2 contour. It is important to note that the fit range in Fig. 19 is the same as was used to fit m_T exponentials to the spectra in Fig. 14.

Centrality (%)	χ^2/DOF	$T_{\rm fo}$(MeV)	$\beta_T^{\rm max}$	$\langle\beta_T\rangle$
0–5	34.0/40	121 ± 4	0.70 ± 0.01	0.47 ± 0.01
5–15	34.7/40	125 ± 2	0.69 ± 0.01	0.46 ± 0.01
15–30	36.2/40	134 ± 2	0.65 ± 0.01	0.43 ± 0.01
30–60	68.9/40	140 ± 4	0.58 ± 0.01	0.39 ± 0.01
60–92	36.3/40	$161\pm^{19}_{12}$	$0.24\pm^{0.16}_{0.2}$	$0.16\pm^{0.16}_{0.2}$

As a linear velocity profile [$n=1$ in Eq. (13)] is assumed, the mean flow velocity in the transverse plane is $\langle\beta_T\rangle=2\beta_T^{\rm max}/3$. If a different particle density distribution [for instance, a Gaussian function for $f(\xi)$] were used, then the average should be determined after weighting accordingly [45].

A similar analysis for Pb+Pb collisions at 158A GeV, was reported by the NA49 Collaboration in Ref. [46]. Using the same hydrodynamic parametrization, simultaneous fits of several hadron species for the highest energy results in $T_{\rm fo}=127\pm1$ MeV and $\beta_T^{\rm max}=0.48\pm0.01$ with $\chi^2/NDF=120/43$ for positive particles and $T_{\rm fo}=114\pm2$ MeV and $\beta_T^{\rm max}=0.50\pm0.01$ with $\chi^2/NDF=91/41$ for negative particles (statistical errors only). Pions and deuterons are excluded from the fits to avoid dealing with resonance contributions to the pion yield and formation of deuterons by coalescence. The ϕ meson is included in the fit together with the negative particles. Previously, NA49 used a different parametrization to fit the charged hadron and deuteron spectra, as well as the m_T dependence of measured Hanbury Brown–Twiss source radii, resulting in overlapping χ^2 contours with $T_{\rm fo}=120\pm12$ MeV and $\beta_T^{\rm max}=0.55\pm0.12$ [47].

1. Velocity and particle density profile

In order to use $\beta_T^{\rm max}$ and $T_{\rm fo}$ from the fits described above, one needs to know their sensitivity to the assumed velocity and particle density profiles in the emitting source. The

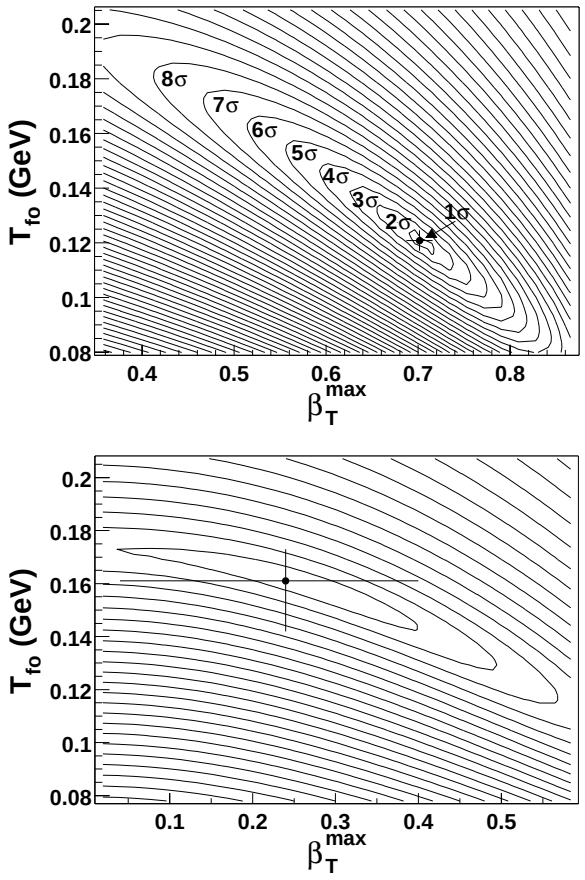

FIG. 20. The χ^2 contours in the parameter space $T_{\rm fo}$ and $\beta_T^{\rm max}$ that result after simultaneously fitting hadrons in the 0–5 % centrality (top) and 60–92 % (bottom). The *n*-sigma contours are labeled accordingly in the top panel. The fit results are tabulated in Table VI.

choice of a linear velocity profile within the source is motivated by the profile observed in a full hydrodynamic calculation [48], which shows a nearly perfect linear increase of $\beta(r)$ with r. Nevertheless, we also used a parabolic profile to check the sensitivity of the results to details of the velocity profile. For a parabolic velocity profile [$n=2$ in Eq. (13)], $\beta_T^{\rm max}$ increases by $\approx$13% and $T_{\rm fo}$ increases by $\approx$5%.

A Gaussian density profile used with a linear velocity profile increases $\beta_T^{\rm max}$ by $\approx$2%, with a negligible difference in the temperature $T_{\rm fo}$. As a test of the assumption that all the particles freeze out at a common temperature, the simultaneous fits were repeated without the kaons. The difference in $T_{\rm fo}$ is within the measured uncertainties.

2. Influence of resonance production

The functional forms given by Eqs. (10) and (17) do not include particles arising from resonance or weak decays. As resonance decays are known to result in pions at low transverse momenta [49–51], we place a p_T threshold of 500 MeV/c on pions included in the hydrodynamic fit. A similar approach was followed by NA44, E814, and other experiments at lower energies, which performed in-depth studies of resonance decays feeding hadron spectra. However, these were for systems with higher baryon density, so we performed a cross-check on possible systematic uncertainties arising from the pion threshold used in the fits. To estimate the effect of resonance decays were they not excluded from the fit, we calculate resonance contributions following Wiedemann [52].

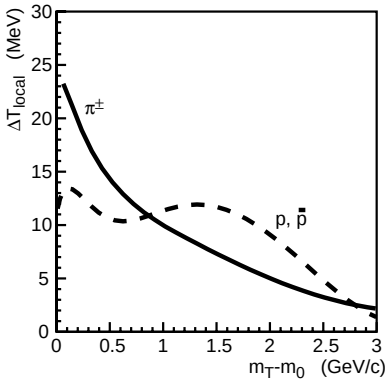

FIG. 21. The difference in the local slope for direct and inclusive pions (solid) and (anti)protons (dashed).

In order to reproduce the relative yields of different particle types, a chemical freeze-out temperature—different from the kinetic freeze-out temperature—and a baryonic chemical potential are introduced. Direct production and resonance contribution are calculated for pions and (anti)protons assuming a kinetic freeze-out temperature of 123 MeV, a transverse flow velocity of 0.612 (equivalent to $\langle\beta_T\rangle = 0.44$), a baryon chemical potential of 37 MeV, and a chemical freeze-out temperature (when particle production stops) of 172 MeV. These parameters are chosen as they provide a reasonable description of the (anti)proton and pion spectra and yields (10% most central) and are in good agreement with chemical freeze-out analyses [53]. Most spectra from resonance decays show a steeper falloff than the direct production, which should lead to a smaller apparent inverse slope, depending on what fraction of the low p_T part of the spectrum is included in the fits.

To measure the effect of resonance production on the spectral shape, the local slope is determined. For a given m_T bin number i, the local slope is defined as

$$T_{\rm local}(i) = -\frac{m_T(i+1) - m_T(i-1)}{\ln[N(i+1)] - \ln[N(i-1)]}, \qquad (17)$$

which is identical to the inverse slope independent of m_T for an exponential.

The difference in the local slope,

$$\Delta T_{\rm local} = T_{\rm local}^{\rm direct} - T_{\rm local}^{\rm incl}, \qquad (18)$$

is determined for direct and inclusive pions and (anti)protons. The differences are plotted as a function of $m_T - m_0$ in Fig. 21. The difference in the local slope for protons is below 13 MeV for the full transverse mass range; the nonmonotonic behavior for protons is caused by the relatively strong transverse flow. For pions, $\Delta T_{\rm local}$ decreases monotonically with m_T and is below 10 MeV above m_T

$=1$ GeV/c. A fit of an exponential to the pion spectra for $(m_T - m_0) > 0.38$ GeV (which corresponds to $p_T > 0.5$ GeV/c) yields a difference in the inverse slope of 16 MeV with and without resonances.

B. Comparison with hydrodynamic models

Hydrodynamic parametrizations as used in the preceding Section rely upon many simplifying assumptions. Another approach to the study of collective flow is to compare the data to hydrodynamic models. Such models assume rapid equilibration in the collision and describe the subsequent motion of the matter using the laws of hydrodynamics. Large pressure buildup is found, and we investigate this ansatz by checking the consistency of the data with calculations using a reasonable set of initial conditions. We compare to two separate models, the hydrodynamics model of Kolb and Heinz [54–56] and the "hydro to hadrons" (H2H) model of Teaney and Shuryak [57,58]. The H2H model consists of a hydrodynamics calculation, followed by a hadronic cascade after chemical freeze-out. The cascade step utilizes the relativistic quantum molecular dynamics (RQMD) model, developed for lower energy heavy ion collisions [59].

In both models, initial conditions are tuned to reproduce the shape of the transverse momentum spectra measured in the most central collisions, along with the charged particle yield. Each model also includes the formation and decay of resonances.

In the Kolb and Heinz model [54–56], the initial parameters are the entropy density, baryon number density, the equilibrium time, and the freeze-out temperature which controls the duration of the expansion. The chemical freeze-out temperature is the temperature at which particle production ceases. The initial entropy or energy density and maximum temperature are fixed to match the measured multiplicity for the most central collisions using a parametrization that is tuned to produce the measured $dN_{\rm ch}/d\eta$ dependence on both $N_{\rm part}$ and $N_{\rm coll}$. A kinetic freeze-out temperature of $T_{\rm fo} = 128$ MeV is used. Spectra from the Kolb-Heinz hydrodynamic model are shown in Fig. 22 for pions (upper) and for protons (lower) as dotted lines. The solid lines are the results from the fits described in the previous sections. Figure 22 thus allows two comparisons. The similarity of the dashed and solid lines shows that the hydrodynamic-inspired parametrization used to fit the data results in a p_T distribution similar to this hydrodynamic calculation. Comparing the dashed lines to the data points shows that the hydrodynamic model agrees quite well for most of the centrality ranges. It is important to note that the model parameters are uncertain at the level of 10%, and, more importantly, the application of hydrodynamics to peripheral collisions may be less reasonable than for central collisions, as hydrodynamic calculations assume strong rescattering and a sufficiently large system size (discussed in Ref. [56]).

In Refs. [57,60], the PHENIX $\bar{p}$ spectrum shape is well described by the H2H model with the LH8 equation of state. The cascade step in the H2H model removes the requirement that all particles freeze out at a common temperature. Thus the freeze-out temperature and its profile are predicted, rather

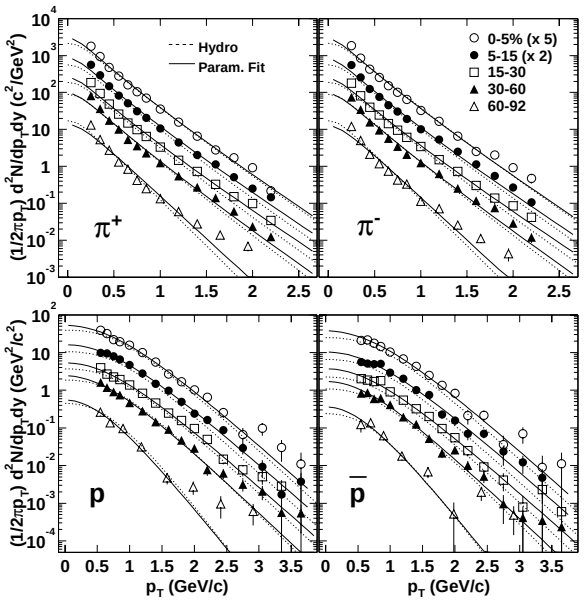

FIG. 22. The hydrodynamics calculation with initial parameters tuned to match the most central spectra in the p_T range 0.3–2.0 GeV/c.

than input parameters. Furthermore, following the hadronic interactions explicitly with RQMD removes the need to rescale the particle ratios at the end of the calculation, as they are fixed by the hadronic cross sections rather than at some particular freeze-out temperature. The LH8 equation of state includes a phase transition with a latent heat of 0.8 GeV. In Refs. [57,60], the Ω and the ϕ are shown to decouple from the expanding system at $T = 160$ MeV, and they receive a flow velocity boost of $0.45c$. Pions and kaons decouple at $T = 135$ MeV with flow velocity equal to 0.55c, while protons have $T = 120$ MeV and flow velocity greater than or equal to 0.6. These temperatures and flow velocities are consistent with the values extracted from the data for the most central events. However, the average initial energy density exceeds the experimental estimate using formation time $\tau_0 = 1$ fm/c.

Figure 23 shows radial flow from the fits of the preceding section as a function of the number of participants for $T_{\rm fo}$ (top) and $\langle \beta_T \rangle$ (bottom). There is a slight decrease of $T_{\rm fo}$, while $\langle \beta_T \rangle$ increases with $N_{\rm part}$, saturating at 0.45. The value of $\langle \beta_T \rangle$ from Kolb and Heinz [54–56] is also shown, and agrees with the data reasonably well. In the plot of $\langle \beta_T \rangle$, the dashed line indicates the results of fitting the parametrization to the data while keeping $T_{\rm fo}$ fixed at 128 MeV to agree with the value used by Kolb and Heinz. Radial flow values for central collisions remain unchanged, while those in peripheral collisions increase. Even with the extreme assumption that all collisions freeze out at the same temperature, regardless of centrality, the trend in the centrality dependence of the radial flow does not change. $\langle \beta_T \rangle$ would increase somewhat if a full feed-down correction for protons and antiprotons could be made. The low-p_T part of the spectrum would flatten slightly, as seen in Fig. 12. The resulting hydrodynamic-inspired fit to the data, shown as the solid line in Fig. 22, would be drawn nearer to the Kolb-Heinz hydrodynamic model indicated by the dashed lines in Fig. 22.

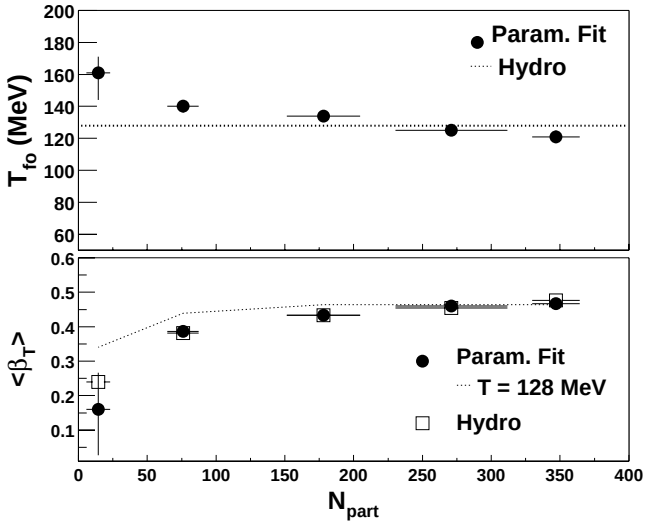

FIG. 23. The expansion parameters $T_{\rm fo}$ and $\beta_T^{\rm max}$ as a function of the number of participants. As a comparison, the results from a hydrodynamic model calculation are also shown (Refs. [54–56]). The dashed line corresponds to a fixed temperature of 128 MeV for all centralities in the parametrized fit to the data.

C. Hydrodynamic contributions at higher p_T

We use the parameters extracted from the fit to the charged hadron spectra in the low-p_T region to extrapolate the effect of the soft physics to higher p_T. This yields a prediction for the spectra of hadrons should a collective expanding thermal source be the only mechanism for particle production in heavy ion collisions. Comparing this prediction to the measured spectrum of charged particles or neutral pions should indicate the p_T range over which soft thermal processes dominate the cross section. Where the data deviate from the hydrodynamic extrapolation, other contributions, as, e.g., from hard processes or nonequilibrium production become visible. The approach described here differs from hydrodynamic fits to the entire hadron spectrum, as we fix the parameters from the low-p_T region alone, where soft physics should be dominant.

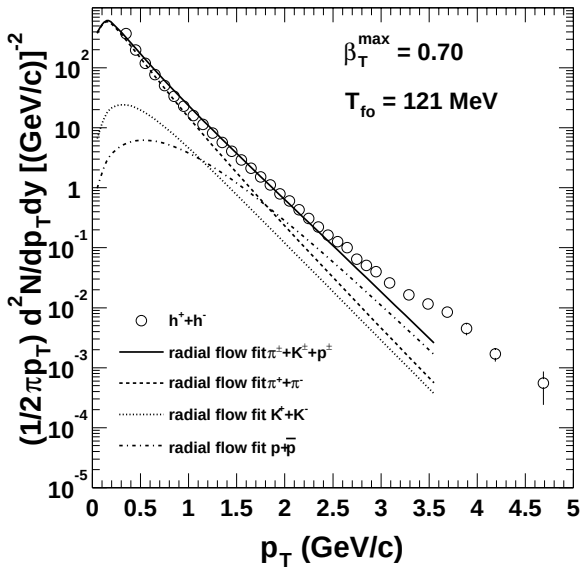

FIG. 24. The high-p_T hadron spectra in Ref. [39] compared to the fit results assuming radial flow from the π, K, p spectra in the 5% central events.

TABLE VII. Fit parameters for each particle species using Eqs. (19) and (20).

Particle	$\alpha_{\rm part}$	$\alpha_{\rm coll}$
π^+	1.06±0.01	0.79±0.01
π^-	1.08±0.01	0.80±0.01
K^+	1.18±0.02	0.88±0.02
K^-	1.20±0.03	0.89±0.02
p^+	1.16±0.02	0.86±0.02
p^-	1.14±0.03	0.84±0.02

The hadron spectrum is calculated using the fit parameters from the low-p_T region fits shown in the preceding section, and extrapolated to higher p_T. Figure 24 shows the calculated spectrum for each particle type, and the sum of the extrapolated spectra is compared to the measured charged hadrons $(h^+ + h^-)$ in the 5% most central collisions. As nonidentified charged hadrons are measured in η rather than in y, the extrapolated spectra are converted to units of η. This conversion is most important in the low-p_T region. No additional scale factor is applied—the extrapolation and data are compared absolutely. Below $\approx$2.5 GeV/c p_T, the agreement is very good, while at higher p_T the data begin to exceed the hydrodynamic extrapolation.

Other hydrodynamic calculations have been successful in describing the distributions over the full p_T range [61] with different parameter values. There are clear indications that particle production from a hydrodynamic source, if invoked to explain the spectra at low p_T, will have a non-negligible influence even at relatively large p_T. Furthermore, the range of p_T populated by hydrodynamically boosted hadrons is species dependent. This is clearly visible in Fig. 24, which shows that the extrapolated proton spectra have a flatter p_T distribution than the extrapolated pions and kaons. The yield of the "soft" protons reaches, and even exceeds, that of the extrapolated soft pions at 2.5 GeV/c p_T. Therefore the transition from soft to hard processes must also be species dependent, and the boost of the protons causes the region

TABLE VIII. Values of the parameters n_{pp} and x from fitting Eq. (21) to the observed dN/dy per $N_{\rm part}$.

	n_{pp}	x
π^+	1.41±0.11	0.028±0.020
π^-	1.10±0.11	0.085±0.030
K^+	0.130±0.021	0.232±0.076
K^-	0.089±0.020	0.326±0.132
p	0.089±0.013	0.181±0.062
$\bar{p}$	0.062±0.010	0.172±0.068

where hard processes dominate the inclusive charged particle spectrum to be at significantly higher transverse momenta in central Au+Au than in $p+p$ collisions. Our analysis suggests this occurs not lower than $p_T=3$ GeV/c.

D. Hadron yields as a function of centrality

The preceding discussion focused on the hadron spectra; now we turn to the centrality dependence of the pion, kaon, proton, and antiproton yields, which can shed further light on the importance of different mechanisms in particle production. It is instructive to see whether yields of the different hadrons scale with the number of participant nucleons, $N_{\rm part}$, the number of binary nucleon-nucleon collisions, $N_{\rm coll}$, or some combination of the two.

The total yields of the hadrons may be expected to be dominated by soft processes, and the wounded nucleon model of soft interactions suggests that the yields should scale as the number of participants, $N_{\rm part}$. If each participant loses a certain fraction of its incoming energy, as, e.g., in string models, where each pair of participants (or wounded nucleons) contributes a color flux tube, the total energy of the fireball formed at central rapidity would be proportional to the number $N_{\rm part}$ of participants. If, furthermore, the fireball is locally thermalized and particle production is determined at a single temperature, the multiplicity would scale with $N_{\rm part}$. On the other hand, at very high p_T, particle production may be dominated by hard processes and scale with $N_{\rm coll}$ [62,63].

In order to investigate the existence of scaling, the multiplicities are parametrized as

$$\frac{dN}{dy} = C(N_{\rm part})^{\alpha_{\rm part}} \tag{19}$$

and

$$\frac{dN}{dy} = C'(N_{\rm coll})^{\alpha_{\rm coll}}. \tag{20}$$

Fit results for these parametrizations are shown in Table VII. As can be seen, the exponents $\alpha_{\rm part}$ are >1 for all species, while $\alpha_{\rm coll}$ is consistently <1. The production of all particles increases more strongly than with $N_{\rm part}$, but not as strongly as with $N_{\rm coll}$. Small differences between the different particle species are apparent: The (anti)proton yield increases more strongly than the pion yield, and the kaon

yield shows the strongest centrality dependence. Remarkably, the yield fraction scaling beyond linear with N_{part} is larger for kaons, protons, and antiprotons than for pions. Perhaps it is not surprising that the yields do not scale simply with N_{part}; the collective flow seen in the p_T spectra already shows that the nucleon-nucleon collisions cannot be independent.

It should be noted that scaling with multiplicity is not actually a good expectation for kaons. Kaon production at the CERN SPS can be well understood with a statistical hadronization model [64,65], if one takes into account the fact that strangeness must be produced in the collisions in $s\bar{s}$ pairs. Strangeness production is suppressed in pp collisions by phase space limitations for $s\bar{s}$ pair production. This suppression, well described by a canonical ensemble treatment, gradually fades away with increasing reaction volume, and grand canonical descriptions suffice for central Au+Au collisions [66]. Therefore, simple scaling with N_{part} should not be expected for kaons. This does not, of course, explain the rise of baryon and antibaryon production faster than linear with N_{part}.

We next check whether the simple model of hadron yields can be brought into agreement with the data by adding a component of the yields scaling as the number of binary collisions, N_{coll}. Such an admixture inspires simple two-component models [62,63]. The nonlinearity of dN/dy on the number of participants is illustrated by the ratio $(dN/dy)/N_{\mathrm{part}}$, shown in Fig. 25 as a function of centrality. The yields are seen to depend linearly on $N_{\mathrm{coll}}/N_{\mathrm{part}}$. As seen already from the exponents in Table VII, the increase with

centrality is strongest for kaons, intermediate for (anti)protons, and weakest for pions. This indicates that protons and antiprotons have a larger component scaling with N_{coll} than pions.

We fit the yields per participant with Eq. (21). As in Refs. [62,63] we parametrize the multiplicity using two free parameters: n_{pp}, the multiplicity in $p+p$ collisions, and x, the relative strength of the component scaling with N_{coll}.

$$R \equiv \frac{dN/dy}{N_{\mathrm{part}}} = (1-x)n_{pp}\frac{1}{2} + xn_{pp}\frac{N_{\mathrm{coll}}}{N_{\mathrm{part}}} = n_{pp}\left[\frac{1}{2} + x\left(\frac{N_{\mathrm{coll}}}{N_{\mathrm{part}}} - \frac{1}{2}\right)\right]. \quad (21)$$

The results of the fit are shown as solid lines in Fig. 25. The fit parameter values are given in Table VIII. All hadron spe-

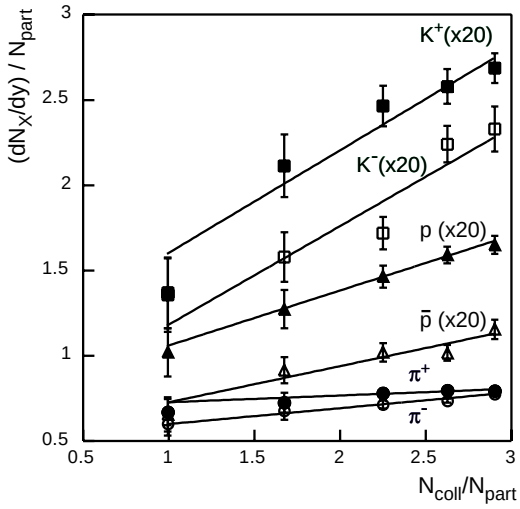

FIG. 25. dN/dy per participant of different particle species as a function of the number of collisions per participant. Kaon and (anti)proton multiplicities are scaled by a factor of 20.

cies are well fit. The importance of the component scaling as N_{coll} is the largest for kaons and smallest for pions.

We check the consistency of the fits in Fig. 25 with known hadron yields in $p+p$ collisions by extrapolating the fits down to two participants (and one binary nucleon-nucleon collision). Isospin differences between $p+p$ and Au+Au are ignored. The check is done by separately extrapolating the fitted fraction of yield which scales with N_{coll} and the fraction scaling with N_{part} down to one nucleon-nucleon collision and two participant nucleons, and summing the result. One obtains particle ratios of $K/\pi=(8.7\pm2.6)\%$ and $\overline{p}/\pi=(4.9\pm0.8)\%$. These values fall between those measured at lower $\sqrt{s}$ at the ISR [67] and those at higher $\sqrt{s}$ at the Tevatron [68], as expected since the RHIC energy lies in-between. Thus the Au+Au data are shown to scale down to $p+p$ reasonably.

One may expect that the particle ratios at very high p_T should be dominated by hard scattering, and therefore scale

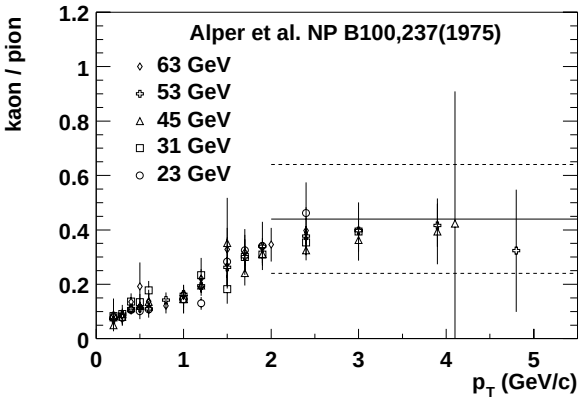

FIG. 26. Kaon to pion ratio as a function of p_T. The different points are measured in $p+p$ collisions (data from Ref. [69]). The solid line is the asymptotic value for high p_T in $p+p$ derived from the hard scattering component of the fits using Eq. (21) to the measured centrality dependence of dN/dy in Au-Au collisions at $\sqrt{s_{NN}}=130$ GeV. The dashed lines indicate the corresponding uncertainty.

with the number of binary collisions. Consequently, we look at ratios of the N_{coll} scaling components alone, extrapolated down to one binary collision. The values are compared to measurements of hadron ratios at the ISR [69] in Figs. 26 and 27. The ratios of the extrapolated Au+Au yield fractions scaling as N_{coll} are shown as solid lines for $p_T\geqslant2$ GeV/c. The agreement with the $p+p$ data at high p_T is quite good.

Finally, we directly compare p/π and $\overline{p}/\pi$ ratios in central Au+Au collisions with $p+p$, as a function of p_T. These ratios from the 10% most central data, using the charged particle measurement from this paper and neutral pions from Ref. [39], are shown in Fig. 28. The ratios show a steady increase up to 2.5 GeV/c in p_T. Even though the simple extrapolation of the N_{coll} scaling yield fraction agreed with $p+p$, the ratios of the full yield significantly exceed those in the ISR measurements [69]. According to Gyulassy and co-

workers [70] this result may give insight into baryon number transport and the interplay between soft and hard processes.

Of course, splitting the observed yields into portions that scale with $N_{\rm part}$ and $N_{\rm coll}$ is by no means a unique explanation of the data. The spectra and yields can also be well reproduced by thermal models, which break such simple scalings due to the multiple interactions suffered by the constituents.

Simple thermal models that ignore transverse and longitudinal flow [71] are able to describe the centrality dependence of the midrapidity $\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$ yields by tuning the chemical freeze-out temperature $T_{\rm ch}$, the baryon chemical potential μ_B and by introducing a strangeness saturation factor γ_s. It was found that μ_B is independent of centrality, while both $\gamma_{\rm s}$ and $T_{\rm ch}$ increase from peripheral to central collisions. Within the same model, the centrality dependence of the particle yields at lower energy ($\sqrt{s_{NN}}=17$ GeV [72,73]) are described by constant $T_{\rm ch}$ and μ_B. The strong centrality dependence in kaon production at both energies is accounted for by the increase in the strangeness saturation factor γ_s. Although the integrated particle yields are very well described, such simple thermal models do not attempt a comparison to the single-particle spectra, which clearly indicate centrality dependent flow effects not included in the model.

Thermal models that include hydrodynamical parameters on a freeze-out hypersurface to account for longitudinal and transverse flow can reproduce the absolutely normalized particle spectra by introducing only two thermal parameters $T_{\rm ch}$ and μ_B [74,75]. In this approach, the thermal parameters are independent of centrality, while the geometric parameters are adjusted to reproduce the spectra. Good agreement with the data is obtained up to $p_T \approx 2-3$ GeV/c, however, an explicit comparison with the centrality dependence of the integrated midrapidity yields has not yet been made.

This section shows that the yields of all hadrons increase more rapidly than linearly with the number of participants, but the increase is weaker than scaling with the number of binary collisions. The excess beyond linear scaling with $N_{\rm part}$ is the strongest for kaons, intermediate for (anti)protons, and weakest for pions. The centrality dependence of the total yields can be well fit with a sum of these two kinds of scaling. At high p_T, the baryon and antibaryon yields greatly exceed expectations from $p+p$ collisions. Thermal models, which do not invoke strict scaling rules, can successfully reproduce the data as well, providing that they include the radial flow required by the p_T spectra.

VI. SUMMARY AND CONCLUSION

We have presented the spectra and yields of identified hadrons produced in $\sqrt{s_{NN}}=130$ GeV Au+Au collisions. The yields of pions increase approximately linearly with the number of participant nucleons, while the yield increase is faster than linear for kaons, protons, and antiprotons.

Hydrodynamic analyses of the particle spectra are performed: the spectra are fit with a hydrodynamic-inspired parametrization to extract freeze-out temperature and radial flow velocity of the particle source. The data are also compared to two full hydrodynamics calculations. The simultaneous fits of pion, kaon, proton, and antiproton spectra show that radial flow in central collisions at RHIC exceeds that at lower energies and increases with centrality of the collision. The hydrodynamic models are consistent with the measured spectral shapes, extracted freeze-out temperature $T_{\rm fo}$, and the flow velocity β_T in central collisions.

Extrapolating the fits to estimate thermal particle production at higher p_T allows us to study the soft-hard physics boundary by comparing to measured spectra at high p_T. The yield of the soft protons reaches, and even exceeds, that of the extrapolated soft pions at 2 GeV/c p_T. The sum of the extrapolated soft spectra agrees with the measured inclusive data to $p_T \approx 2.5-3$ GeV/c. The transition from soft to hard processes must be species dependent, and the admixture of boosted nucleons implies that hard processes do not dominate the inclusive charged particle spectra until ≈ 3 GeV/c.

APPENDIX A: DETERMINING N_{part} AND N_{coll}

As only the fraction of the total cross section is measured in both ZDC and BBC detectors, a model-dependent calculation is used to map collision centrality to the number of participant nucleons, N_{part}, and the number of binary nucleon-nucleon collisions, N_{coll}. A discussion of this calculation at RHIC can be found elsewhere [62].

Using a Glauber model combined with a simulation of the BBC and ZDC responses, N_{part} and N_{coll} are determined in each centrality. The model provides the thickness of nuclear matter in the direct path of each oncoming nucleon, and uses the inelastic nucleon-nucleon cross section $\sigma_{N+N}^{\mathrm{inel}}$ to determine whether or not a nucleon-nucleon collision occurs. We assume the following.

(1) The nucleons travel in straight-line paths, parallel to the velocity of its respective nucleus.

(2) An inelastic collision occurs if the relative distance between two nucleons is less than $\sqrt{\sigma_{N+N}^{\mathrm{inel}}/\pi}$.

(3) Fluctuations are introduced by using the simulated detector response for both ZDC and BBC.

In this calculation, the Woods-Saxon nuclear density distribution $[\rho(r)]$ is used for each nucleus with two parameters, the nuclear radius $R=6.38^{+0.27}_{-0.13}$ fm and diffusivity $d=0.53\pm0.01$ fm [16]. The central density ρ_0 is determined by normalization to the correct number of nucleons. The inelastic nucleon-nucleon cross section is $\sigma_{N+N}^{\mathrm{inel}}=40\pm3$ mb,

$$\rho(r)=\frac{\rho_0}{1+e^{(r-r_n)/d}}. \tag{A1}$$

APPENDIX B: INVARIANT YIELDS

Tabulated here are the measured invariant yields of pions, kaons, and (anti)protons produced in Au+Au collisions at 130 GeV. Tables IX–XII show the invariant yields plotted in Figs. 9 and 10. Tables XIII–XVI show the invariant yields in equal p_T bins as used in Fig. 11.

APPENDIX C: FREEZE-OUT SURFACE ASSUMPTIONS

The freeze-out surface is $\sigma(r,\phi,\eta)$, where the radius r is between zero and R, the radius at freeze-out, the azimuthal

angle ϕ is between zero and 2π, and the longitudinal space-time rapidity variable η varies between $-\eta_{\max}$ and $\eta_{\max}$. In the Bjorken scenario, the freeze-out surface in space-time is hyperbolic, with contours of constant proper time $\tau = \sqrt{t^2 - z^2}$. Assuming instantaneous freeze-out in the radial direction and longitudinal boost invariance, the model dependence factors out of Eq. (17) and is included in the normalization constant A.

At 130 GeV, the PHOBOS experiment measures the total charged particle pseudorapidity distribution to be flat over 2 units of pseudorapidity [43]. The measured rapidity in PHOBOS is taken to be the same as the rapidity of the fireball, defined here as z. The rapidity variables in the integrand vanish for $|z| > 2$. Therefore, the integration over the fireball rapidity is generally taken to be from $-\infty$ to $+\infty$ using the modified K_1 Bessel function

$$K_1(m_T/T) = \int_0^\infty \cosh(z) e^{-m_T \cosh(z)/T} dz, \qquad \text{(C1)}$$

where the variable z is the fireball rapidity variable. The K_1 bessel function can also result by integration over the measured rapidity y with the assumption that the freeze-out is instantaneous in the radial direction. In this case, no assumption is made on the shape of the freeze-out hypersurface. This also assumes that the total rapidity distribution is measured in the detector. What results is the single differential $1/m_T\, dN/dm_T$ [76].

(Received 8 July 2003; published 5 February 2004)

J/ψ production has been measured in proton-proton collisions at $\sqrt{s} = 200$ GeV over a wide rapidity and transverse momentum range by the PHENIX experiment at the Relativistic Heavy Ion Collider. Distributions of the rapidity and transverse momentum, along with measurements of the mean transverse momentum and total production cross section are presented and compared to available theoretical calculations. The total J/ψ cross section is $4.0 \pm 0.6(\text{stat}) \pm 0.6(\text{syst}) \pm 0.4(\text{abs})$ μb. The mean transverse momentum is $1.80 \pm 0.23(\text{stat}) \pm 0.16(\text{syst})$ GeV/c.

DOI: 10.1103/PhysRevLett.92.051802 PACS numbers: 13.85.Ni, 13.20.Fc, 14.40.Gx, 25.75.Dw

Understanding J/ψ production mechanisms requires data over a large range of collision energies and with broad coverage in rapidity and transverse momentum (p_T). Existing data at lower energies from fixed target hadron experiments yield total cross sections and mean p_T ($\langle p_T \rangle$) values in the energy range $\sqrt{s} = 7$–38.8 GeV [1]. Limited kinematic coverage in collider experiments [1–3] has so far meant that total cross sections and mean

p_T values could not be measured. The systematic study of J/ψ production at Relativistic Heavy Ion Collider (RHIC) energies with wide p_T and rapidity coverage should therefore provide crucial tests of J/ψ production models. In addition, the RHIC proton-proton results provide a baseline for studying cold and hot nuclear matter in proton-nucleus and nucleus-nucleus collisions using J/ψ yields as a probe.

Intense theoretical interest in the J/ψ production mechanism was stimulated when the color singlet model (CSM) was found [4] to dramatically underpredict the high p_T prompt J/ψ and $\psi(2S)$ cross sections measured with the collider detector at Fermilab (CDF) [3]. Attention turned toward models in which color octet $c\bar{c}$ states can also contribute to the J/ψ yield. The color octet model (COM), which is based on the nonrelativistic QCD (NRQCD) approach [5], has been successful in reproducing the high p_T CDF prompt J/ψ cross sections, as has the more phenomenological color evaporation model (CEM) [6].

In this Letter we report results of the first measurements of $pp \to J/\psi + X$ at RHIC, made at $\sqrt{s} = 200$ GeV by the PHENIX experiment. The data yield the first total cross sections for J/ψ production beyond fixed target energies, and the first measurement of $\langle p_T \rangle$ beyond $\sqrt{s} =$ 63 GeV. They will constrain models in the lower p_T region where gluon fusion is expected to dominate. At p_T beyond about 5 GeV/c, the direct J/ψ production cross section is expected to be dominated by fragmentation of high p_T gluons [7].

The PHENIX experiment [8] detects electrons in the pseudorapidity range $|\eta| \leq 0.35$ in two central spectrometer arms covering $\Delta\phi = 90°$, and forward rapidity muons in two muon arms covering $\Delta\phi = 360°$. Only one muon arm, covering $1.2 < \eta < 2.2$, was operational for this data set. Electrons are identified by matching charged particle tracks to energy deposits in the electromagnetic calorimeter (EMC) and to rings in the ring imaging Čerenkov detector (RICH), which has a threshold of 4.7 GeV/c for pions. Muons are identified by finding deeply penetrating roads in the muon identifier (MuID) and matching them to tracks in the muon tracker (MuTr).

The data were recorded during the $\sqrt{s} = 200$ GeV pp run covering the end of 2001 and the beginning of 2002. After quality assurance and vertex cuts (± 35 cm for ee and ± 38 cm for $\mu\mu$), 67 nb^{-1} were used for the $J/\psi \to \mu^+\mu^-$ analysis, and 82 nb^{-1} for $J/\psi \to e^+e^-$. The minimum bias interaction trigger required at least one hit on each side of the interaction vertex in the beam-beam counter (BBC), which covers $3.1 < |\eta| < 3.9$. Minimum bias trigger rates varied from 5 to 30 kHz. Events containing J/ψ decays were selected using level-1 triggers in coincidence with the minimum bias interaction trigger. The $J/\psi \to e^+e^-$ trigger required a minimum energy deposit of either 0.75 GeV in a 2×2 tile of EMC towers or 2.1 GeV in a 4×4 tile. The $J/\psi \to \mu^+\mu^-$ trigger required at least two deeply penetrating roads in separate azimuthal quadrants of the MuID [9].

J/ψ yields in the central arms were obtained by reconstructing electron-positron pairs. Electron candidates were charged particle tracks that were associated with a RICH ring (≥ 2 hit phototubes) and an EMC hit ($\pm 4\sigma$ position association cut), and which satisfied $0.5 < E/p < 1.5$, where E is the EMC cluster energy and p is the reconstructed track momentum. A 5 GeV/c upper limit on electron momentum prevented charged pions from firing the RICH.

J/ψ yields in the muon arm were obtained by reconstructing $\mu^+\mu^-$ pairs. Muon tracks were reconstructed by finding a track seed in the MuID and matching it to clusters of hits in each of the three MuTr stations. The momentum was determined by fitting, with a correction for energy loss, the MuID and MuTr hit positions and the BBC vertex position. Each track was required to pass 5σ cuts on the χ^2 from the track fit and on the radial distance of the fitted track from the measured z-vertex position.

Unlike-sign pairs and, for background estimation, like-sign pairs satisfying the above conditions were combined to form invariant mass spectra. Simulations show that the acceptance for like-sign and unlike-sign pairs is the same to within a few percent for invariant masses above 1 GeV/c^2 for electrons. In Fig. 1, unlike-sign and like-sign invariant mass spectra from the entire pp data set are shown together. For electrons, the net yield inside 2.8–3.4 GeV/c^2 is 46 ± 7.4, and for muons inside 2.71–3.67 GeV/c^2 it is 65 ± 9.5. For electrons, the peak width is 110 MeV/c^2 and the centroid agrees well with the Particle Data Group (PDG) value [10]. For muons, the width is 160 MeV/c^2. The muon peak centroid is higher than the PDG value by about 3%, consistent with the uncertainty in the muon magnetic field calibration. In both cases the width of the mass window was chosen to be 6 times the standard deviation expected from simulations.

The J/ψ cross sections were determined from the measured yields using

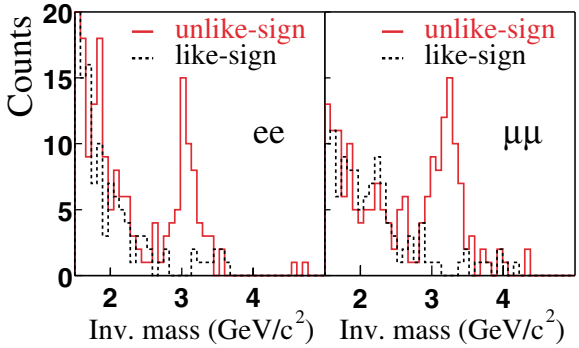

FIG. 1 (color online). The invariant mass spectra for dielectron and dimuon pairs. Unlike-sign pairs are shown as solid lines, and the sum of like-sign pairs as dashed lines.

$$B_{ll}\frac{d^2\sigma_{J/\psi}}{dydp_T} = \frac{N_{J/\psi}}{(\int \mathcal{L}dt)\Delta y \Delta p_T}\frac{1}{\epsilon_{\rm bias}\epsilon_{lvl1}}\frac{1}{A\epsilon_{\rm rec}},$$

where $N_{J/\psi}$ is the measured J/ψ yield, $\int \mathcal{L}dt$ is the integrated luminosity measured by the minimum bias trigger, B_{ll} is the branching fraction for the J/ψ to either e^+e^- or $\mu^+\mu^-$ pairs (PDG average value 5.9% [10]), $\epsilon_{\rm bias}$ is the minimum bias trigger efficiency for an event containing a J/ψ, ϵ_{lvl1} is the level-1 trigger efficiency for detecting a J/ψ, and $A\epsilon_{\rm rec}$ is the acceptance times reconstruction efficiency for a J/ψ.

The integrated luminosity can be written as $\int \mathcal{L}dt = N_{\rm MB}/\sigma_{\rm BBC}$, where $N_{\rm MB}$ is the number of minimum bias triggers and $\sigma_{\rm BBC}$ is the minimum bias trigger cross section. Using a van der Meer scan measurement, $\sigma_{\rm BBC}$ was determined to be 21.8 ± 2.1 mb [11]. We have estimated $\epsilon_{\rm bias}$ in two ways. First, the minimum bias trigger efficiency for J/ψ events from a simulation study using PYTHIA [12] [with the GRV94NLO parton distribution functions (PDFs)] was 0.74, with no p_T dependence. Good agreement is observed in the $dN_{ch}/d\eta$ distribution between PYTHIA simulations and measurements [13] for events involving high p_T π^0 production. Second, we measured [11] our minimum bias trigger efficiency for high p_T π^0 production using events recorded with a high p_T EMC trigger. The efficiency of $0.75 \pm 3\%$ is constant within uncertainties over the measured range of $1.5 < p_T < 9$ GeV/c. We chose to use our measured trigger efficiency from high p_T π^0 events when calculating the J/ψ cross section, assuming that the trigger efficiency is the same for both processes.

For the electron analysis, $A\epsilon_{\rm rec}$ was determined as a function of p_T using a full GEANT simulation of single J/ψ events with flat distributions in dN/dy ($|y| < 0.6$), p_T ($p_T < 6$ GeV/c), and collision vertex ($|z| < 35$ cm). The GEANT simulations were tuned to match real detector responses for single electrons. The reconstruction efficiency calculations used a typical dead channel map. An average correction for run-to-run variations in detector active area was determined from single electron yields. An estimate of the systematic uncertainty in $A\epsilon_{\rm rec}$ due to z vertex dependence of the acceptance, momentum resolution effects, the pair mass cut, and electron identification cuts is given in Table I, along with the uncertainty in the yield due to Drell-Yan and correlated charm decay contributions. The efficiency ϵ_{lvl1} of the level-1 J/ψ triggers in the central arms was determined as a function of p_T by using a software trigger-emulator to analyze simulated single J/ψ events. The results are shown in Table I. The trigger emulator was tuned by analyzing simulated single electrons and comparing with the real single electron trigger efficiency.

TABLE I. Table of quantities and their systematic error estimates (in parentheses). Ranges are given for p_T dependent quantities. For the $\mu^+\mu^-$ case the values of $A\epsilon_{\rm rec}$ and ϵ_{lvl1} are combined. The absolute cross section normalization uncertainty from $\epsilon_{\rm bias}$ and $\int \mathcal{L}dt$ is kept separate and is labeled (abs).

Quantity	e^+e^-	$\mu^+\mu^-$
Yield	($\pm$ 5%)	($\pm$5%)
$A\epsilon_{\rm rec}$	0.026–0.010($\pm$13%)	0.038–0.017($\pm$13%)
ϵ_{lvl1}	(2 × 2) 0.87–0.90($\pm$5%)	
	(4 × 4) 0.30–0.74($\pm$36%)	
$\epsilon_{\rm bias}$	0.75($\pm$3%)	0.75($\pm$3%)
$\int \mathcal{L}dt$	82 nb^{-1} ($\pm$9.6%)	67 nb^{-1} ($\pm$9.6%)
Total	$\pm$15%(syst) $\pm$ 10%(abs)	$\pm$14%(syst) $\pm$ 10%(abs)

For the muon arm, $A\epsilon_{\rm rec}\,\epsilon_{lvl1}$ was determined as an average within each rapidity and p_T bin, using a full GEANT simulation with J/ψ events generated by PYTHIA (with GRV94LO PDFs). The PYTHIA J/ψ rapidity and p_T distributions are very similar to those of the real data, so that bin averaging effects should be approximately accounted for by this procedure. The simulated events were reconstructed using the same reconstruction software and cuts as for the real data, assuming nominal detector efficiencies and typical realistic dead channel and dead high-voltage maps. Each event had to pass the simulated dimuon trigger. The systematic error includes discrepancies between Monte Carlo and real detector response, run to run variations in the detector state, and uncertainties in the PYTHIA distributions. The results, integrated over the rapidity range of the muon arm, are shown in Table I, along with an estimate of the systematic error on the yield due to the background subtraction technique. In both the electron and muon cases the J/ψ polarization was assumed to be zero, since existing J/ψ polarization measurements are consistent with zero at low p_T [14]. The effect of the unknown J/ψ polarization has not been included in the systematic error.

The p_T distributions for $J/\psi \to e^+e^-$ and $J/\psi \to \mu^+\mu^-$ are shown in Fig. 2, with predictions [15] from the COM. Predictions of the CSM, which greatly underpredicts the cross sections, are also shown. These

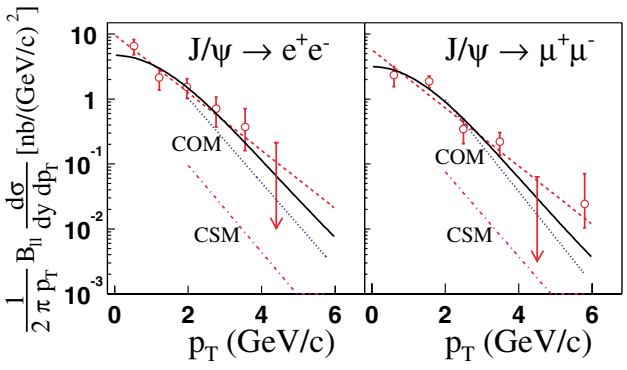

FIG. 2 (color online). The J/ψ p_T distributions for the dielectron and dimuon measurements, with statistical uncertainties. The solid line is a phenomenological fit of the form $(1/2\pi p_T)d\sigma/dp_T = A[1 + (p_T/B)^2]^{-6}$. The dashed line is an exponential fit. The CSM (dot-dashed) and COM (dotted) calculations are from [15].

predictions are limited to $p_T > 2$ GeV/c because parton intrinsic transverse momentum (k_T) broadening is not accounted for properly in the calculation. The COM calculations do not include fragmentation contributions, which become important at around 5 GeV/c [3]. Another calculation for the PHENIX muon arm using NRQCD is available in Ref. [16]. Calculations covering all p_T and including fragmentation contributions are needed. The solid lines are a phenomenological fit of a form that has been shown to fit J/ψ data well at fixed target energies [17]. The dashed line is an exponential fit. The phenomenological fits yield $\langle p_T \rangle$ values of $1.85 \pm 0.46(\text{stat}) \pm 0.16(\text{syst})$ GeV/c (central arm) and $1.78 \pm 0.27(\text{stat}) \pm 0.16(\text{syst})$ GeV/c (muon arm), with a combined value of $1.80 \pm 0.23(\text{stat}) \pm 0.16(\text{syst})$ GeV/c. The systematic uncertainties were estimated from the spread in $\langle p_T \rangle$ from a weighted mean of the binned data, the phenomenological fit, and the exponential fit. An additional 3% was assigned to the muon $\langle p_T \rangle$ due to the uncertainty in momentum scale.

The J/ψ rapidity distribution obtained by combining the dielectron and dimuon measurements is shown in Fig. 3, with the muon arm data divided into two rapidity bins. The COM curves are theoretical shape predictions [9] using the same models as are discussed in connection with Fig. 4(b), except that they are normalized to our data to make the shape comparison clearer. Since gluon fusion is the dominant process in all of the models, the rapidity shape depends mostly on the gluon distribution function and is not very sensitive to the production model. Most of the available PDFs are consistent with the data, and improved statistical precision will be needed to constrain them. A PYTHIA calculation that reproduces the shape of our data best is also shown in Fig. 3. Normalizing this to the data, the total cross section was determined to be $4.0 \pm 0.6(\text{stat}) \pm 0.6(\text{syst}) \pm 0.4(\text{abs})$ μb. The quoted systematic error was estimated by setting the measured cross sections all to their upper systematic error limits or all to their lower systematic error limits and noting how the cross section changed. The variation in the total cross section extracted if we use the same procedure with different PDF choices and models was estimated to be small (3%). We note that the minimum bias trigger efficiency for a single or double diffractive event producing a J/ψ will be different from the one we have assumed. However, the measured diffractive component of the J/ψ cross section at $\sqrt{s} = 1.8$ TeV and $p_T > 2$ GeV/c for both muons is only 1.45% [18], with little or no p_T dependence, suggesting that the diffractive component should be negligible in our case.

A comparison is made in Fig. 4(a) of the present $\langle p_T \rangle$ value with values from previous experiments [1]. There are no theoretical predictions that we can compare with the $\langle p_T \rangle$ measurements. The total J/ψ cross section determined in this analysis is shown in Fig. 4(b), along with cross sections determined by lower energy experiments [1] and predictions from the COM [9] using two different PDFs. The $\sqrt{s}$ dependence of the cross section is sensitive to the factorization scale Q, since the shape of the PDFs depends on Q. The values of Q (3.1 GeV for GRV98NLO and 2.3 GeV for MRST2001NLO) were chosen to give good agreement with the data. The total cross section normalization was obtained using color octet matrix elements from [19], but has large theoretical uncertainties associated with the charm quark mass and the renormalization scale. The renormalization scale was taken to be equal to the quark mass M_c, and their values (1.48 GeV for GRV98NLO and 1.55 GeV for MRST2001NLO) were chosen to give good agreement with the data. The CEM is also able to describe the total cross section data [6]. All measurements and models include feed-down from the χ_c and the ψ' to the J/ψ. We estimate [20] that B decay feed-down contributes less than 4% to the J/ψ total cross section at $\sqrt{s} = 200$ GeV.

In summary, we have presented the first $pp \to J/\psi + X$ measurements from RHIC, obtained at $\sqrt{s} = 200$ GeV. The rapidity distributions, p_T distributions,

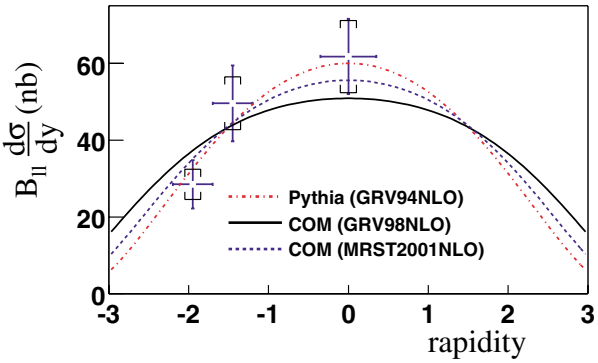

FIG. 3 (color online). The central rapidity point is from $J/\psi \to e^+e^-$, the others from $J/\psi \to \mu^+\mu^-$. The brackets represent systematic uncertainties. All curves have their overall normalization fitted to the data. The PYTHIA shape was used to determine the cross section. There is an overall 10% absolute normalization error not shown.

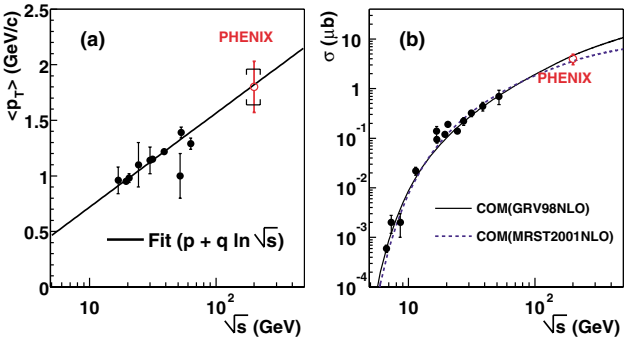

FIG. 4 (color online). (a) The present J/ψ mean p_T value compared with previous measurements at lower energy [1]. The linear fit parameters are $p = 0.53$, $q = 0.19$. (b) The present J/ψ total cross section compared with previous measurements at other values of $\sqrt{s}$ [1]. The curves are discussed in the text.

$\langle p_T \rangle$, and total cross sections have been presented and compared with available model calculations. The transverse momentum distributions above 2 GeV/c are reasonably well described by the COM. With the present statistical precision, our rapidity distribution shape is consistent with most of the available PDFs. COM calculations are able to reproduce the $\sqrt{s}$ dependence of the cross section using color octet matrix elements found in the literature, with a reasonable choice of QCD parameters.

RHIC is expected to have proton-proton runs with enhanced luminosity at $\sqrt{s} = 200$ and 500 GeV in the near future. The increased luminosity will improve the statistical precision and p_T reach of the PHENIX data, and will ultimately make it possible to measure the J/ψ polarization, which has been an important test for models [14].

(Received 18 June 2003; published 15 August 2003)

Transverse momentum spectra of charged hadrons with $p_T < 8$ GeV/c and neutral pions with $p_T < 10$ GeV/c have been measured at midrapidity by the PHENIX experiment at BNL RHIC in $d + \mathrm{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV. The measured yields are compared to those in $p + p$ collisions at the same $\sqrt{s_{NN}}$ scaled up by the number of underlying nucleon-nucleon collisions in $d + \mathrm{Au}$. The yield ratio does not show the suppression observed in central Au + Au collisions at RHIC. Instead, there is a small enhancement in the yield of high momentum particles.

DOI: 10.1103/PhysRevLett.91.072303 PACS numbers: 25.75.Dw

High transverse momentum ($p_T > 2$ GeV/c) hadrons provide an excellent probe of the high energy density matter created in relativistic heavy ion collisions [1,2]. They arise from fragmentation of quarks and gluons (partons) scattered with large momentum transfer, Q^2, in the initial parton-parton interactions [3]. In the

absence of medium effects, these hard scattering yields in nucleus-nucleus collisions should scale with the average number of inelastic nucleon-nucleon collisions $N_{\rm coll}$ (binary scaling). One of the most intriguing observations from experiments at the BNL Relativistic Heavy Ion Collider (RHIC) is the large suppression of high p_T neutral pion and charged hadron yields in central Au + Au collisions with respect to $p + p$ results scaled by the number of binary nucleon-nucleon collisions [4–7].

Theoretical studies of parton propagation in high density matter suggest that partons lose a significant fraction of their energy through gluon bremsstrahlung [1,2], reducing the parton momentum and depleting the yield of high p_T hadrons [8–13]. This is a final-state effect in the spatially extended medium created in $A + A$ collisions. Initial-state effects include nuclear modifications to the parton momentum distributions (structure functions), and soft scatterings of the incoming parton prior to its hard scattering. These should be present in $p + A$, $d + A$, and $A + A$. Interpretations of Au + Au collisions based on initial-state parton saturation effects [14] or final-state hadronic interactions [15] also predict a considerable suppression of the hadron production at high p_T. It is therefore of paramount interest to determine experimentally the modification, if any, of high p_T hadron yields due to initial-state nuclear effects for a system in which a hot, dense medium is not produced in the final state. This Letter reports on charged hadron and π^0 production at midrapidity obtained by the PHENIX [16] experiment at RHIC in d + Au collisions at $\sqrt{s_{NN}} =$ 200 GeV. The results are compared to those in $p + p$ and Au + Au [7,17,18] at the same nucleon-nucleon center-of-mass energy. Similar d + Au measurements are also reported in [19,20].

The data were collected under two different trigger conditions. Minimum bias events with vertex position along the beam axis within $|z| < 30$ cm were triggered by the beam-beam counters (BBC) [16] which cover $|\eta| = 3.0$–3.9. The minimum bias trigger accepts $(88\% \pm 4\%)$ of all inelastic d + Au collisions that satisfy the vertex condition. A total of 1.2×10^7 and 1.7×10^7 events were analyzed for charged hadron and π^0 spectra, respectively. A second "photon triggered" sample, requiring showers above 2.5 GeV for lead-scintillator (PbSc) and 3.5 GeV for lead-glass (PbGl) electromagnetic calorimeters (EMCal) [16] in addition to the BBC requirement, is used to extend the π^0 measurements to higher p_T. This trigger sampled a total of 1.7×10^9 events.

Neutral pions were measured by the PHENIX EMCal via the $\pi^0 \to \gamma\gamma$ decay. The EMCal covers $|\eta| \leq 0.35$ in pseudorapidity and $\Delta\phi = \pi$ in azimuth. It consists of six PbSc and two PbGl sectors, each covering $\pi/8$ in azimuth. The data from PbSc and PbGl were analyzed separately. The energy calibration is obtained from beam tests, cosmic rays, minimum ionizing energy peaks of charged hadrons, and the energy/momentum ratio of electrons identified with the Ring Imaging Čerenkov Detector. The combined uncertainty on the energy scale and linearity is $\leq 1.5\%$, determined from the response to identified electrons, and confirmed by the positions and widths of the observed π^0 mass peaks.

Photonlike energy clusters in the calorimeter are selected via shower profile cuts. The invariant mass for all photon pairs with energy asymmetry $|E_1 - E_2|/(E_1 + E_2) < 0.7$ is calculated and binned in p_T. The π^0 yield in each p_T bin is determined by integrating the background subtracted two-photon invariant mass distribution [7]; the background is determined from mixed events. The peak-to-background ratio increases from ~ 0.3 at $p_T = 1.25$ GeV/c to more than 5 above 4.25 GeV/c. The raw π^0 spectra are corrected by Monte Carlo simulations for trigger efficiency and acceptance, and for π^0 reconstruction efficiency including dead areas, effects of energy resolution, photon identification cuts, and peak extraction window. Finally, the yields are corrected to the center of the p_T bin using the observed slope of the spectrum. Below $p_T =$ 5 GeV/c the yields are determined from the minimum bias data sample while above 5 GeV/c the photon triggered sample is used. The main sources of systematic errors are listed in Table I. The final systematic errors on the spectra are 10% to 16%, increasing with p_T.

Charged particles are reconstructed using a drift chamber (DC) followed by two layers of multiwire proportional chambers with pad readout (PC1, PC3) [16]. In this analysis tracks were reconstructed over a restricted pseudorapidity range $|\eta| < 0.18$. Pattern recognition in the DC is based on a combinatorial Hough transform in the track bend plane, while the polar angle is determined by PC1 and the location of the collision vertex along the beam direction [21]. The vertex was constrained to be within $|z| < 18$ cm for analysis of the charged tracks. The track reconstruction efficiency is approximately 98%, independent of p_T. Particle momenta are measured with

TABLE I. Systematic errors in percent on π^0 invariant yields for PbSc (PbGl), as a function of p_T (in GeV/c). There are three categories of uncertainty: Type A is a point-to-point error uncorrelated between p_T bins, type B is p_T correlated, where all points move in the same direction but not by the same factor, while in type C all points move by the same factor independent of p_T.

	Type	$p_T = 2$	$p_T = 6$	$p_T = 10$
Peak extraction	A	5.0(5.0)	5.0(5.0)	5.0(5.0)

Energy scale	B	4.0(4.0)	9.0(9.0)	11.0(11.0)
Trigger eff.	B	···	5.0(10.0)	3.0(3.0)
Trigger norm.	C	···	5.0(5.0)	5.0(5.0)
Conversion corr.	C	2.8(2.8)	2.8(2.8)	2.8(2.8)
Total error		8.6(8.6)	14(16)	15(15)

a resolution $\delta p/p = 0.7\% \oplus 1.1\% p$ (GeV/c). The momentum scale is known to 0.7%, from the reconstructed proton mass using the time of flight. A confirmation hit is required in PC3, located at a radius of 5 m, within a 2.5σ matching window to eliminate most albedo, conversions, and decays. The remaining background above $p_T = 5$ GeV/c is subtracted statistically using identified conversions and weak decays (primarily kaons) [18].

Corrections to the charged particle spectrum for geometrical acceptance, decays in flight, reconstruction efficiency, and momentum resolution are determined using a single-particle GEANT Monte Carlo simulation. All analysis steps, including the outer detector matching cuts are applied consistently in simulation and data. As the DC and PC occupancies in d + Au are low, no multiplicity-dependent occupancy corrections are required. The yield was corrected to the center of the p_T bin. Table II lists the source and magnitude of each contribution to the systematic uncertainties on the charged particle spectra.

The fully corrected p_T distributions of π^0's and $(h^+ + h^-)/2$ are shown in Fig. 1. Each panel shows the reference spectrum from $p + p$ collisions along with the particle spectrum from d + Au. The reference for π^0 is the π^0 spectrum measured in $p + p$ by PHENIX [17], shown on the right panel. For charged hadrons, the reference is obtained by scaling up the π^0 spectrum by the p_T-dependent h/π ratio observed at the CERN Intersecting Storage Rings [22] at $\sqrt{s} = 23$ to 63 GeV and measured by PHENIX. The value of h/π is constant at 1.6 ± 0.16 above 1.5 GeV/c, and decreases at lower p_T to a value of $1.25^{+0.12}_{-0.25}$. Table III summarizes uncertainties on the reference spectra.

A standard way to quantify nuclear medium effects on high p_T production is by the *nuclear modification factor,* which we define for d + Au collisions as the ratio of invariant yield in d + Au to that of $p + p$, scaled by the number of binary collisions.

$$R_{dA}(p_T) = \frac{(1/N_{dA}^{\rm evt})\, d^2N_{dA}/d\eta dp_T}{\langle N_{\rm coll}\rangle/\sigma_{pp}^{\rm inel}\, d^2\sigma_{pp}/d\eta dp_T},$$

where $\langle N_{\rm coll}\rangle$ is the average number of inelastic nucleon-nucleon (NN) collisions per event in the minimum bias collisions, and $\langle N_{\rm coll}\rangle/\sigma_{pp}^{\rm inel}$ is the nuclear overlap function $\langle T_{dA}(b)\rangle$. Using a Glauber model [23] and simulation of the BBC, $\langle N_{\rm coll}\rangle$ is 8.5 ± 0.4 in minimum bias d + Au.

TABLE II. Systematic errors in percent on the $(h^+ + h^-)/2$ invariant yields. Error types are as in Table I.

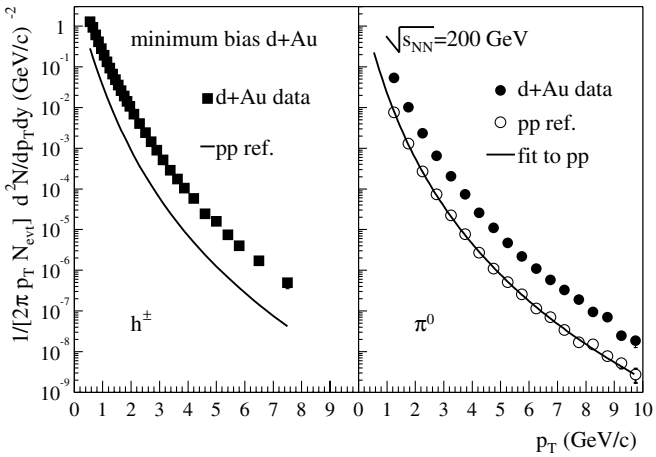

FIG. 1. Midrapidity p_T spectra for charged hadrons and π^0. Total uncertainties are shown. The π^0 below 5 GeV/c are from minimum bias triggered events, and above from photon triggered events. Lines show fits to reference spectra from $p + p$ collisions, and open points show the $p + p$ π^0 spectrum measured by PHENIX [17].

The ratio R_{dA} is plotted separately for π^0 measured in the PbGl and in the PbSc calorimeters in Fig. 2. The two analyses are consistent within errors. The data are compared to the corresponding nuclear modification factor R_{AA} obtained from central Au + Au collisions. The top panel of Fig. 3 shows R_{dA} for inclusive charged particles $(h^+ + h^-)/2$, again compared with R_{AA} observed in central Au + Au collisions, while the lower panel compares $(h^+ + h^-)/2$ with π^0. In both Figs. 2 and 3, the uncertainties are plotted as follows: error bars represent the quadrature sum of statistical errors and those systematic errors which vary point to point in p_T; systematic errors on the absolute yield and the systematic errors which are correlated point to point are shown as bands. All procedures for estimating the various systematic errors have been adjusted to provide estimates corresponding to 1σ error values.

The data clearly indicate that there is no suppression of high p_T particles in d + Au collisions. We do, however, observe an enhancement in inclusive charged particle production at $p_T > 2$ GeV/c. A similar enhancement

TABLE III. Systematic errors on the $p + p$ reference spectrum.

[a]Errors affect only the charged (neutral) analysis, and include h/π_0, and fits to reference (point by point pp) errors.

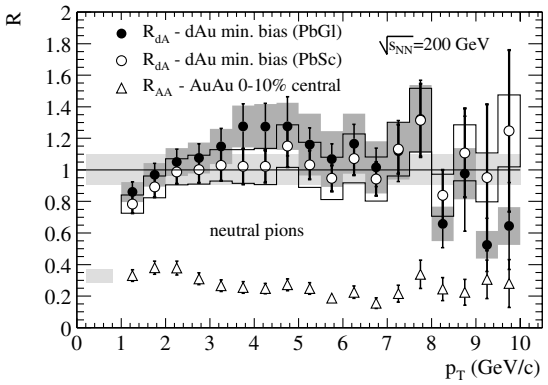

FIG. 2. Nuclear modification factor R_{dA} for π^0 in the PbGl and PbSc calorimeters in minimum bias d + Au. The bands around the data points show systematic errors which can vary with p_T, while the shaded band around unity indicates the normalization uncertainty. The nuclear modification factor R_{AA} in 10% most central Au + Au collisions is also shown.

was observed in $p + A$ fixed-target experiments [24] and is generally referred to as the "Cronin effect." To facilitate comparison of the Cronin effect in inclusive charged particles and π^0, the lower part of Fig. 3 shows all systematic uncertainties common to both analyses in the bar on the left. It should be noted that this uncertainty must be added in quadrature with the bands shown for each curve to obtain the 1σ allowed range of R_{dA} from the data. The π^0 data suggest a smaller enhancement for pions than for inclusive charged particles at $p_T = 2$–4 GeV/c. We note that the charged spectrum includes baryons and antibaryons, which may have a different nuclear enhancement than the mesons [24].

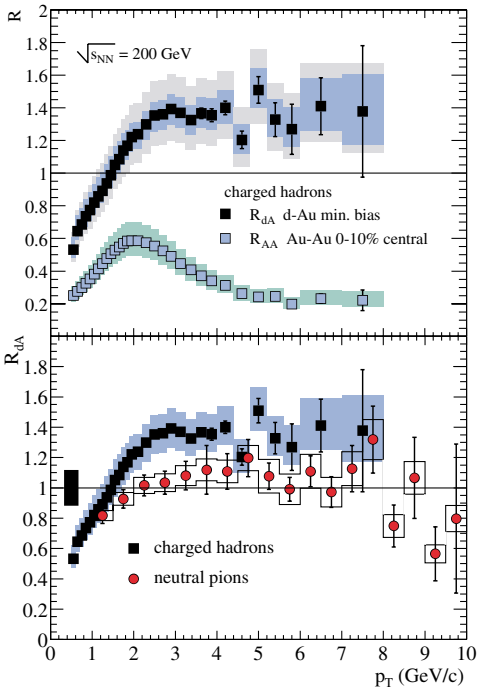

FIG. 3 (color online). Top: Nuclear modification factor R_{dA} for $(h^+ + h^-)/2$ in minimum bias d + Au compared to R_{AA} in the 10% most central Au + Au collisions. Inner bands show systematic errors which can vary with p_T, and outer bands include also the normalization uncertainty. Bottom: Comparison of R_{dA} for $(h^+ + h^-)/2$ and the average of the π^0 measurements in d + Au. The bar at the left indicates the systematic uncertainty in common for the charged and π^0 measurements.

The various models of the suppression observed in Au + Au predict a different dependence on $N_{\rm coll}$ in d + Au [14,25,26]. Therefore, a second data sample was selected by requiring observation of a neutron in the zero-degree calorimeter on the deuteron-going side of PHENIX. This, together with the requirement of particles entering both beam-beam counters, selects a class of events in which only the proton from the deuteron interacts with the Au nucleus. The mean number of binary collisions for this sample is calculated with the Glauber model to be 3.6 ± 0.3. Particle yields in this sample have a $<5\%$ uncertainty beyond that of the minimum bias sample, arising from trigger bias.

Figure 4 shows the ratios of R_{dA} in minimum bias d + Au to R_{pA} in the neutron tagged sample, for both $(h^+ + h^-)/2$ and π^0. Systematic uncertainties on the spectra cancel in the ratio; the band around unity shows the uncertainty on the ratio of the number of binary collisions in the two samples. Average values of $N_{\rm coll}$ are 3.6 per participating proton in the neutron tagged sample and 8.5 for 1.7 participating nucleons from the deuteron in minimum bias d + Au. Given the systematic uncertainties on $N_{\rm coll}$, we cannot exclude a small centrality dependence for $p_T > 1$ GeV/c. It should be noted that the figure also indicates that d + Au collisions provide a good measure of the physics of p + Au.

The observation of an enhancement of high-p_T hadron production in both the minimum bias d + Au and the neutron tagged sample of p + Au collisions indicates that the suppression in central Au + Au collisions is not an initial-state effect. Nor does it arise from modification of parton structure functions in nuclei. The data suggest,

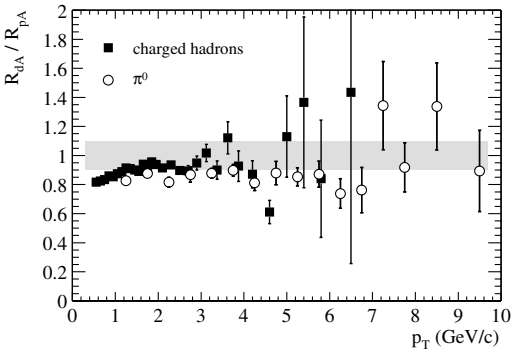

FIG. 4. Ratio of R_{dA} in minimum bias d + Au and R_{pA} from neutron tagged d + Au collisions for $(h^+ + h^-)/2$ and π^0. The band shows the uncertainty on the number of binary collisions; all other systematic errors cancel.

instead, that the suppression of high p_T hadrons in Au + Au is more likely a final-state effect of the produced dense medium.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We acknowledge support from the Department of Energy and NSF (U.S.A.), MEXT and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), IN2P3/CNRS and CEA (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE and DST (India), ISF (Israel), KRF and CHEP (Korea), RMIST, RAS, and RMAE (Russia), VR and KAW (Sweden), U.S. CRDF for the FSU, U.S.-Hungarian NSF-OTKA-MTA, and U.S.-Israel BSF.

(Received 30 May 2003; published 21 October 2003)

We report on the yield of protons and antiprotons, as a function of centrality and transverse momentum, in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV measured at midrapidity by the PHENIX experiment at the BNL Relativistic Heavy Ion Collider. In central collisions at intermediate transverse momenta ($1.5 < p_T < 4.5$ GeV/c) a significant fraction of all produced particles are protons and antiprotons. They show a centrality-scaling behavior different from that of pions. The $\overline{p}/\pi$ and p/π ratios are enhanced compared to peripheral Au + Au, $p + p$, and e^+e^- collisions. This enhancement is limited to $p_T < 5$ GeV/c as deduced from the ratio of charged hadrons to π^0 measured in the range $1.5 < p_T < 9$ GeV/c.

DOI: 10.1103/PhysRevLett.91.172301 PACS numbers: 25.75.Dw

Heavy-ion collisions at the BNL Relativistic Heavy Ion Collider (RHIC) energies permit the study of nuclear matter at extreme energy densities. Hadrons originating from fragmentation of partons that have undergone large momentum transfer (hard) scatterings are sensitive probes of the hottest and densest stage of the collision. Data collected during the first RHIC run at $\sqrt{s_{NN}} = 130$ GeV led to the discovery of suppression of high transverse momentum ($p_T \geq 2$ GeV/c) hadron production in central Au + Au collisions [1–3] when compared to expectations from nucleon-nucleon collisions. This effect, quantified in terms of a nuclear modification factor $R_{\rm AA} = (\text{yield}_{\rm AA}/N_{\rm coll})/\text{yield}_{pp}$, where $N_{\rm coll}$ is the average number of binary nucleon-nucleon collisions, had been discussed as a possible consequence of the energy loss suffered by partons moving in a dense medium [4,5]. Unexpectedly, it was found that $R_{\rm AA}$ is more strongly suppressed for π^0 than for charged hadrons [1], and that the yields of p and $\overline{p}$ near 2 GeV/c in central events [6] are comparable to the yield of pions ($p/\pi \sim 1$). This is in contrast to the p/π ratios of ~0.1–0.3, measured in $p + p$ [7] and e^+e^- [8] collisions, and to perturbative quantum chromodynamics phenomenology [9]. These results suggest that an investigation of particle composition is important for understanding the medium effect on high-p_T phenomena at RHIC. During the 2001 Au + Au run at $\sqrt{s_{NN}} = 200$ GeV the PHENIX experiment collected data to study the scaling properties of p and $\overline{p}$ production as well as the p/π, $\overline{p}/\pi$, and charged hadron to pion (h/π) ratios as a function of centrality.

The PHENIX detector [10] combines high momentum resolution with diverse particle identification (PID), resulting in hadron identification over a broad momentum range. The present results combine the measurements of $\pi^{\pm}$, p, and $\overline{p}$ with those of neutral pions [11] and inclusive charged hadrons [12]. A "minimum bias" trigger based on signals from the beam-beam counters (BBC) and zero-degree calorimeter (ZDC) sampled $92.2^{+2.5}_{-3}\%$ of the inelastic Au + Au cross section of $\sigma^{\rm AuAu}_{\rm inel} = 6.9$ b [11]. The collision vertex is restricted to ± 30 cm of the nominal origin. Approximately 2×10^7 (3×10^7) minimum bias events are used in the charged (neutral) particle analysis. These samples are subdivided into seven centrality classes based on cuts in the combined ZDC and BBC response: 0–10%, 10–20%, 20–30%, 30–40%, 40–50%, 50–60%, and 60–92% of $\sigma^{\rm AuAu}_{\rm inel}$. The average number of participants ($N_{\rm part}$) and collisions ($N_{\rm coll}$) for each centrality class are derived from a Glauber model calculation [11].

Identified charged particles are measured over a subset of the PHENIX East-arm spectrometer covering pseudorapidity $|\eta| < 0.35$ and $\Delta\phi = \pi/8$ in azimuthal angle. PID is based on particle mass calculated from the measured momentum and velocity. The momentum resolution is $\delta p/p \simeq 0.7\% \oplus 1\% \times p(\text{GeV}/c)$ and is provided by a multilayer drift chamber followed by a multiwire proportional chamber with pad readout (PC1). The velocity is obtained by measuring the time of flight (TOF) and the path length along the trajectory. The timing system uses the BBC to provide a global start signal; hits on the TOF scintillator wall, located at a radial distance of 5.06 m, provide individual stop signals. The resolution is $\sigma \simeq 115$ ps, which allows a 4σ π/K and K/p separation up to $p_T \simeq 2$ GeV/c and $p_T \simeq 4$ GeV/c, respectively. A 2σ momentum dependent cut in mass squared is used up to $p_T = 2$ GeV/c and $p_T = 4$ GeV/c to select π and $(\overline{p})p$. Asymmetric cuts are applied at higher momenta to extend the π/K and K/p separation up to p_T of 3 and 4.5 GeV/c. The spectra are corrected for geometrical acceptance, decay in flight, and reconstruction efficiency using a GEANT-based Monte Carlo (MC) simulation and embedding simulated tracks into real events with different particle multiplicities.

The p and $\overline{p}$ yields are corrected for feed down from weak decays using a MC simulation and the measured Λ/p and $\overline{\Lambda}/\overline{p}$ ratios at $\sqrt{s_{NN}} = 130$ GeV [13] which include contributions from Ξ and Σ^0. Corrections for feed down from $\Sigma^{\pm}$ are not applied, but estimates based on HIJING MC give less than ~5% contribution. At $p_T = 0.65$ GeV/c, about 40% of the inclusive $(\overline{p})p$ come from weak decays. This fraction reduces to $\approx 25\%$ at 4 GeV/c. The systematic uncertainty of this correction is estimated at 6% by varying the Λ/p ($\overline{\Lambda}/\overline{p}$) ratios within the $\pm 24\%$ errors of the $\sqrt{s_{NN}} = 130$ GeV measurement and assuming m_T scaling at high p_T. The above uncertainty could be larger if the Λ/p ($\overline{\Lambda}/\overline{p}$) ratios change significantly with p_T and beam energy. The additional systematic error on the overall normalization is 8% for $p_T < 3$ GeV/c and 12% above 3 GeV/c. Added in quadrature, the total systematic errors are 11% and 14%; the larger value is for $p_T > 3$ GeV/c.

Inclusive charged hadrons are measured in the West-arm spectrometer covering $|\eta| < 0.35$ and $\Delta\phi = \pi/2$. Two pad chambers (PC2, PC3) located at 4.2 and 5 m, respectively, and a ring imaging Čerenkov counter [12] are used to reject and subtract high-p_T background. The systematic errors on the yields range from 11% for $p_T <$ 5 GeV/c to 45% at 9 GeV/c.

Neutral pions are reconstructed via the decay $\pi^0 \rightarrow \gamma\gamma$ through an invariant mass analysis of γ pairs detected in the electromagnetic calorimeter (EMCal), which covers $\Delta\eta = 0.7$ and $\Delta\phi = \pi$. The absolute energy scale is known to $\leq 1.5\%$. The systematic errors on the π^0 spectra range from 10% to 17%, from low to high p_T [11].

Figure 1 shows the p/π and $\overline{p}/\pi$ ratios as a function of p_T measured at midrapidity in central (0–10%), midcentral (20–30%), and peripheral (60–92%) Au + Au collisons. The open symbols represent the p/π^+ and $\overline{p}/\pi^-$ measurements, while the closed symbols represent the corresponding p/π^0 and $\overline{p}/\pi^0$ ratios. The error bars are the quadratic sum of statistical errors and point-to-point systematic errors. There is an additional normalization

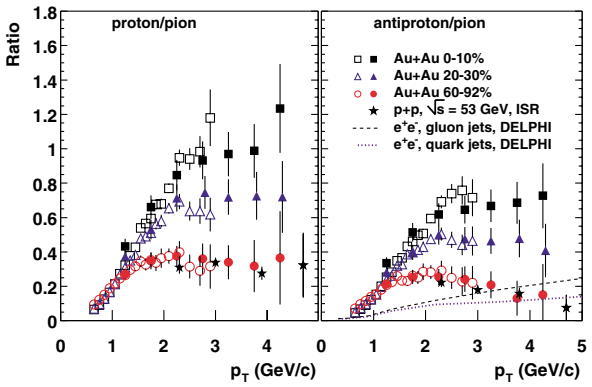

FIG. 1 (color online). p/π (left) and $\overline{p}/\pi$ ratios for central (0–10%), midcentral (20–30%), and peripheral (60–92%) Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Open (filled) points are for $\pi^{\pm}$ (π^0), respectively. Data from $\sqrt{s} = 53$ GeV $p + p$ collisions [7] are shown with stars. The dashed and dotted lines are $(\overline{p} + p)/(\pi^+ + \pi^-)$ ratios in gluon and in quark jets [8].

uncertainty of ~8% (for p/π^+, $\overline{p}/\pi^-$) and 12% (for p/π^0, $\overline{p}/\pi^0$), which may shift the curves up or down, but does not affect their shapes. In the region of overlap, the $\pi^{\pm}$ and π^0 measurements, with very different systematics, are consistent to within 5% to 15%. For all centralities the ratios rise steeply at low p_T and then, at a value of p_T which increases from peripheral to central collisions, level off. In central collisions the ratios are a factor of ~3 larger than in peripheral events. At $p_T > 2$ GeV/c the peripheral Au + Au data agree well with the ratios observed in $p + p$ collisions at lower energies [7] (shown with stars). The $(p + \overline{p})/(\pi^+ + \pi^-)$ ratios in gluon and quark jets produced in e^+e^- collisions [8] are shown with a dashed (dotted) line. Above 3 GeV/c the p/π, $\overline{p}/\pi$ ratios from peripheral collisions are also consistent with gluon and quark jet fragmentation, which should be independent of the collision system. Deviations from jet fragmentation below 3 GeV/c indicate the absence of soft hadron production in the e^+e^- data.

Hydrodynamic models have had success reproducing $(\overline{p})p$ [6,14] and π data [6] from $\sqrt{s_{NN}} = 130$ GeV Au + Au collisions [15,16] and preliminary 200 GeV data [17]. The calculations show good agreement with the central p, $\overline{p}$ and $\pi^{\pm}$ spectra up to $p_T \simeq 3$ and 2 GeV/c, respectively. In peripheral collisions the calculations deviate from the data above $p_T \simeq 1$ GeV/c. Within these models the large $\overline{p}/\pi$ ratio is a natural consequence of the strong radial flow [18]. All particle spectra converge to the same slope if p_T is sufficiently larger than the particle mass m_0. The $\overline{p}/\pi$ ratio is $R_{\overline{p}/\pi} \simeq 2\exp(-\mu_b/T_{\rm ch})$, governed only by the baryon chemical potential μ_b and the chemical freezeout temperature $T_{\rm ch}$. Using $T_{\rm ch} = 177$ MeV and $\mu_b = 29$ MeV [19], $R_{\overline{p}/\pi}$ reaches a limiting value of 1.7. Within 10%, the same limiting behavior is expected for all centralities, since the thermal parameters vary only weakly with centrality [20]. The data are not only below the asymptotic value but also show a more pronounced centrality dependence than can be accommodated by hydrodynamics models. This suggests that other mechanisms begin to play a role before the asymptotic value is reached. At intermediate p_T ($2 < p_T < 4$ GeV/c), hard scattering is one possible mechanism that competes with "soft" processes as described by hydrodynamics.

Figure 2 shows the p and $\overline{p}$ spectra for different centralities (0–10%, 20–30%, 40–50%, 60–92%) scaled by the corresponding value of $N_{\rm coll}$ [11]. Error bars are statistical only. Multiplicity dependent systematic errors are of the order of 3%. Errors on $N_{\rm coll}$ range from ~10% for central to ~28% for the peripheral event class. Below $p_T \simeq 1.5$ GeV/c the p and $\overline{p}$ yields scale slower than $N_{\rm coll}$ as expected for soft processes, and the effect of the radial flow on the shape of the spectra is clearly visible. The inverse slopes gradually increase from the most peripheral to the most central event class. Beyond $p_T \simeq 1.5$ GeV/c all spectra converge to the same slope and seem to obey $N_{\rm coll}$ scaling as expected for production due to hard processes in the absence of nuclear effects.

Figure 3 compares the $N_{\rm coll}$ scaled central to peripheral yield ratios,

$$R_{\rm CP} = \frac{\text{yield}^{0-10\%}/N_{\rm coll}^{0-10\%}}{\text{yield}^{60-92\%}/N_{\rm coll}^{60-92\%}}, \qquad (1)$$

for $(p + \overline{p})/2$ and π^0. In the p_T range from 1.5 to 4.5 GeV/c, p and $\overline{p}$ are not suppressed in contrast to π^0 which is reduced by a factor of 2–3. Moreover, this behavior holds for all centrality selections (Fig. 2), while the suppression in the π^0 yields increases from peripheral to central collisions [11]. The apparent scaling with $N_{\rm part}$ for $p_T \simeq 4$ GeV/c of inclusive charged hadrons [21], which has been interpreted in terms of saturation scenario [22], appears to be somewhat coincidental, since we

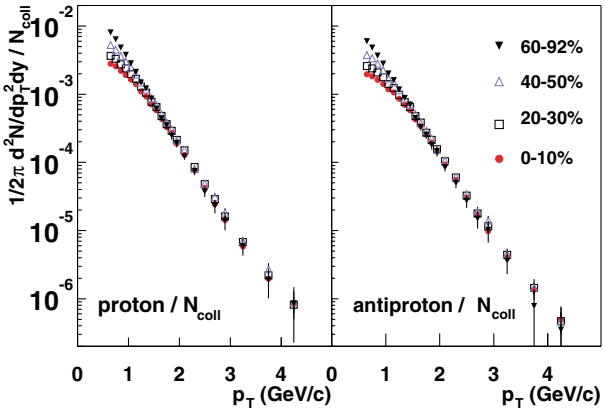

FIG. 2 (color online). p and $\overline{p}$ invariant yields scaled by $N_{\rm coll}$. Error bars are statistical. Systematic errors on $N_{\rm coll}$ range from ~10% for central to ~28% for 60–92% centrality. Multiplicity dependent normalization errors are ~3%.

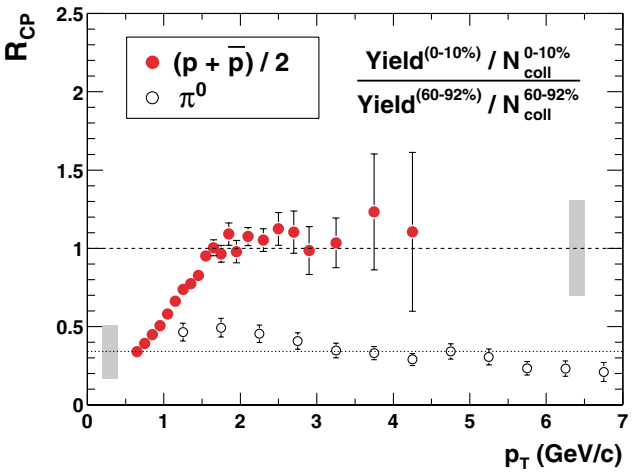

FIG. 3 (color online). Nuclear modification factor R_{CP} for $(p + \overline{p})/2$ (filled circles) and π^0. Dashed and dotted lines indicate N_{coll} and N_{part} scaling; the shaded bars show the systematic errors on these quantities.

observe a strong species dependence not expected in the model. However, the interpretation in terms of soft and hard processes is also not straightforward. If both π and p, $\overline{p}$ originate from the fragmentation of hard-scattered partons that lose energy in the medium, the nuclear modification factor R_{CP} should be independent of particle species contrary to our result. As discussed above, for a "hard" description to hold, the particle ratios $\overline{p}/\pi$ and p/π should reflect the fragmentation function, which favors pion production.

It is possible that nuclear effects such as the "Cronin effect" [23,24] contribute to the observed large $(\overline{p})p/\pi$ ratios. In $p + A$ collisions at energies up to $\sqrt{s} = 38.8$ GeV a nuclear enhancement beyond N_{coll} scaling has been observed for π, K, p and their antiparticles [25]. The effect is larger for $p(\overline{p})$ than for π which leads to an enhancement of the $(\overline{p})p/\pi$ ratio compared to $p + p$ collisions. For $p + W$ the increase is a factor of ~ 2 in the range $3 < p_T < 6$ GeV/c. Theoretical descriptions assume that the effect is due to initial state scattering or p_T broadening [26]. Recent results comparing charged hadrons to π^0 to $d + \mathrm{Au}$ at $\sqrt{s_{NN}} = 200$ GeV suggest that the Cronin effect in baryons is different from that in mesons [27]. Another possibility is that the variation in the p/π ratio with centrality reflects a medium-induced difference in the formation time of baryons and mesons—an effect which has been cited to explain DIS results [28].

Recently, the abundance of p relative to π in central collisions has been attributed to the recombination, rather than fragmentation, of quarks [29]. In this model, recombination for p and $\overline{p}$ is effective up to $p_T \simeq 5$ GeV above which fragmentation dominates for all particle species. Another explanation of the observed large baryon content invokes a topological gluon configuration: the baryon junction [30]. A centrality dependence, which is in qualitative agreement with our results, has been predicted [9]. In both theoretical models, the baryon/meson enhancement is limited to $p_T < 5$–6 GeV/c. The identification of charged particles beyond $p_T \approx 4.5$ GeV/c is not yet possible with the current PHENIX configuration; however, the baryon content at high p_T can be tracked indirectly using the h/π^0 ratio.

Figure 4 shows h/π^0 for central and peripheral Au + Au collisions. The error bars represent the quadratic sum of statistical and point-to-point systematic errors. In peripheral Au + Au collisions, R_{h/π^0} is consistent with the measurement in $p + p$. In central collisions in the region $1 < p_T < 4.5$ GeV/c, R_{h/π^0} is enhanced by as much as 50% above the $p + p$ value. As shown in Fig. 1, this enhancement is due to a large baryon contribution. Above $p_T \simeq 5$ GeV/c, the particle composition is consistent with that measured in $p + p$ collisions. This indicates that the centrality scaling of the p yields should become consistent with that of π at higher p_T ($\gtrsim 5$ GeV/c). Similar trends are observed in Λ and K^0_S measurements by the STAR Collaboration [31].

We have presented a systematic study of high-p_T particle composition in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV as a function of centrality. A large p and $\overline{p}$ contribution which increases from peripheral to central collisions is observed in the range $1.5 < p_T < 4.5$ GeV/c. In this p_T range, the p and $\overline{p}$ yields scale with N_{coll}, as expected for hard scattering. This is in contrast to the

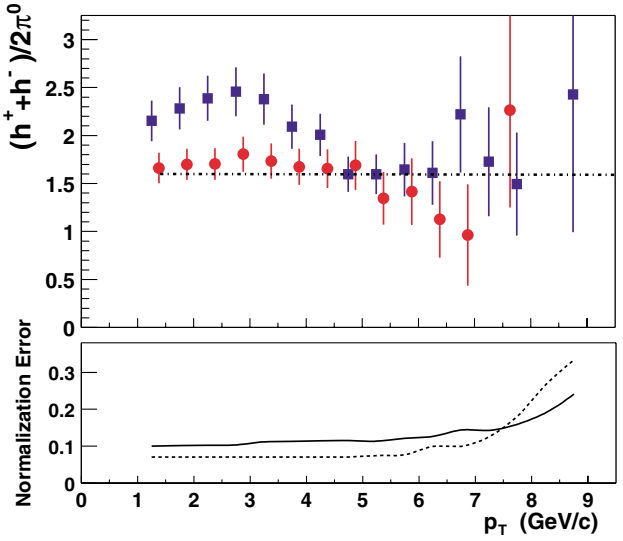

FIG. 4 (color online). Charged hadron to π^0 ratio in central (0–10% squares) and peripheral (60–92% circles) Au + Au collisions. The peripheral data points are offset by +130 MeV/c for clarity. The line at 1.6 is the h/π ratio measured in $p + p$ collisions [7]. The lower panel shows the fractional normalization error common to both centrality selections (solid line) and the relative error between the two (dashed line).

centrality-dependent suppression of π^0 production. The baryon enhancement with respect to π seems to be limited to transverse momenta $p_T \sim 5$ GeV/c, as deduced from the measurement of the ratio of inclusive charged hadrons to π^0. We conclude that π and $(\overline{p})p$ have different dominant production mechanisms for $p_T < 5$ GeV/c.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 27 May 2003; published 26 January 2004)

First results on charm quarkonia production in heavy ion collisions at the Relativistic Heavy Ion Collider (RHIC) are presented. The yield of J/ψ's measured in the PHENIX experiment via electron-positron decay pairs at midrapidity for Au-Au reactions at $\sqrt{s_{NN}}=200$ GeV is analyzed as a function of collision centrality. For this analysis we have studied 49.3×10^6 minimum bias Au-Au reactions. We present the J/ψ invariant yield dN/dy for peripheral and midcentral reactions. For the most central collisions where we observe no signal above background, we quote 90% confidence level upper limits. We compare these results with our J/ψ measurement from proton-proton reactions at the same energy. We find that our measurements are not consistent with models that predict strong enhancement relative to binary collision scaling.

I. INTRODUCTION

Lattice quantum chromodynamics (QCD) calculations indicate that there is a transition of nuclear matter from confined to deconfined quarks and gluons at a temperature of order $T_c=170$ MeV. Characteristic of this deconfined state of matter is the dynamic screening of the long-range confining potential of QCD. Color screening is predicted to reduce the attraction between heavy quark-antiquark pairs, and thus leads to a decrease in the ratio of hidden charm and beauty (quarkonia) to open charm and beauty [1,2]. Thus, one expects a suppression of quarkonium states $[J/\psi, \psi', \chi_c, \Upsilon(1s, 2s, 3s)]$ depending on their binding energy and the temperature of the surrounding system.

In relativistic heavy ion collisions a state of a deconfined thermalized quark-gluon plasma may be created. Measurements in Pb-Pb reactions at $\sqrt{s_{NN}}=17.3$ GeV by the NA50 experiment [3] show a suppression of heavy quarkonia production relative to "normal" nuclear absorption, the dissociation of $c\bar{c}$ pairs by interactions with the nucleons into separate quarks that eventually hadronize into D mesons [4–7]. This suppression has been interpreted in the context of color screening in a quark-gluon plasma [6,8], additional absorption with comoving hadrons [9,10], and multiple scattering between the charm quarks and the surrounding medium [11,12].

At Relativistic Heavy Ion Collider (RHIC) energies, where of order 10 $c\bar{c}$ pairs are produced in central Au-Au reactions [13,14], some models predict an enhancement of heavy quarkonia due to $c\bar{c}$ coalescence in a quark-gluon plasma [15], detailed balance of $D+\bar{D}\leftrightarrow J/\psi+X$ [16], and/or statistical J/ψ production [17]. In addition, at RHIC energies initial state effects of shadowing and possible parton saturation may play a role in initial charm production [18]. Disentangling these competing effects will require a systematic study of yields of various quarkonium states in different colliding systems [proton-proton, proton (or deuteron)-ion, and ion-ion] and over a wide kinematic range in terms of transverse momentum and x_F.

We report here the first results on J/ψ production via electron-positron decay pairs at midrapidity from Au-Au collisions at $\sqrt{s_{NN}}=200$ GeV from data taken during Run 2 at RHIC in 2001. For peripheral and midcentral Au-Au collisions, we present the most probable yield values, while for central reactions, we observe no signal above background and thus quote 90% confidence level upper limits on J/ψ production.

II. PHENIX EXPERIMENT

The PHENIX experiment is specifically designed to make use of high-luminosity ion-ion, proton-ion, and proton-proton collisions at the Relativistic Heavy Ion Collider to sample rare physics probes including the J/ψ and other heavy quarkonium states. The PHENIX experiment includes two central rapidity spectrometer arms, each covering the pseudorapidity range $|\eta|<0.35$ and an interval of 90° in azimuthal angle ϕ. The spectrometers are composed from the inner radius outward of a multiplicity and vertex detector, drift chambers (DC), pixel pad chambers (PC), ring imaging cerenkov counters (RICH), time-of-flight scintillator wall, time expansion chambers (TEC), and two types of electromagnetic calorimeters (EMC). This combination of detectors allows for the clean identification of electrons over a broad range in transverse momentum. Further details of the detector design and performance are given in Ref. [19].

The Au-Au event centrality is estimated using the combined data from our beam-beam counters (BBCs) and zero degree calorimeters (ZDCs). While the ZDCs measure forward neutrons that result from fragmentation of the colliding nuclei, the BBCs are sensitive to charged particles produced in the collisions. Together, both detectors yield information on the impact parameter of the nuclear reaction [20]. These observables, combined with a Glauber model for the nuclear geometry, allow us to determine different collision geometry categories, referred to as centrality ranges [21].

For the analysis presented here, the electron (positron) momentum and charge sign are determined from tracking using the DC and the PC and then projecting back through the PHENIX axial magnetic field to the collision point determined by the BBC [22]. The momentum resolution achieved is $\delta p/p=0.7\% \oplus 1.0\% \times p$ (in GeV/c). Electrons are cleanly separated from the large background of charged pions and kaons by associating the tracks with at least three active photomultiplier tubes in the RICH [23]. In addition, we compare the track momentum (p) to the energy (E) measured in the electromagnetic calorimeter. The E/p ratio is used to further reduce the pion contamination in the electron sample. Pions typically deposit only a fraction of their energy in the calorimeter whereas electrons deposit all of their energy. These selections are augmented by requiring that the calorimeter shower position and time-of-flight information agree with the track projection. Thus, we obtain a clean sample of electron and positron candidates with less than 5% contamination.

III. DATA SELECTION AND TRIGGERS

The Au-Au data at $\sqrt{s_{NN}}=200$ GeV used in this analysis were recorded during Run 2 at RHIC in the fall of 2001. For our "minimum bias" Au-Au event selection, we use a level-1 trigger that requires a coincidence between our BBCs. We place an additional offline requirement of at least one forward neutron in each of our ZDCs to remove beam related backgrounds. Our "minimum bias" sample includes 92% of the 6.9 barn Au-Au inelastic cross section [21]. We further restrict our analysis to 90% of the inelastic cross section to remove a small remaining contribution from beam related background events.

We observed a Au-Au inelastic collision rate that increased during the running period from 100 to 1200 Hz. The level-2 triggers are implemented in a personal-computer-based farm with 30 processors in run 2, as part of the PHENIX Event Builder [19]. The level-2 J/ψ trigger algorithm identified electron candidates by starting with rings in the RICH and then searching for possible matching showers in the EMC. The EMC search window based on the RICH ring is obtained from a lookup table, generated using Monte Carlo simulations of single electrons. Possible matches were

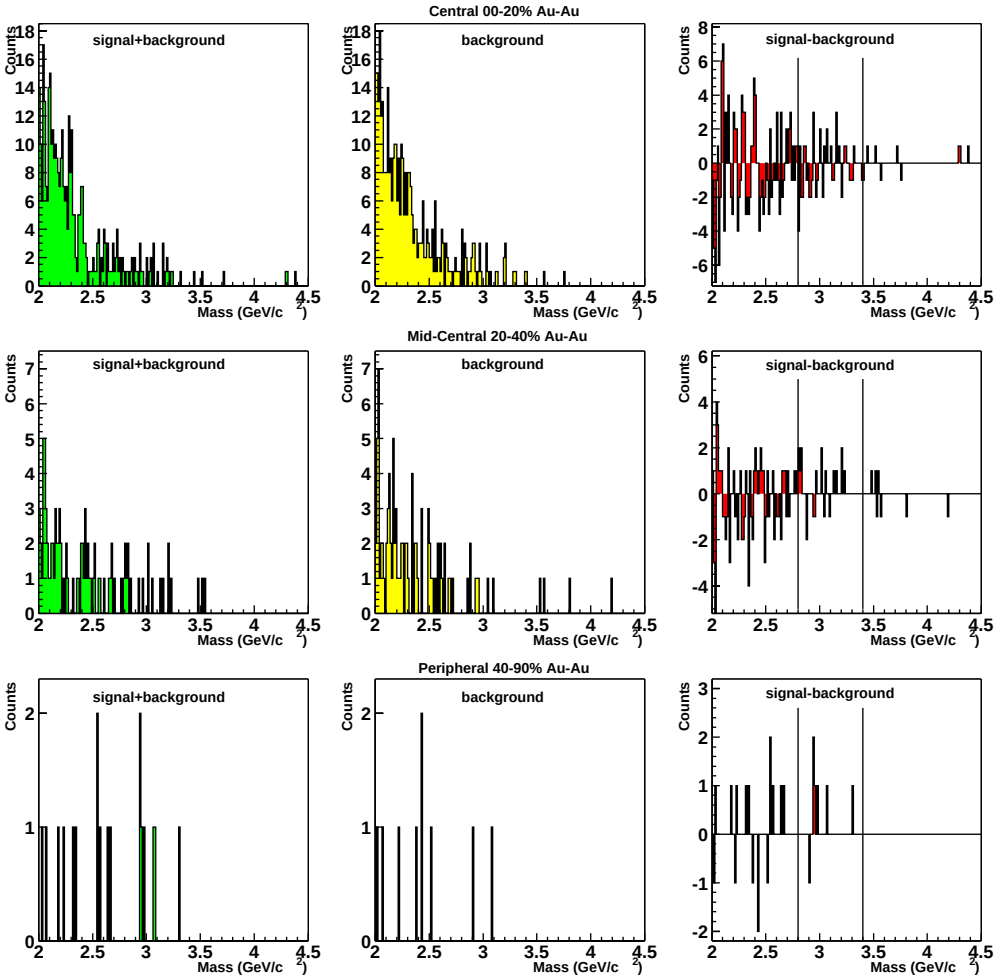

FIG. 1. (Color online) Dielectron invariant mass distribution in Au-Au reactions (top row, most central, 0–20 % central; middle row, midcentral, 20–40 % central; and bottom row, peripheral, 40–90 % central) for unlike sign pairs containing signal+background (left column), like sign pairs containing only background (center column), and the subtracted difference (right column).

assumed to be electron candidates, and the electron momentum was taken to be the EMC shower energy. The invariant mass was calculated for all electron candidate pairs within an event, regardless of the candidate's charge sign. If the invariant mass was higher than 2.2 GeV/c^2, the pair was accepted as a J/ψ candidate, and the entire event was archived. The level-2 trigger provided a rejection factor of order 30 relative to our "minimum bias" level-1 trigger sample.

An additional offline requirement was imposed that the collisions have a z vertex satisfying $|z|<30$ cm in order to eliminate collisions taking place near the PHENIX magnet. After this selection, we have analyzed 25.9×10^6 "minimum bias" Au-Au reactions as triggered by our BBC level-1 trigger. In addition, from the high-luminosity period of running, we also processed 23.4×10^6 "minimum bias" events with our J/ψ level-2 trigger.

IV. J/ψ SIGNAL COUNTING

For three exclusive centrality bins—0–20%, 20–40%, and 40–90% of the total Au-Au cross section, we show the dielectron invariant mass distributions for unlike sign pairs (e^+e^-), like sign pairs (e^+e^+ or e^-e^-), and the subtracted difference in Fig. 1. The number of J/ψ counts for each centrality range is determined from the number of signal counts above "background" within a fixed invariant mass window. The PHENIX acceptance and level-2 trigger efficiencies are the same within a few percent for unlike sign pairs and like sign pairs in the J/ψ mass region. Therefore, the sample of like sign pairs is a good representation with no additional scale factor of the "background" due to simple combinatorics.

In order to extract a J/ψ signal strength, we employ a counting method where we subtract from the number of unlike sign pairs the number of like sign pairs in the mass window $2.8<m<3.4$ GeV/c^2. We have chosen a wide invariant mass window to be consistent with the signal extraction method from our proton-proton analysis [24], and to limit our sensitivity to the exact mass width value. Although we expect from our Monte Carlo studies a mass width of order 60 MeV, we cannot quantitatively verify this even with our proton-proton data sample due to low statistics. We note, that in principle, there is more information to be utilized in the exact distribution of the candidates within the mass window. However, we have found that this does not add to the

TABLE I. Statistical results for J/ψ counts are shown for three exclusive centrality ranges. Shown are the number of unlike and like sign counts within the mass window ($2.8<m<3.4$ GeV/c^2). Also shown are the most likely signal value with the 68% statistics confidence interval (for the peripheral and midcentral cases), and the 90% confidence level upper limits.

Cent.	Unlike sign counts	Like sign counts	Most likely signal	90% C.L.
0–20 %	33	41	0	9.9
20–40 %	16	8	$8^{+4.8}_{-4.1}$	14.4
40–90 %	7	2	$5^{+3.1}_{-2.6}$	9.3

significance of the result, given the low counts and the lack of constraint on the J/ψ and background line shape.

Table I shows the number of unlike and like sign counts within the mass window. For given observed counts of N_l (like sign) and N_u (unlike sign), the likelihood $L(\nu_l, \nu_u)$ for the expectation values ν_l and ν_u is given as

$$L(\nu_l, \nu_u) = \frac{\nu_l^{N_l} e^{-\nu_l}}{N_l!} \times \frac{\nu_u^{N_u} e^{-\nu_u}}{N_u!}. \quad (1)$$

We then integrate $L(\nu_l, \nu_u)$ to give the likelihood $L(\nu_s)$ for the expectation value of the net signal counts $\nu_s = \nu_u - \nu_l$,

$$L(\nu_s) = \int_0^\infty \int_0^\infty L(\nu_l, \nu_u)\delta(\nu_s - \nu_u + \nu_l) d\nu_l d\nu_u \quad (2)$$

We show the likelihood distribution $L(\nu_s)$ for the midcentral (20–40 %) events in Fig. 2. Although $L(\nu_s)$ is normalized such that $\int_{-\infty}^{\infty} L(\nu_s) d\nu_s = 1$, it has a nonzero probability for negative expected net signal value ($\nu_s<0$). Since the unlike sign contains signal + background, and the like sign contains only *background*, the only physically allowed values for ν_s are greater than or equal to zero. Thus, we remove the probability range corresponding to $\nu_s<0$, and renormalize the remaining probability integral to one [25], as shown in Fig. 2. We then determine for each centrality the 90% confidence level upper limit, and the 68% confidence interval around the most likely value for the peripheral and midcentral ranges. These values are shown in Table I.

Since the net signal is negative for the 0–20 % central event class, we can only quote a 90% confidence level upper limit. Also, even for the 20–40 % and 40–90 % centrality classes, the signal observed is not significant at the two standard deviation level and thus we also show 90% confidence level upper limits for completeness. The limited statistical significance of the results is clear from the mass distributions shown in Fig. 1.

In the intermediate mass region below the J/ψ, $2.0<m<2.8$ GeV/c^2, the shapes and absolute yield of like sign and unlike sign dielectron mass distributions are well reproduced by an event mixing method within a few percent. This indicates that most of the dielectron pairs are from uncorrelated electron and positron candidates. They are originating from Dalitz decays, photon conversions, open charm/

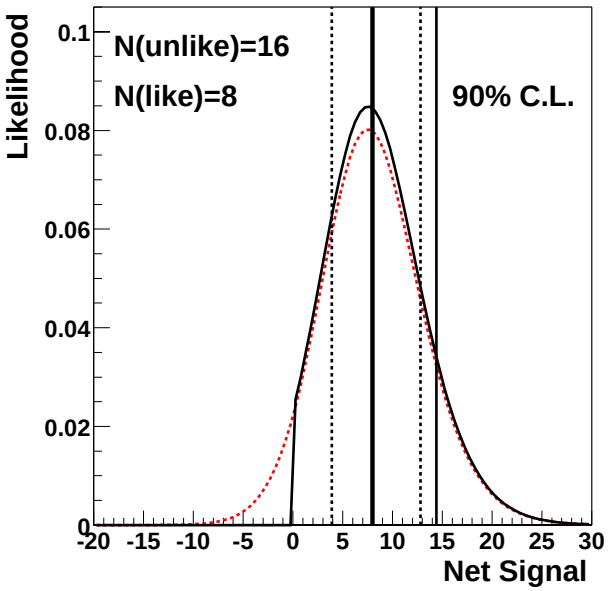

FIG. 2. (Color online) The Poisson statistical likelihood distribution as a function of the expected net signal. The distributions are for the midcentral case of $N_{unlike}=16$ and $N_{like}=8$. The dashed curve is the likelihood distribution, and the black is after eliminating the unphysical net signal less than zero and renormalizing. Vertical lines are shown to indicate the most likely value (8), the 68% confidence interval values, and the 90% confidence level upper limit.

beauty semileptonic decays, and a small contamination of misidentified hadrons. The unlike sign pairs should also have a component from semileptonic decays of charm and anticharm pairs, but its contribution is less than the statistical uncertainty of the data [26]. A complete analysis of the intermediate mass region will be presented elsewhere [27].

Our method of measurement does not separate contributions from decay feed-down from other states such as the χ_c and ψ', and thus our J/ψ counts include these feed-down sources. Our acceptance and efficiency is identical for the resulting J/ψ from these decays as for prompt J/ψ, and thus they enter our signal weighted simply by their relative production and branching fraction into $J/\psi+X$. Another contribution may result from B meson decays into J/ψ. However, if we assume a $b\bar{b}$ cross section in proton-proton reactions $\sigma_{b\bar{b}} \approx 2-5$ μb [28] and that beauty production scales with binary collisions, we would expect a contribution of order 1–4 % relative to primary J/ψ or J/ψ from χ_c. This percentage contribution calculation assumes that the primary J/ψ also scales with binary collisions. If primary J/ψ are substantially suppressed, the B meson decay contribution would constitute a larger fraction of our measured J/ψ, especially at higher p_T.

It should also be noted that some signal in the unlike sign pairs from correlated open charm $c\bar{c} \rightarrow D(\rightarrow e^+ + X) + D(\rightarrow e^- + X)$ will contribute in our mass window. Assuming binary scaling in charm production with a proton-proton cross section $\sigma_{c\bar{c}} \approx 650$ μb [14], this contribution in the J/ψ mass region is estimated to be about 0.1 events in the 0–20 %, 0.05 events in the 20–40 %, and 0.02 events in the 40–90 % centrality bins.

V. J/ψ YIELD CALCULATION

We quote our results as the branching fraction of $J/\psi \rightarrow e^+e^-$ ($B=5.93\pm0.10\times10^{-2}$ [25]) times the invariant yield at midrapidity $dN/dy|_{y=0}$. We calculate this quantity for three exclusive centrality ranges as detailed below,

$$B\left.\frac{dN}{dy}\right|_{y=0} = \frac{N_{J/\psi}}{N_{mb-evt} + (\epsilon_{lvl2-eff} N_{lvl2-evt})} \times \frac{1}{\Delta y} \frac{1}{\epsilon_{acc-eff} \times \epsilon_{cent}}. \tag{3}$$

The number of signal counts $N_{J/\psi}$ from both the "minimum bias" and level-2 triggered event samples are shown in Table I. The number of events from the "minimum bias" sample $N_{mb\text{-}evt}$ is 25.9×10^6 Au-Au events. The number of effective events sampled by the level-2 trigger is ($\epsilon_{lvl2\text{-}eff} \times N_{lvl2\text{-}evt}$), which is the level-2 trigger efficiency times the number of events processed by the level-2 trigger, 23.4×10^6 Au-Au events. This formulation appropriately weights the two data samples by the expected number of J/ψ.

The efficiency of the level-2 trigger $\epsilon_{lvl2\text{-}eff}$ was determined by running the trigger algorithm on simulated J/ψ and carrying out a full offline reconstruction of the resulting electron-positron decay pair. The efficiency was calculated via counting the fraction of successfully reconstructed J/ψ events that were also found by the trigger. In these trigger simulations, the channel-by-channel calibrations for the RICH and EMC were used to convert the simulated signals into realistic values representative of a specific period in the run, before passing them to the level-2 trigger.

The overall J/ψ trigger efficiency from the trigger simulations was $\epsilon_{lvl2\text{-}eff}=0.75\pm0.04$. The systematic error was determined by studying the dependence of the trigger efficiency on the collision vertex position, the assumed J/ψ transverse momentum and rapidity distribution, collision centrality, and the period of the run from which the channel-by-channel calibrations were taken. After evaluating all of the above dependencies, we assign a 5% systematic error to the J/ψ trigger efficiency.

The efficiency result from the trigger simulations was confirmed using real data in two ways. First, the minimum bias data sample in Au-Au collisions was analyzed to calculate the J/ψ trigger efficiency. This was done by taking the ratio of the events that have an electron pair with invariant mass between 2.8 and 3.4 GeV/c^2 that fired the J/ψ trigger to all of the events having electron pairs in that invariant mass range. The trigger efficiency estimate from this check is 0.67 ± 0.10 (stat). Second, the triggers were run on a sample of 26 events from the proton-proton dataset that passed all of the J/ψ cuts in the offline analysis and had invariant masses between 2.8 and 3.4 GeV/c^2. The level-2 J/ψ trigger accepted 19 of these events, yielding an estimate of $0.73\pm^{0.07}_{0.10}$ (stat), in very good agreement with the trigger simulation result. These results verify that the trigger performance is similar for real data and simulations.

The J/ψ acceptance and efficiency $\epsilon_{acc\text{-}eff}$ is determined with a GEANT based Monte Carlo simulation of the PHENIX experiment. The detector response has been tuned to reproduce the resolution and performance of the real detector. The efficiency includes not only the tracking efficiency, but also the probability for passing all of the electron identification selection cuts. The electron identification efficiency determined by the Monte Carlo simulation is verified by a clean electron sample from conversion photons. We also account for run by run efficiency changes by counting the relative number of reconstructed electrons and positrons per event in our data sample. We show the PHENIX acceptance and efficiency as a function of transverse momentum in Fig. 3.

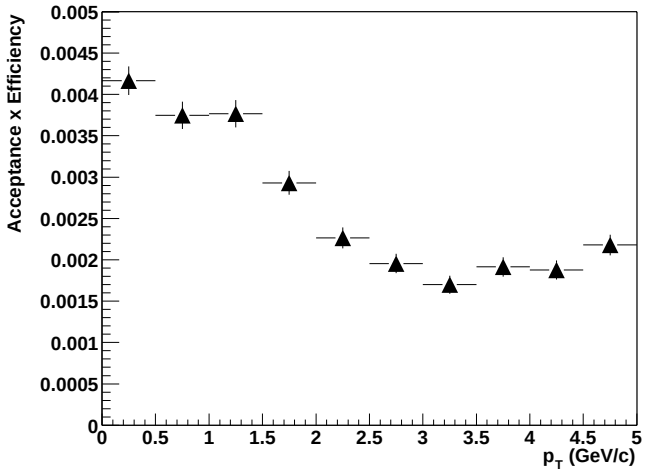

FIG. 3. The PHENIX J/ψ acceptance $\times$ efficiency as a function of the J/ψ transverse momentum is shown. Most of the acceptance is with one lepton into each of the two PHENIX central spectrometers. This contribution peaks at $p_T=0$ and decreases with increasing p_T. The rise in the acceptance at high p_T is from contributions where both electron and positron are accepted into one of the PHENIX central spectrometers.

Since we do not have the statistics to determine the transverse momentum distribution of the J/ψ, we must employ a model for the p_T dependence to determine an overall acceptance and efficiency. We use two different functional forms for the p_T distributions to test the model sensitivity of our acceptance. We use an exponential in p_T and an exponential in p_T^2 as motivated by fits to J/ψ data at lower energies [29]. The two models give similar acceptance values given a common $\langle p_T \rangle$ value input. The largest uncertainty comes from the value of $\langle p_T \rangle$ assumed. PHENIX has measured J/ψ production in proton-proton reactions at $\sqrt{s}=200$ GeV and finds a $\langle p_T \rangle = 1.80\pm0.23(\text{stat})\pm0.16(\text{syst})\text{GeV}/c$ [24]. We use this value to determine our acceptance and efficiency averaged over all p_T. The J/ψ $\langle p_T \rangle$ in Au-Au collisions may differ from that in proton-proton reactions. Therefore we vary the $\langle p_T \rangle$

TABLE II. The J/ψ acceptance $\times$ efficiency and the centrality dependent efficiency are shown for three exclusive Au-Au centrality event classes.

Centrality bin	$\epsilon_{acc\text{-}eff}$	ϵ_{cent}
0–20 %	$0.0027\pm^{0.0009}_{0.0005}$ (syst)	0.61 ± 0.06 (syst)
20–40 %	$0.0027\pm^{0.0009}_{0.0005}$ (syst)	0.78 ± 0.08 (syst)
40–90 %	$0.0027\pm^{0.0009}_{0.0005}$ (syst)	0.90 ± 0.09 (syst)

TABLE III. We show the statistically most likely J/ψ invariant yield ($B\ dN/dy|_{y=0}$) value and the 68% confidence interval for peripheral (40–90 %) and midcentral (20–40 %) collisions. We also show the 90% confidence level upper limit and the systematic error on this limit for all three different centrality ranges of Au-Au collisions.

	$B\ dN/dy\|_{y=0}(\times 10^{-4})$	
Centrality	Most likely value	90% C.L. upper limit
0–20 %	N.A.	$6.08+1.56$ (syst)
20–40 %	$4.00^{+2.34}_{-2.01}$ (stat)$^{+1.36}_{-1.60}$ (syst)	$7.19+2.43$ (syst)
40–90 %	$0.86^{+0.52}_{-0.44}$ (stat)$^{+0.29}_{-0.35}$ (syst)	$1.60+0.54$ (syst)

from 1.0 to 3.0 GeV/c to determine our model dependent systematic errors. We assume that the J/ψ rapidity distribution is flat over the range $-0.35<y<0.35$ where we measure. The final value for the J/ψ acceptance and efficiency is shown in Table II. This acceptance and efficiency has a 20% systematic error from uncertainties in matching the Monte Carlo to the detector response, a 10% systematic error from run-to-run variation corrections, and a $\pm^{32}_{24}$% systematic error from the uncertainty in the $\langle p_T\rangle$.

Our tracking and electron identification efficiencies exhibit a centrality dependence due to overlapping hits and energy contamination in the calorimeter. We determine this dependence by embedding Monte Carlo J/ψ into real data events of different centrality selections. The corresponding efficiency factor ϵ_{cent} varies from 56% for the 0–5 % most central events to 98% for the 85–90 % most peripheral events.

The final values for the embedding efficiency in our wide centrality bins are sensitive to the true centrality dependence of the J/ψ production. In order to estimate the systematic error due to this uncertainty we assume two different centrality dependence models: (1) binary collision scaling and (2) participant collision scaling. Within our centrality ranges, we find that these two models yield less than a 5% difference and we include this in our systematic error. We assign an additional 10% systematic error to account for uncertainties in the Monte Carlo embedding procedure. The centrality dependent efficiency values are shown in Table II.

In our $B\ dN/dy$ calculation, we have added the systematic errors from all of the contributing factors in quadrature and find +35% and −41% total systematic error on the invariant yield in each of the centrality ranges. The dominant systematic error results from the uncertainty in the $\langle p_T\rangle$ of the J/ψ distribution.

VI. RESULTS

The $B\ dN/dy|_{y=0}$ values for the three exclusive centrality selections are shown in Table III. We have calculated using a Glauber model [21] the number of expected participating nucleons N_{part} and the number of expected binary collisions N_{coll} for each centrality range. These results are shown in Table IV, in addition to the $B\ dN/dy|_{y=0}$ values divided by the expected number of binary collisions.

The PHENIX result for the J/ψ invariant yield in proton-proton induced reactions at $\sqrt{s}=200$ GeV at midrapidity [24] is

$$B dN/dy|_{y=0}(pp) = 1.46 \pm 0.23(\text{stat}) \pm 0.22(\text{syst}) \pm 0.15(\text{abs}) \times 10^{-6}. \quad (4)$$

The systematic error (abs) represents the uncertainty of the normalization of the total proton-proton invariant yield.

We show in Fig. 4 the results from the three Au-Au centrality bins and the proton-proton data normalized per binary collision as a function of the number of participating nucleons. Note that for proton-proton reactions, there are two participating nucleons and one binary collision.

VII. DISCUSSION

Despite the limited statistical significance and systematic uncertainty of these first J/ψ results, we can address some important physics questions raised by the numerous theoretical frameworks in which J/ψ rates are calculated.

We show in Fig. 5 binary scaling expectations as a gray band. We also show a calculation of the suppression expected from "normal" nuclear absorption using a $\sigma_{c\bar{c}-N}=4.4$ mb [30] and 7.1 mb [31,6]. A recent measurement in proton-nucleus collisions at lower energies [30] favors the smaller absorption cross section, thus underscoring the importance of measuring J/ψ in proton(deuteron)-nucleus collisions at RHIC energies. We also show the NA50 suppression pattern relative to binary scaling [3], normalized to

TABLE IV. We show the number of participating nucleons and the number of binary collisions for three different centrality ranges of Au-Au collisions, and the associated systematic errors. We show the statistically most likely value for the J/ψ invariant yield ($B\ dN/dy|_{y=0}$) divided by the expected number of binary collisions for peripheral (40–90 %) and midcentral (20–40 %) collisions. We also show the 90% confidence level upper limit and the systematic error on this limit for all three different centrality ranges of Au-Au collisions. The systematic error in the invariant yield per binary collision does not include the systematic error in the expected number of binary collisions. This error contribution is negligible for the central and midcentral categories and would increase the systematic error for the peripheral category by 6%.

			$B\ dN/dy\|_{y=0}$ per binary collision ($\times 10^{-6}$)

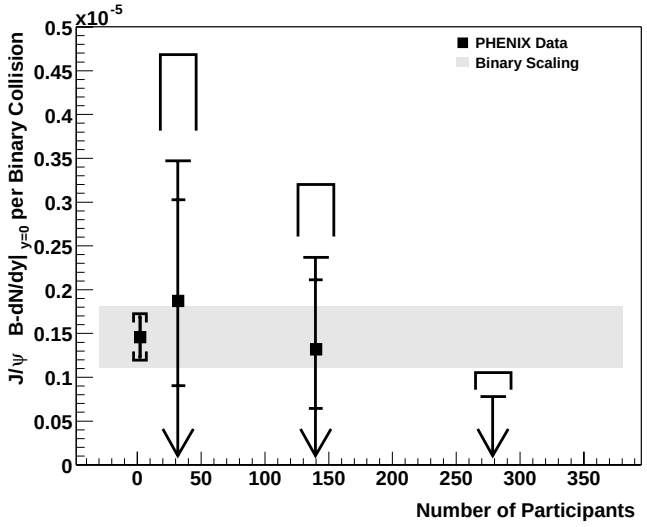

FIG. 4. The J/ψ invariant yield per binary collision is shown for proton-proton reactions and three exclusive centrality ranges of Au-Au reactions all at $\sqrt{s_{NN}}=200$ GeV. For the proton-proton reactions, we show the most likely value as a data point (square), the statistical error, and the estimated systematic errors as brackets. For the three Au-Au data points, we show as arrows the 90% confidence level upper limits. The bracket above the limit includes the estimated systematic error on these limits. In the case of the peripheral and midcentral ranges, we also show, as a square marker, the statistically most likely value and as two horizontal dashes the 68% confidence interval. The gray band indicates binary scaling and the width is the quadrature sum of the statistical and systematic error on our proton-proton data point. For the Au-Au points, the systematic error in the invariant yield per binary collision does not include the systematic error in the expected number of binary collisions. This error contribution is negligible for the central and midcentral categories and would increase the systematic error for the peripheral category by 6%.

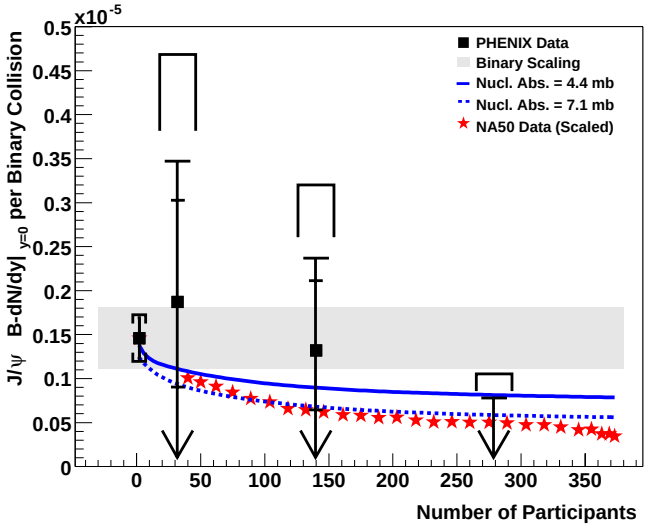

FIG. 5. (Color online) The J/ψ invariant yield per binary collision is shown from proton-proton reactions and three exclusive centrality ranges of Au-Au reactions all at $\sqrt{s_{NN}}=200$ GeV. The lines are the theoretical expectations from "normal" nuclear absorption with $\sigma_{c\bar{c}-N}=4.4$ mb (solid curve) and 7.1 mb (dashed curve) cross section. The stars are the J/ψ per binary collision measured by the NA50 experiment at lower collision energy. In order to compare the shapes of the distribution, we have normalized the NA50 data to match the central value for our proton-proton results.

match our proton-proton data point at 200 GeV. The data disfavor binary scaling, while they are consistent with "normal" nuclear absorption alone and also the NA50 suppression pattern measured at lower energies, within our large statistical errors.

One model calculation [16] including just the "normal" nuclear and plasma absorption components at RHIC energies is shown in Fig. 6. The higher temperature (T) and longer time duration of the system at RHIC lead to a predicted larger suppression of J/ψ relative to binary collision scaling. This specific model [16], and in general this class of models [32,8], cannot be ruled out at this time due to our null result (90% confidence level upper limit) for the most central collisions.

Many recent theoretical calculations also include the possibility for additional late stage re-creation or coalescence of J/ψ states. In Ref. [16], they include both breakup and creation reactions $D+D\leftrightarrow J/\psi+X$. At the lower fixed target CERN energies, this represents a very small contribution due to the small charm production cross section. However, at RHIC energies, where in central Au-Au collisions there are of order 10 $c\bar{c}$ pairs produced, the contribution is significant. The sum of the initial production, absorption, and re-creation as shown in Fig. 6 is also consistent with our experimental data.

A different calculation [15] assumes the formation of a quark-gluon plasma in which the mobility of heavy quarks in the deconfined region leads to increased $c\bar{c}$ coalescence. This leads to a very large enhancement of J/ψ production at RHIC energies for the most central reactions. The model considers the plasma temperature (T) and the rapidity width (Δy) of charm quark production as input parameters. Shown in Fig. 6 are the calculation results for $T=400$ MeV and $\Delta y=1.0, 2.0, 3.0, 4.0$. The narrower the rapidity window in which all charm quarks reside, the larger the probability for J/ψ formation. $\Delta y=1.0$ is consistent with the three dimensional spherically symmetric thermal distribution, and results in a charm yield at midrapidity that is inconsistent with the PHENIX preliminary charm yield as determined from single electron measurements [14]. $\Delta y=4.0$ is consistent with expectations from factorized QCD and PYTHIA with CTEQ5L structure functions [13]. All of these parameters within this model predict a J/ψ enhancement relative to binary collisions scaling, which is disfavored by our data.

Another framework for determining quarkonia yields is to assume a statistical distribution of charm quarks that may then form quarkonia. A calculation assuming thermal, but not chemical, equilibration [17] is shown in Figure 6, and is also consistent with our data.

Significantly larger datasets are required to address the various models that are still consistent with our first measurement. Key tests will be the p_T and x_F dependence of the J/ψ yields, and how these compare with other quarkonium states such as the ψ'.

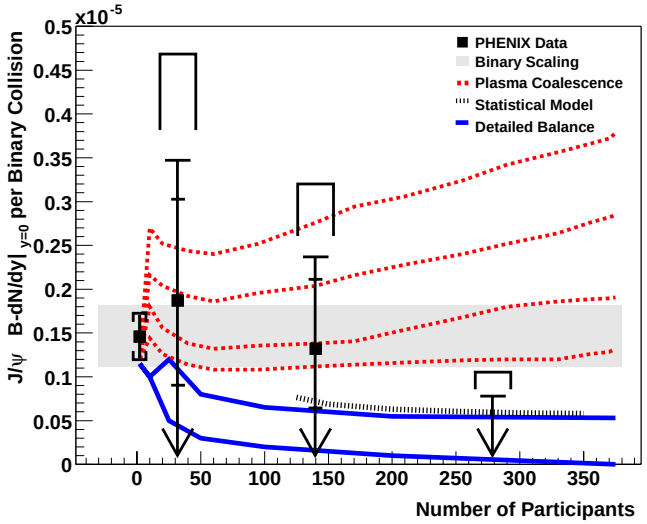

FIG. 6. (Color online) The J/ψ invariant yield per binary collision is shown from proton-proton reactions and three exclusive centrality ranges of Au-Au reactions all at $\sqrt{s_{NN}}=200$ GeV. The lowest curve is a calculation including "normal" nuclear absorption in addition to substantial absorption in a high-temperature quark-gluon plasma [16]. The curve above this is including backward reactions that recreate J/ψ. The statistical model [17] result is shown as a dotted curve for midcentral to central collisions just above that. The four highest dashed curves are from the plasma coalescence model [15] for a temperature parameter of $T=400$ MeV and charm rapidity widths of $\Delta y=1.0, 2.0, 3.0, 4.0$, from the highest to the lowest curve, respectively.

VIII. SUMMARY

PHENIX has shown first results on J/ψ production in Au-Au collisions at $\sqrt{s_{NN}}=200$ GeV at midrapidity as measured via electron-positron pairs. We find that models that predict J/ψ enhancement relative to binary collision scaling are disfavored, while we cannot discriminate between various scenarios leading to suppression relative to binary scaling.

This first measurement from PHENIX will be followed with high statistics measurements in both the electron channel at midrapidity and at forward and backward rapidities in the PHENIX muon spectrometers. Such measurements are expected in the next few years and will address the full range of heavy quarkonia production and evolution models.

ACKNOWLEDGMENTS

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions. We acknowledge support from the Department of Energy, Office of Science, Nuclear Physics Division, the National Science Foundation, Abilene Christian University Research Council, Research Foundation of SUNY, and Dean of the College of Arts and Sciences, Vanderbilt University (USA), Ministry of Education, Culture, Sports, Science, and Technology and the Japan Society for the Promotion of Science (Japan), Conselho Nacional de Desenvolvimento Científico e Tecnológico and Fundação de Amparo à Pesquisa do Estado de São Paulo (Brazil), Natural Science Foundation of China (People's Republic of China), IN2P3/CNRS and Commissariat a l'Energie Atomique (France), Bundesministerium fuer Bildung und Forschung, Deutscher Akademischer Austausch Dienst, and Alexander von Humboldt Stiftung (Germany), Hungarian National Science Fund, OTKA (Hungary), Department of Atomic Energy and Department of Science and Technology (India), Israel Science Foundation (Israel), Korea Research Foundation and Center for High Energy Physics (Korea), Russian Academy of Science, Ministry of Atomic Energy of Russian Federation, Ministry of Industry, Science, and Technologies of Russian Federation (Russia), VR and the Wallenberg Foundation (Sweden), the U.S. Civilian Research and Development Foundation for the Independent States of the Former Soviet Union, the U.S.-Hungarian NSF-OTKA-MTA, the U.S.-Israel Binational Science Foundation, and the 5th European Union TMR Marie-Curie Programme.

(Received 16 May 2003; published 30 October 2003)

The anisotropy parameter (v_2), the second harmonic of the azimuthal particle distribution, has been measured with the PHENIX detector in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV for identified and inclusive charged particle production at central rapidities ($|\eta| < 0.35$) with respect to the reaction plane defined at high rapidities ($|\eta| = 3$–4). We observe that the v_2 of mesons falls below that of (anti)-baryons for $p_T > 2$ GeV/c, in marked contrast to the predictions of a hydrodynamical model. A quark-coalescence model is also investigated.

DOI: 10.1103/PhysRevLett.91.182301 PACS numbers: 25.75.Dw

Event anisotropy is expected to be sensitive to the early stage of ultrarelativistic nuclear collisions at the BNL Relativistic Heavy Ion Collider (RHIC). The possible formation of a quark-gluon plasma could affect how the initial anisotropy in coordinate space is transferred into momentum space in the final state. The anisotropy parameter

v_2 for a selection of produced particles is derived from the azimuthal distribution of those particles.

$$\frac{dN}{d\phi} \propto 1 + 2v_2 \cos 2(\phi - \Phi_{\mathrm{RP}}), \quad (1)$$

where ϕ is the azimuthal direction of the particle and Φ_{RP} is the direction of the nuclear impact parameter ("reaction plane") in a given collision. Measurements of the parameter v_2 in RHIC collisions have been performed [1–6] for charged particles and for identified particles. The current work reports results for charged particles versus transverse momentum (p_T) out to 5 GeV/c, and extends previous measurements for identified particles out to 3 GeV/c for π and K, and to 4 GeV/c for protons. (Previous measurements of the v_2 for π, K, and p extended to 1 GeV/c at $\sqrt{s_{NN}} = 130$ GeV[2].) Detailed measurements of the azimuthal anisotropy are important to eventually discriminate among different possible scenarios for its physical origin. Such scenarios include hydrodynamical flow of compressed hadronic matter, the production of multiple minijets, and an anisotropy developed during an early quark-matter phase of the collision. It has been observed that v_2 saturates at $p_T \sim 2$ GeV/c and above [4,5]. The cause of this saturation is not yet known; however, we note that at this momentum the particle composition is very different than at low momentum in that the proton yield is comparable to the pion yield [7]. This makes the measurement of v_2 for separately identified particles especially interesting.

The measurements described here were carried out in the PHENIX experiment at RHIC [8]. About 28×10^6 minimum-bias Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV from the 2001–2002 run period (Run-2) are used in the analysis. Charged particles are measured in the central arm spectrometers ($|\eta| < 0.35$) [9] where PHENIX has excellent particle identification capabilities[10]. The drift chamber and the first pad chamber plane (PC1) together with the collision vertex define the charged particle tracks. In order to reduce background, the reconstructed tracks are confirmed by requiring matching hits in the outer detectors, i.e., the third pad chamber plane (PC3) and the electromagnetic calorimeter or the time-of-flight detector (TOF). In this analysis, the TOF detector is used to identify charged particles up to 4 GeV/c in p_T. Particle time-of-flight is measured using the TOF with respect to the collision time defined by beam counters (BBC), and is used to calculate mass squared using the particle momentum and the flight path length [7]. The timing resolution of the system is $\simeq 120$ ps. A momentum dependent $\pm 2\sigma$ cut on mass squared allows particle identification in the following p_T ranges: $0.2 < p_T < 3$ GeV/c for pions, $0.3 < p_T < 3$ GeV/c for kaons, and $0.5 < p_T < 4$ GeV/c for protons. The contamination of misidentified particles is less than 10%. In addition to collision time, the BBC provide z-vertex position information. The two beam counters are located at $|z| = 1.5$ m from the collision point, covering $|\eta| = 3$–4. They consist of 64 photomultiplier tubes (PMT) equipped with quartz Cherenkov radiators in front surrounding the beam pipe. The large charged multiplicity (a few hundred) in $|\eta| = 3$–4 and the nonzero signal of event anisotropy in this η range enable us to estimate the azimuthal angle of the reaction plane in each event using the BBC with full azimuthal angle coverage.

Since the v_2 parameter is in effect a quadrupole moment, the anisotropy which gives rise to a nonzero v_2 is often referred to as an "elliptic flow." It is extracted by first determining the reaction plane angle Φ_{RP} for each event,

$$\tan 2\Phi_{\mathrm{RP}} = \frac{\Sigma n_{\mathrm{ch}} \sin 2\phi_{\mathrm{PMT}}}{\Sigma n_{\mathrm{ch}} \cos 2\phi_{\mathrm{PMT}}}, \quad (2)$$

where n_{ch} is the number of charged particles per PMT (determined from the pulse height in each PMT) and ϕ_{PMT} is the azimuthal angle of each PMT. Then, it is calculated by the Fourier moment $v_2 = \langle \cos 2(\phi - \Phi_{\mathrm{RP}}) \rangle$ over all particles, for all events in a given sample [11]. Corrections [11–14] are applied to account for finite resolution in the reaction plane determination, and for possible azimuthal asymmetries in the reaction plane detector response. The bottom-left panel in Fig. 1 shows the average cosine of the difference between the two reaction planes defined by the beam counters at $\eta = 3$–4 and at $\eta = -4$–-3 using the elliptic (second) moment definition. In order to improve the reaction plane resolution, a combined reaction plane is defined by averaging the reaction plane angles obtained from each BBC, using the elliptic moment in each. The estimated resolution of the combined reaction plane [11], $\langle \cos 2(\Phi_{\mathrm{meas}} - \Phi_{\mathrm{true}}) \rangle$, has an average of 0.3 over centrality with a maximum of about 0.4. The estimated correction factor, which is the inverse of the resolution

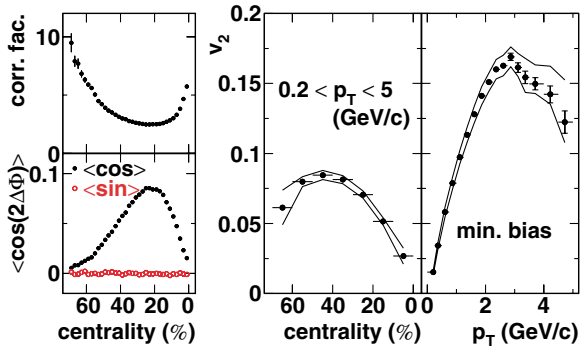

FIG. 1 (color online). Correlation of reaction planes between two beam counters for the second moment is shown as a function of centrality (bottom-left panel) and the correction factor for the combined reaction plane resolution of two beam counters is shown as a function of centrality (top-left panel). The value of v_2 for charged particles is shown as a function of centrality (middle panel) and as a function of p_T (right panel).

for the combined reaction plane, is shown in the top-left panel in Fig. 1.

The present technique is distinguished by defining the reaction plane angle using particles at high rapidity when measuring v_2 for particles at midrapidity. Other measurements of v_2 for midrapidity particles at RHIC have used reaction planes defined with midrapidity particles, or have employed a technique of measuring angular correlations between pairs of particles at midrapidity. While these different approaches generally seek to measure the same thing, they are not identical and a variety of physics effects can cause them to yield different results from the same collision sample [4,15,16]. Because of the large rapidity gap between the reaction plane and the midrapidity acceptance of about three units, it is expected that this analysis is less affected by nonflow contributions. However, we do not observe any substantial difference between the v_2 results shown here and published results for the v_2 of charged particles at RHIC in the p_T range where they are available.

The centrality of each collision is defined using the simultaneous measurement of the total number of particles measured in the BBC and the total energy measured in the zero degree calorimeter [17]. The middle panel in Fig. 1 shows the centrality dependence of v_2 for charged particles measured at midrapidity ($|\eta| < 0.35$) with respect to the reaction plane defined above. The centrality is measured in percentile from the most central collision. The v_2 parameter decreases for both peripheral and central collisions with a maximum at about 50% of the geometric cross section. Beyond 70%, the correction factor due to the reaction plane resolution is large, as shown in the leftmost panel in Fig. 1. This limits the centrality range used in this analysis.

The rightmost panel in Fig. 1 shows the transverse momentum dependence of v_2 for charged particles with respect to the reaction plane for minimum-bias events. The data above a p_T of 2 GeV/c clearly show a deviation from the monotonically increasing behavior seen at smaller p_T. The systematic errors are shown as line bands, which are estimated by several reaction plane methods using the two single beam counters or combined beam counters and by several different ways to correct nonuniform reaction plane distribution: "inverse weighting," "recentering of sine and cosine summation," "Fourier expansion," and combinations of those above [11,18]. Those systematic errors are estimated to be about 10%, depending on centrality, and are independent of p_T. Above 3 GeV/c, background tracks result in an additional systematic error of about 10%, depending on p_T, which is included in the upper error band [19].

In Fig. 2, the transverse momentum dependence of v_2 for identified particles is shown. The top-left panel shows negatively charged particles, while the top-right panel shows positively charged particles as described in the figure caption. The statistical errors and the systematic errors are plotted independently. From the lambda particle spectra measured in the PHENIX central arm, it is determined that approximately 35% of the protons originate from lambda decays ("lambda feed-down")[22]. The effect of the lambda feed-down on the measured v_2 of the proton is studied by varying the lambda v_2 with Monte Carlo simulation. Protons resulting from lambda feed-down increase the measured v_2 value. Using the value of the lambda v_2 measured at $\sqrt{s_{NN}} = 130$ GeV at RHIC [3], the effect on the proton v_2 would be less than 10%. Less than 5% of protons originate from decays of particles not involving the lambda. Based on further simulations of their decays to protons, we estimate that the total systematic error due to feed-down is at most 11% depending on p_T, which is included in the lower systematic error band in Fig. 2.

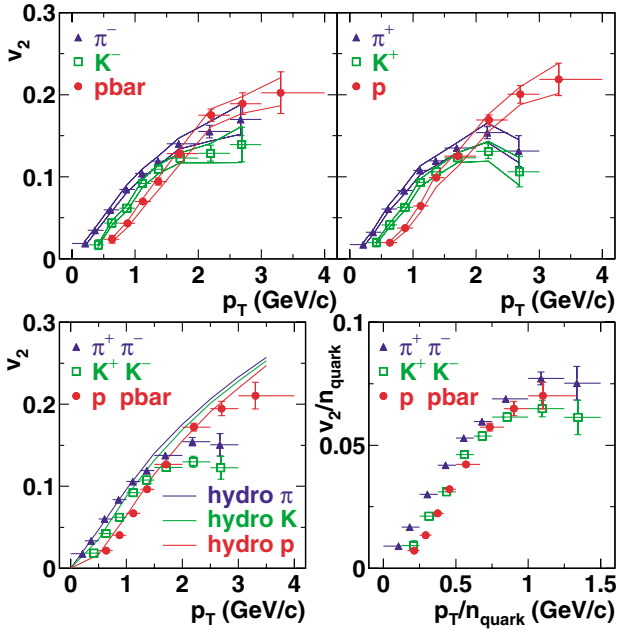

FIG. 2 (color online). Transverse momentum dependence of v_2 for identified particles, π^-, K^-, $\overline{p}$ (top-left panel) and π^+, K^+, p (top-right panel). The circles show p and $\overline{p}$, the squares show K^+ and K^-, and the triangles show π^+ and π^- for minimum-bias events. Statistical errors are represented by error bars and overall systematic error due to all sources by the solid lines in the top two panels. The combined positive particles and negative particles are shown in the bottom-left panel, and the lines there represent the result of a hydrodynamical calculation [20] including a first-order phase transition with a freeze-out temperature of 120 MeV for π, K, and p from upper to lower curves, respectively. The bottom-right panel shows the quark v_2 as a function of the quark p_T by scaling both axes with the number of quarks for each particle, as motivated by a quark-coalescence model [21].

The combined positive and negative particles are shown in the bottom-left panel. The lines in that panel represent a hydrodynamical calculation [20] including a first-order phase transition with a freeze-out temperature of 120 MeV. The data show that at lower p_T (<2 GeV/c), the lighter mass particles have a larger v_2 at a given p_T,

which is reproduced by the model calculations. We note, however, that the difference between the charged kaons and charged pions is larger than the model predicts.

A striking feature observed at higher p_T is that the v_2 of p and $\overline{p}$ are larger than for π and K at $p_T > 2$ GeV/c. This is in sharp contrast to the hydrodynamical picture, which would predict the same mass ordering for v_2 at all p_T. In our data the mesons begin to show a departure from the hydrodynamical prediction at p_T of about 1.5 GeV/c, while the (anti)baryons agree with the prediction up until 3 GeV/c but may be deviating at higher p_T. Such behavior is predicted by the quark-coalescence mechanism [21], as shown in the bottom-right panel where both v_2 and p_T have been scaled by the number of quarks. This could be an indication that the v_2 of measured hadrons is already established in a quark-matter phase, although it does not explain why the quark v_2 would saturate with p_T. There exist other scenarios that could be applicable at RHIC, but we have selected two simple models (hydrodynamical and quark coalescence) only to emphasize the experimental evidence of the crossing of v_2 for mesons and baryons.

As an additional illustration of the different behavior for mesons and baryons, the transverse momentum dependences of the v_2 parameter are shown in Fig. 3 for different particles and different centralities. Since the particle identification separation of K and p goes up to 4 GeV/c, the combined π and K can be compared with protons up to 4 GeV/c. The charged particle acceptance is larger than the TOF acceptance where the particle identification can be performed. Therefore, the statistical fluctuations for the charged particle v_2 are smaller than for the p, $\overline{p}$, and $\pi + K$. The trend exhibited in Fig. 2 for minimum-bias spectra, in which the v_2 for (anti)-baryons exceed those for mesons at $p_T > 2$ GeV/c, is shown here to occur for all centralities.

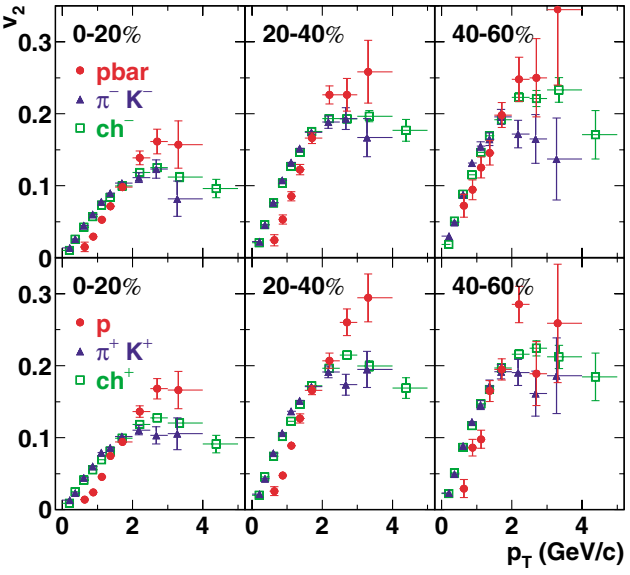

FIG. 3 (color online). Transverse momentum dependence of v_2 for combined π^- and K^- (top) or π^+ and K^+ (bottom) compared with $\overline{p}$ (top) and p (bottom). In addition, results for inclusive negative (top) and positive (bottom) charged particle distributions are plotted as open squares. From left to right, the different centrality selections are shown for 0%–20% (left), 20%–40% (middle), and 40%–60% (right).

In summary, the value of the v_2 parameter for identified and inclusive charged particle production at midrapidity has been measured with respect to the reaction plane defined in the forward and backward rapidity regions in $\sqrt{s_{NN}} = 200$ GeV Au + Au collisions, using the PHENIX experiment at RHIC. The value of v_2 for charged particles decreases for both peripheral and central collisions with a maximum at about the 50th percentile of the geometric cross section. We have observed that for charged particles v_2 increases with p_T up to about 2 GeV/c, then starts to saturate or decrease slightly. However, the detailed behavior is different for different particle species. The lighter particles have larger v_2 than the heavier particles for p_T below 2 GeV/c. This trend is partly reversed above 2 GeV/c where the proton and antiproton have larger v_2 than mesons, a pattern which persists over all centralities. A hydrodynamical calculation can reproduce the mass ordering and magnitude of v_2 for the different particles in the region up to 2 GeV/c, but fails to reproduce either in the p_T region above 2 GeV/c. As an alternative, we investigated the quark-coalescence scenario, in which the anisotropy of the final-state hadrons is largely inherited from the anisotropy of quarks in a preceding quark-matter phase. The quark-coalescence model makes a definite prediction for a simple scaling behavior between the v_2 for mesons and for (anti)baryons, and this scaling behavior is largely, though not perfectly, borne out in our data. Further measurements extending to higher p_T involving more identified species will be required to discriminate among alternative scenarios for the origin of elliptic flow at RHIC.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 28 April 2003; published 13 August 2003)

Transverse momentum spectra of neutral pions in the range $1 < p_T < 10$ GeV/c have been measured at midrapidity by the PHENIX experiment at BNL RHIC in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The π^0 multiplicity in central reactions is significantly below the yields measured at the same $\sqrt{s_{NN}}$ in peripheral Au + Au and $p + p$ reactions scaled by the number of nucleon-nucleon collisions. For the most central bin, the suppression factor is ~2.5 at $p_T = 2$ GeV/c and increases to ~4–5 at $p_T \approx 4$ GeV/c. At larger p_T, the suppression remains constant within errors. The deficit is already apparent in semiperipheral reactions and increases smoothly with centrality.

DOI: 10.1103/PhysRevLett.91.072301 PACS numbers: 25.75.Dw

High energy collisions of heavy ions provide the means to study quantum chromodynamics (QCD) at energy densities where lattice calculations [1] predict a transition from hadronic matter to a deconfined, chirally symmetric plasma of quarks and gluons (QGP). The large center-of-mass energies, $\sqrt{s_{NN}} \approx 200$ GeV, available in Au + Au collisions at the BNL Relativistic Heavy Ion Collider (RHIC), have resulted in a significant production of high transverse momentum hadrons ($p_T > 2$ GeV/c) for the first time in heavy-ion physics. High p_T particle production in hadronic collisions results from the fragmentation of quarks and gluons emerging from the initial high Q^2 parton-parton scatterings [2]. Thus, hard processes in nucleus-nucleus (AA) collisions provide direct information on the early partonic phases of the reaction. In the absence of nuclear medium effects, hard scattering yields in AA reactions are expected to scale like an incoherent superposition of nucleon-nucleon (NN) collisions because of the small probability of hard scattering processes per NN collision. In AA reactions, the number of NN collisions ($N_{\rm coll}$) at impact parameter b is simply proportional to the geometric nuclear overlap function, $T_{AA}(b)$, and can be calculated in an eikonal approach [3]. After scaling by the nuclear geometry, spectra of high p_T particles measured in AA reactions can be compared to the baseline $p + p$, $p + A$ data, as well as to perturbative [4–7] and classical-field [8] QCD predictions. Any departure from the expected $N_{\rm coll}$-scaled result provides information on the strongly interacting medium in central heavy-ion reactions.

One of the most significant observations from the first RHIC run (run 1) was the suppressed yield of moderately high p_T neutral pions ($p_T \approx 1.5$–4.0 GeV/c) in central Au + Au at $\sqrt{s_{NN}} = 130$ GeV with respect to the $N_{\rm coll}$-scaled $p + p$ and peripheral Au + Au data [9]. This result points to strong medium effects present in central Au + Au and has triggered extensive theoretical studies on its origin [4–8,10–13]. Most of these studies are based on the prediction [14,15] that a QGP would induce multiple gluon radiations from the scattered fast partons, effectively leading to a suppression of high p_T hadronic fragmentation products ("jet quenching"). Alternative interpretations have been proposed based on initial-state gluon saturation [8] or final-state hadronic interactions [13].

This Letter presents π^0 results obtained by the PHENIX experiment in Au + Au collisions at $\sqrt{s_{NN}} =$ 200 GeV and compares them to the $p + p \to \pi^0 X$ data measured in the same experiment at the same center-of-mass energy [16]. The analysis uses 30×10^6 minimum bias events, triggered by a coincidence between the zero degree calorimeters (ZDC) and the beam-beam counters (BBC), with vertex position $|z| < 30$ cm. In run 2, the electromagnetic calorimeter (EMCal) was fully instrumented providing a total solid angle coverage at midrapidity of approximately $\Delta\eta = 0.7$ and $\Delta\phi = \pi$ and the total collected π^0 statistics was a factor of $\sim$100 larger than in run 1 [9]. The combination of larger acceptance, high statistics, and the measurement of $p + p$ data in the same detector permits a precise study of the high p_T π^0 production mechanisms in AA collisions at RHIC.

Neutral pions are reconstructed via their $\pi^0 \to \gamma\gamma$ decay through an invariant mass analysis of γ pairs detected in the EMCal [17] which consists of six lead-scintillator (PbSc) and two lead-glass Čerenkov (PbGl) sectors. The large radial distance of the calorimeters to the interaction region (> 5 m) and their fine granularity ($\Delta\eta \times \Delta\phi \approx 0.01 \times 0.01$) keep the tower occupancy low, $<10\%$ even in the highest multiplicity Au + Au events. The energy calibration is obtained from beam tests and, in the case of PbSc, from cosmic rays data and the known minimum ionizing energy peak of charged hadrons traversing the calorimeter. It is then confirmed using the π^0 mass, as well as the agreement of the calorimeter energy with the measured momentum of identified electrons. The systematic error on the absolute energy scale is less than 1.5%. Photonlike clusters are identified in the EMCal by applying time-of-flight and shower profile cuts [17]. The selected clusters are binned in pair invariant mass $m_{\gamma\gamma}$ and p_T. An additional energy asymmetry cut, $|E_{\gamma 1} - E_{\gamma 2}|/(E_{\gamma 1} + E_{\gamma 2}) <$ 0.7(PbGl), 0.8(PbSc), is applied to the reconstructed pairs. The signal-to-background in peripheral (central) is approximately 20 (5) and 0.5 (0.01) for the highest and lowest p_T, respectively. The combinatorial background is estimated and subtracted by mixing clusters from different events with similar centrality and vertex, and normalizing the distribution in a region outside the π^0 mass peak. The π^0 yield in each p_T bin is determined by integrating the subtracted $m_{\gamma\gamma}$ distribution in a $\pm 3\sigma$ window determined by a p_T-dependent parametrization of Gaussian fits to the π^0 peaks.

The raw PbSc and PbGl π^0 spectra are normalized to one unit of rapidity and full azimuth (this acceptance correction quickly reaches the $\sim 1/0.35$ pure geometric factor at high p_T). The spectra are further corrected for (i) the detector response (energy resolution, dead areas), (ii) the reconstruction efficiency (analysis cuts), and (iii) the occupancy effects (cluster overlaps). These corrections are quantified by embedding simulated single π^0's from a full PHENIX GEANT [18] simulation into real events, and analyzing the merged events with the same analysis cuts used to obtain the real yields. Each correction is determined, for each centrality bin, as the ratio of the input to the reconstructed simulated p_T distributions. The overall yield correction amounts to $\sim$2.5 with a centrality dependence $\lesssim 25\%$. The losses are dominated by fiducial and asymmetry cuts.

The main sources of systematic errors in the PbSc and PbGl measurements are due to the uncertainties in (i) the yield extraction (background subtraction and $m_{\rm inv}$ integration), (ii) the yield correction (efficiency factors), and

TABLE I. Summary of the dominant sources of systematic errors on the PbSc and PbGl π^0 yields and total errors on the combined measurements. The error ranges are quoted for the lowest to highest p_T values.

Source		Syst. error PbSc	Syst. error PbGl	
Yield extraction		10%	6%–7%	
Yield correction		8%	8%	
Energy scale		3%–11%	7%–13%	
Total error (%)	Stat.	Syst.	Normalization Central	Peripheral
Comb. π^0 spectra	2–40	10–17	5	5
R_{AA}	2–45	11–22	14	30

(iii) the energy scale (absolute calibration of the calorimeter). The relative contributions of these effects to the total error differ for the PbSc and PbGl (Table I). The weighted average of the two independent measurements reduces the total error. The nominal energy resolution [17] is adjusted in the simulation to reproduce the true width of the π^0 peak observed at each p_T, smearing the energies with a constant term of 7% for PbSc and ~9% for PbGl. The shape, position, and width of the π^0 peak measured in all different centralities are then confirmed to be well reproduced by the embedded data. The final systematic errors on the spectra are at the level of ~10% at 1 GeV/c and ~17% at the highest p_T (Table I). A correction for the true mean value of the p_T bin is applied to the steeply falling spectra. No corrections have been applied to account for the contribution of feed-down π^0's (mainly coming from K^0_s and η decays) which are <5% based on HIJING [19] simulations.

The event centrality is determined by correlating the charge detected in the BBC with the energy measured in the ZDC detectors. A Glauber model Monte Carlo (MC) calculation combined with a simulation of the BBC and ZDC responses [20–22] gives an estimate of the associated averaged number of binary collisions ($\langle N_{\rm coll}\rangle$) and participating nucleons ($\langle N_{\rm part}\rangle$) in each centrality bin (Table II). Fully corrected and combined PbSc and PbGl π^0 p_T distributions are shown in Fig. 1 for minimum bias and for nine centrality bins scaled by factors of 10.

We quantify the medium effects on high p_T production in AA collisions with the *nuclear modification factor* given by the ratio of the measured AA invariant yields to the NN collision scaled $p + p$ invariant yields:

$$R_{AA}(p_T) = \frac{(1/N^{\rm evt}_{AA}) d^2N^{\pi^0}_{AA}/dp_T dy}{\langle N_{\rm coll}\rangle/\sigma^{\rm inel}_{pp} \times d^2\sigma^{\pi^0}_{pp}/dp_T dy}, \quad (1)$$

where the $\langle N_{\rm coll}\rangle/\sigma^{\rm inel}_{pp}$ is just the average Glauber nuclear overlap function, $\langle T_{\rm AuAu}\rangle$, in the centrality bin under consideration (Table II). $R_{AA}(p_T)$ measures the deviation of AA data from an incoherent superposition of NN collisions. For $p_T \lesssim 2$ GeV/c, R_{AA} is known to be below unity, since the bulk of particle production is due to soft processes which scale closer to the number of participant nucleons [20] than to $\langle N_{\rm coll}\rangle$.

TABLE II. Centrality bin, average nuclear overlap function, number of NN collisions, and number of participant nucleons from a Glauber MC [21,22] and the BBC and ZDC responses for Au + Au at $\sqrt{s_{NN}} = 200$ GeV. The centrality bin is expressed as percentiles of $\sigma_{\rm AuAu} = 6.9$ b.

Centrality	$\langle T_{\rm AuAu}\rangle$ (mb^{-1})	$\langle N_{\rm coll}\rangle$	$\langle N_{\rm part}\rangle$
0%–10%	22.75 ± 1.56	955.4 ± 93.6	325.2 ± 3.3

Figure 2 shows R_{AA} as a function of p_T for π^0 measured in 0%–10% central (closed circles) and 80%–92% peripheral (open circles) Au + Au. The PHENIX $p + p \rightarrow \pi^0$ data [16] is used as the reference in the denominator. The R_{AA} values for central collisions are noticeably below unity, as found at 130 GeV [9]. This is in contrast to the enhanced high p_T π^0 production ($R_{AA} > 1$) observed

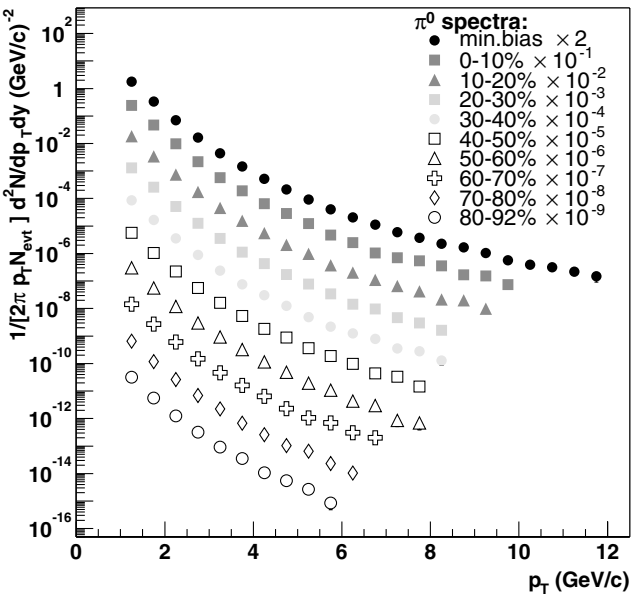

FIG. 1. Invariant π^0 yields at midrapidity as a function of p_T for minimum bias and nine centralities in Au + Au at $\sqrt{s_{NN}} = 200$ GeV [0%–10% (80%–92%) is most central (peripheral)].

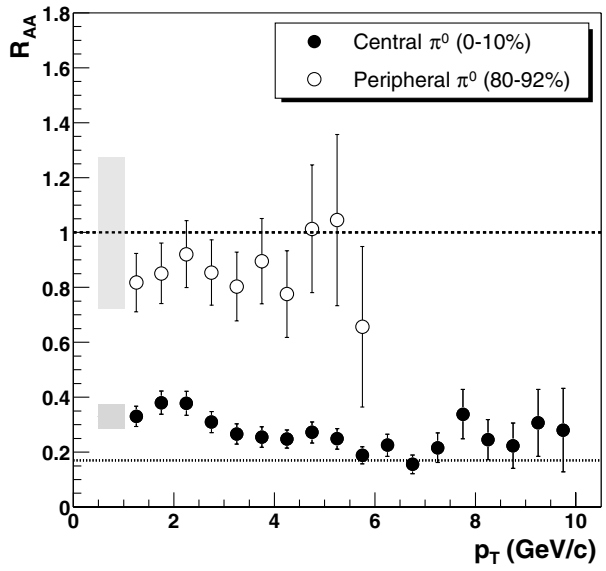

FIG. 2. Nuclear modification factor $R_{AA}(p_T)$ for π^0 in central (closed circles) and peripheral (open circles) Au + Au at $\sqrt{s_{NN}} = 200$ GeV. The error bars include all point-to-point experimental ($p + p$, Au + Au) errors. The shaded bands represent the fractional uncertainties in $\langle T_{\mathrm{AuAu}} \rangle$ and in the π^0 yields normalization added in quadrature, which can move all the points up or down together (in the central case the shaded band shown is the fractional error for the first point).

at CERN Super Proton Synchrotron energies [23], interpreted in terms of initial-state p_T broadening effects ("Cronin effect" [24]). Within errors, peripheral Au + Au collisions behave like a superposition of $p + p$ collisions with regard to high p_T π^0 production ($R_{AA} \approx 1$). In central collisions, the suppression is smallest at 2 GeV/c and increases to an approximately constant suppression factor of $1/R_{AA} \approx 4$–5 over the p_T range of 4–10 GeV/c, ~30% above the expectation from N_{part} scaling (dotted line in Fig. 2).

The magnitude and p_T dependence of R_{AA} (corresponding to parton fractional momenta $x \approx 2p_T/\sqrt{s} \sim 0.02$–$0.1$ at midrapidity) is inconsistent with the expectations of leading-twist "shadowing" effects on the nuclear parton distribution functions alone [25]. Different jet quenching calculations [4–7,10–12], based on medium-induced radiative energy loss, can reproduce the magnitude of the π^0 suppression assuming the formation of a hot and dense partonic system. The predicted p_T dependence of the quenching, however, varies in the different models. All models that include the Landau-Pomeranchuck-Migdal (LPM) interference effect [15,26] predict R_{AA} effectively $\propto \sqrt{p_T}$ [10]. Such a trend is not compatible with our data over the entire p_T range. Analyses which combine LPM jet quenching together with shadowing and initial-state p_T broadening generally reproduce the whole p_T dependence of the π^0 suppression [4], as do recent approaches that take into account detailed balance between parton emission and absorption [7]. However, based solely on the data presented here, we are not able to distinguish between partonic or hadronic [13] energy loss scenarios.

The centrality dependence of the high p_T π^0 suppression is shown in Fig. 3 as a function of $\langle N_{\mathrm{part}} \rangle$. The suppression is characterized as the ratio of Au + Au over $p + p$ yields integrated above 4 GeV/c and normalized using two different scalings. R_{AA} (circles) denotes the N_{coll} scaling as in Eq. (1), whereas R_{AA}^{part} (crosses) indicates N_{part} scaling expected in scenarios dominated either by gluon saturation [8] or by surface emission of the quenched jets [10]. Figure 3 indicates that the transition from the N_{coll} scaling behavior ($R_{AA} \sim 1$) apparent in the most peripheral region, to the strong suppression seen in central reactions ($R_{AA} \sim 0.25$) is smooth. In addition, although there is no exact participant scaling ($R_{AA}^{\mathrm{part}} > 1$ for all centralities), the π^0 production per participant pair above 4 GeV/c is approximately constant over a wide range of intermediate centralities, in qualitative agreement with a parton saturation model prediction [8].

In summary, transverse momentum spectra of neutral pions have been measured at midrapidity up to $p_T \approx 10$ GeV/c for nine centrality bins of Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. The spectral shape and invariant yield for peripheral reactions are consistent with those of $p + p$ reactions scaled by the average number of inelastic NN collisions. Central yields, on the other hand, are significantly lower than peripheral Au + Au and $p + p$ scaled yields, as found at $\sqrt{s_{NN}} = 130$ GeV. The observed suppression increases slowly with p_T to as much as a factor of 4–5 in the 10% most central collisions,

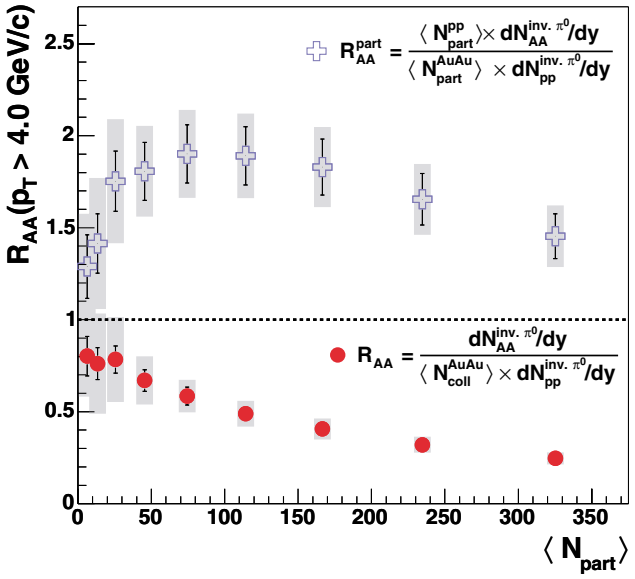

FIG. 3 (color online). Ratio of Au + Au over $p + p$ π^0 yields integrated above 4 GeV/c and normalized using $\langle N_{\mathrm{coll}} \rangle$ (circles) and $\langle N_{\mathrm{part}} \rangle$ (crosses), as a function of centrality given by $\langle N_{\mathrm{part}} \rangle$. The errors bands and bars are the same as for Fig. 2.

remaining constant within errors above ~ 4 GeV/c. The suppression is already apparent in semiperipheral reactions and increases smoothly with centrality. The magnitude of the deficit can be reproduced by parton energy loss calculations in an opaque medium, but its p_T and centrality dependence puts strong constraints on the details of energy loss and the properties of the medium. The role of initial-state effects, including shadowing, p_T broadening, and gluon saturation will be studied with data from the recent RHIC run using $d + \mathrm{Au}$, where final-state medium effects such as jet quenching are minimal.

(Received 28 April 2003; published 11 December 2003)

The invariant differential cross section for inclusive neutral-pion production in $p + p$ collisions at $\sqrt{s} = 200$ GeV has been measured at midrapidity ($|\eta| < 0.35$) over the range $1 < p_T \lesssim 14$ GeV/c by the PHENIX experiment at the Relativistic Heavy Ion Collider. Predictions of next-to-leading order perturbative QCD calculations are consistent with these measurements. The precision of our result is sufficient to differentiate between prevailing gluon-to-pion fragmentation functions.

DOI: 10.1103/PhysRevLett.91.241803 PACS numbers: 13.85.Ni, 13.87.Fh, 25.75.Dw

Particle production at large transverse momenta, p_T, in hadronic reactions has provided an important testing ground for perturbative quantum chromodynamics (pQCD) [1]. Next-to-leading order (NLO) pQCD calculations describe Tevatron ($\sqrt{s} = 1.8$ TeV) measurements of inclusive jet production [2] within 10% and direct photon production [3], in which the elementary quark-gluon scattering produces a photon directly, within 50%.

For high-p_T pion production, the recent calculations have not been compared with the UA2 data [4] obtained at $\sqrt{s} = 540$ GeV. However, at lower center of mass energies ($\sqrt{s} \lesssim 63$ GeV), they underestimate the data by a factor of $\sim$2.5 [5]. Similar discrepancies were observed for direct photon measurements from fixed target experiments [6] and were attributed to effects of soft-gluon radiations beyond NLO [7], to effects of initial intrinsic transverse momentum, k_T [8], or to experimental problems in the difficult direct photon measurements [9,10]. The π^0 calculations, as compared to the jet or direct photon calculations, also require the probability for the scattered quark or gluon to fragment into a pion.

Information on fragmentation to pions [11–15] has principally come from global analyses of inclusive hadron production in e^+e^- annihilation. These analyses constrain the quark-to-pion fragmentation functions well but, via the scale dependence, the gluon-to-pion fragmentation function to a lesser extent. For example, the latter function at a scale of 100 GeV^2 can vary by a factor of 2 to 10 when the fraction of the initial gluon momentum carried by the pion is above 0.5. The more direct measurements of gluon fragmentation functions from b-tagged, three jet event data from the Large Electron-Positron Collider [16] have played a limited role in the global analyses because NLO corrections are unavailable for the quantitative treatment, including scale and scheme dependencies, of these data. As has been explored for measurements of inclusive hadron production in $p + \bar{p}$ collisions [17], results from inclusive pion production at high p_T can be included in the global NLO analyses and thus may provide meaningful constraints on the gluon-to-pion fragmentation. These results also provide a reference needed for quantifying the suppression of π^0 production observed in Au-Au collisions at the Relativistic Heavy Ion Collider (RHIC) [18] and, to the extent of agreement with the calculations, the foundations for the planned polarized gluon density measurement with polarized protons in the RHIC [19].

In this Letter, we report the first results on inclusive neutral-pion production in $p + p$ collisions at a center of mass energy ($\sqrt{s}$) of 200 GeV as extracted from the data collected during the 2001–2002 run period (Run-2) of RHIC. The bunched proton beams in the collider were vertically polarized with spin orientations alternating in successive bunches. By balancing the integrated luminosity in the different spin states, the effects from polarization were canceled at the 0.1% level.

In Run-2, the PHENIX experiment [20] operated two central arm spectrometers, one muon arm spectrometer, and other detectors for triggering and vertex determination. This work used the beam-beam counters (BBC) [21] for determining the collision vertex and constructing the minimum bias (MB) trigger, and the electromagnetic calorimeters (EMCal) [22] for detecting the neutral pions and deriving high-p_T triggers.

The unbiased differential cross section for π^0 production is calculated from the MB triggered data sample as

$$E\frac{d^3\sigma}{dp^3} = \frac{1}{\hat{\mathcal{L}}}\frac{1}{2\pi p_T^*}\frac{C_{\rm reco}C_{\rm conv}}{f_{\pi^0}}\frac{N_{\pi^0}}{\Delta p_T \Delta y}, \qquad (1)$$

where N_{π^0} is the number of π^0's observed in a Δp_T wide bin at p_T^* defined as the p_T for which the cross section equals its average over the bin; Δy is the rapidity range; $C_{\rm reco}$ is a correction for the acceptance, reconstruction efficiency, and p_T smearing; $C_{\rm conv}$ is a correction for the conversion of decay photons; f_{π^0} is the fraction of the inclusive π^0 yield for which the MB trigger condition was satisfied; and $\hat{\mathcal{L}}$ is the integrated luminosity for the analyzed data sample. The high-p_T triggered sample required an additional correction to account for the efficiency of this trigger for π^0 detection.

The MB trigger imposed the requirement that the collision vertex was within 75 cm of the center of the interaction region. This vertex was reconstructed from the difference in the arrival times of particles at the BBCs which were located along the beam line at ± 1.44 m from the nominal interaction point and subtended the pseudorapidity range $\pm(3.0$–$3.9)$ with full azimuthal coverage. In the analysis of the data, a more restrictive requirement of ± 30 cm was applied.

The EMCal consisted of two subsystems: a six sector, lead scintillator (PbSc) calorimeter and a two sector, lead glass (PbGl) calorimeter. Located at a radial distance of $\sim$5 m from the beam line, each of these sectors covered the pseudorapidity range of $|\eta| < 0.35$ and an azimuthal angle interval of $\Delta\phi \approx 22.5°$. Each of the towers in the calorimeter subtended $\Delta\phi \times \Delta\eta \sim 0.01 \times 0.01$, thus ensuring that the two photons from a decayed π^0 were clearly resolved up to a p_T of 12 GeV/c. Shower profile analysis can extend this p_T range beyond 20 GeV/c. The energy calibration was corroborated by the position of the π^0 invariant mass peak, the energy deposit from minimum ionizing charged particles traversing the EMCal (PbSc), and the correlation between the energy deposit in the EMCal and the measured momentum for electrons and positrons identified by the ring-imaging Čerenkov detector. These studies showed that the accuracy of the energy measurement was within 1.5%. At a p_T of $\sim$11 GeV/c, this uncertainty translates into a systematic error on the π^0 yield of $\sim$12%. The effective energy resolution for the data set was deduced from the widths of the π^0 mass peaks, which varied with p_T from 7% to 10% (PbSc) and from 12% to 13% (PbGl), and a comparison of the measured energy and momentum for identified electrons and positrons.

The number of recorded high-p_T π^0's was enhanced by a high-p_T trigger (denoted as 2×2) in which threshold discrimination was applied independently to sums of the analog signals from nonoverlapping, 2×2 groupings (called tiles) of adjacent EMCal towers. During this run, the thresholds corresponded to a deposited energy of 0.75 GeV. The efficiency of this trigger for π^0

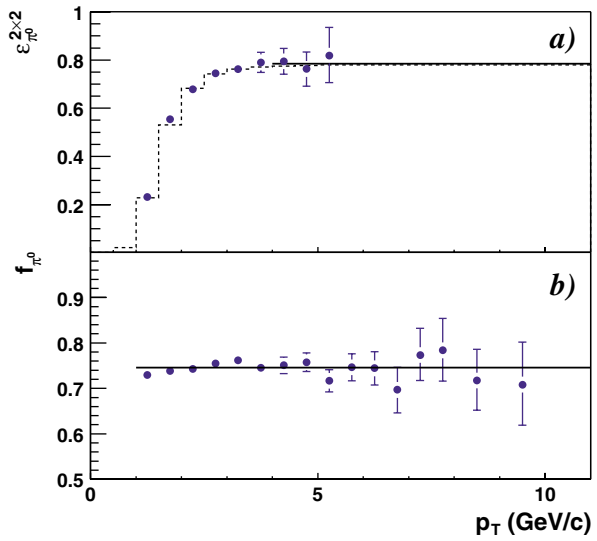

FIG. 1 (color online). (a) The efficiency of the 2×2 high-p_T trigger for π^0 as a function of the p_T of the π^0. The dashed and solid lines show the results of a Monte Carlo simulation based on the 2×2 trigger tile efficiencies and the limit derived from the fraction of active trigger tiles, respectively. (b) The fraction of the inclusive π^0 yield which satisfied the MB trigger condition. The solid line shows a fit of these data to a constant.

detection, $\varepsilon_{\pi^0}^{2\times2}(p_T)$, was obtained from the MB data. As shown in Fig. 1(a), this efficiency reached a plateau at a p_T of $\sim$3 GeV/c. This dependence was reproduced by Monte Carlo calculations which included the tile threshold curves, the EMCal detector response, and the geometry of the active trigger tiles. The plateau level, 0.78 ± 0.03 for both PbSc and PbGl, was consistent with the geometrical acceptance of the active trigger tiles.

Since only a fraction of inelastic $p + p$ collisions produce particles which enter both BBCs, the MB trigger condition biased the recorded data sample, so only a fraction, f_{π^0}, of the inclusive π^0 yield was detected. This fraction was determined from data collected by an additional, high-p_T trigger which had not been operated in coincidence with the MB trigger. This trigger was formed by threshold discrimination of the sums of the analog signals from overlapping 2×2 groupings of adjacent 2×2 trigger tiles. As shown in Fig. 1(b), the fraction of these high-p_T events with π^0's for which the MB condition was also satisfied was 0.75 ± 0.02, independent of p_T.

In each event, the two photon invariant mass was calculated for each pairing of clusters. Clusters were paired if the energy asymmetry, $|E_1 - E_2|/(E_1 + E_2)$, was less than 0.8 (PbSc) or 0.7 (PbGl). For the PbGl, the pairings were further restricted to those clusters which were identified as electromagnetic via the shower profile and time of flight. The π^0 yield was extracted by integrating the invariant mass spectrum over a region around the π^0 mass. The background contribution in each p_T bin was estimated and then subtracted by fitting the invariant mass distribution outside the peak region (PbSc) or using the mixed event technique (PbGl). For the PbSc and the PbGl, the background to signal ratio varied with increasing p_T from 1 to 0.1 and 1 to 0.03, respectively.

The raw yields were corrected for the p_T smearing arising from the EMCal energy resolution and the steeply falling spectrum, and for the losses due to disabled towers, incomplete azimuthal coverage, energy asymmetry cut, and photon identification cut (PbGl). The correction for these effects, C_{reco}, was calculated with Monte Carlo simulations which contained the configuration of the active EMCal towers. The energy and position of the decay photons were smeared with the measured test beam resolutions [22] augmented by a constant energy smearing of 5% (12%) for the PbSc (PbGl) to match the response of the EMCal.

The correction for the losses due to conversions of decay photons, C_{conv}, was determined to be 4% (PbSc) and 9% (PbGl) by using a GEANT3 [23] simulation of the PHENIX detector. The same simulation, using $p + p$ events from the PYTHIA generator [24], showed that the contribution of π^0's from secondary interactions was negligible and that the contribution from decays of other hadrons (e.g., K^0 and η mesons) was less than 6%. The π^0 spectrum was not corrected for these decays.

The integrated luminosity, $\hat{\mathcal{L}}$, was determined from the number of MB events using an absolute calibration of the trigger cross section obtained via the van der Meer scan technique [25]. In a scan, the transverse profile of the beam overlap is measured by sweeping one beam across the other in steps while monitoring the MB trigger rate. This information, the bunch intensities of the two beams ($\sim 10^{11}$/bunch), and the revolution frequency (78 kHz) are then used to compute the instantaneous luminosity. The trigger cross section is the ratio of the MB trigger rate when the beams were overlapping maximally to the instantaneous luminosity. Based on three scans, this cross section was 21.8 ± 0.9 (2.8) mb at the 68.5% (95%) confidence level with an absolute error of 0.7 mb. From the linear sum of the absolute error and half of the 95% confidence level, point-to-point systematic error, an error of 9.6% was assigned for the luminosity normalization.

During the run, the maximum and average instantaneous luminosities were 1.5×10^{30} and 0.5×10^{30} cm^{-2} s^{-1}, respectively. Contributions from multiple collisions per bunch crossing and beam-gas interactions were negligible. The MB trigger sample of 16×10^6 events corresponded to 0.7 nb^{-1}. As computed from the fraction of recorded MB events which also met the 2×2 high-p_T trigger condition ($\sim 1/47$), the 18×10^6 high-p_T triggered events corresponded to an effective luminosity of 39 nb^{-1}.

The invariant differential cross sections obtained from the MB and high-p_T samples were consistent within the statistical errors over the p_T region of overlap ($p_T \leq 5.5$ GeV/c). Moreover, the results determined

independently from the PbSc and the PbGl data samples were consistent within the total error as computed as the quadrature sum of the statistical and point-to-point systematic errors. The main sources of the latter were (i) the absolute energy scale, (ii) the extraction of the yield, (iii) the correction of the yield for reconstruction efficiency, and (iv) the correction of the yield for the geometric acceptance. The magnitude of these errors is tabulated for a low- and a high-p_T bin in Table I.

From the MB and the high-p_T trigger samples for p_T below and above 4 GeV/c, respectively, the cross section and the errors were obtained by averaging the PbSc and PbGl results using the total error for the weighting. Figures 2(a) and 2(b) show this combined result and its fractional statistical and systematic uncertainties ($\Delta\sigma/\sigma$). The data are well parametrized by a power-law form $A(1 + p_T/p_0)^{-n}$ with parameters of $A = 393\ \text{mb}\,\text{GeV}^{-2}\,c^3$, $p_0 = 1.212$ GeV/c, and $n = 9.97$.

In Fig. 2, our results are compared with NLO pQCD calculations [26–28]. In these calculations, the cross section is factorized into parton distribution functions (PDFs) for the protons, parton-to-pion fragmentation functions, and short-distance partonic hard-scattering cross sections which can be evaluated using perturbative QCD. Because of this factorization, the calculations depend on unphysical, factorization and renormalization scales which are of the order of the hard scale p_T. This dependence is reduced as higher order terms are included in the perturbation expansion and thus serves as a gauge for the uncertainty of calculations truncated at a given order.

The calculations in Fig. 2 were performed with equal renormalization and factorization scales of $p_T/2$, p_T, and $2p_T$, the CTEQ6M [29] set of PDFs, and two sets of fragmentation functions. In general, these calculations are consistent with the data, even at low p_T (<2 GeV/c) where the theory might be expected to be less applicable. The calculations vary slightly (~15%) with the choice of PDFs, whereas they change markedly with the choice of fragmentation functions. As shown in Figs. 2(c) and 2(d), the calculation with the "Kniehl-Kramer-Pötter" (KKP) set of fragmentation functions [12] agrees with our data better than the calculation with the "Kretzer" set [13] does. These two sets differ mainly in that the gluon-to-pion fragmentation function, D_g^π, is greater in the KKP set. This difference is exhibited primarily at low p_T because of the dominance of gluon-gluon and gluon-quark interactions for p_T below ~10 GeV/c [26]. Our data are the first from a hadron experiment from which an unambiguous conclusion may be drawn about D_g^π.

In summary, the invariant differential cross section for inclusive neutral-pion production in $p + p$ collisions at $\sqrt{s} = 200$ GeV was measured at midrapidity ($|\eta| < 0.35$) as a function of p_T up to ~14 GeV/c. These results were compared with two NLO pQCD calculations which differed in the choice of fragmentation functions. Over the full range of p_T, the calculations were consistent with the results within the uncertainty of the calculations as judged from the scale dependence, although the results favored a larger gluon-to-pion fragmentation function.

TABLE I. Summary of the sources of systematic errors on the π^0 yields and the total systematic error for p_T of 1.2 and 10.9 GeV/c. The normalization error of 9.6% is not listed.

	% Error (PbSc)		% Error (PbGl)	
p_T (in GeV/c)	1.2	10.9	1.2	10.9
Energy scale	3	11	6	12
Yield extraction	7	4	5	5
Yield correction	3	6	6	11
Acceptance stability	4.5	4.5	3	2
Total	9	14	10	17

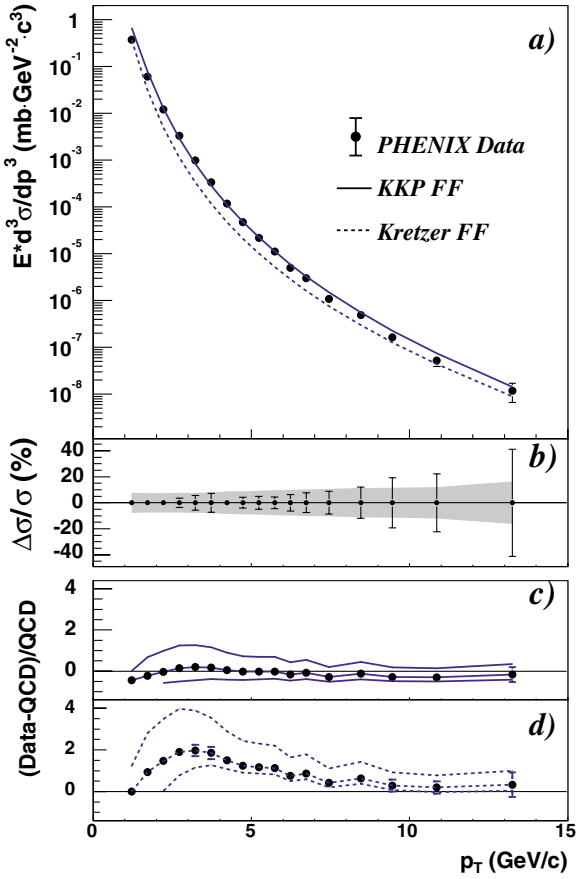

FIG. 2 (color online). (a) The invariant differential cross section for inclusive π^0 production (points) and the results from NLO pQCD calculations with equal renormalization and factorization scales of p_T using the "Kniehl-Kramer-Pötter" (solid line) and "Kretzer" (dashed line) sets of fragmentation functions. (b) The relative statistical (points) and point-to-point systematic (band) errors. (c),(d) The relative difference between the data and the theory using KKP (c) and Kretzer (d) fragmentation functions with scales of $p_T/2$ (lower curve), p_T, and $2p_T$ (upper curve). In all figures, the normalization error of 9.6% is not shown.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We thank Werner Vogelsang and Stefan Kretzer for their interest and input. (Received 1 October 2002; published 31 January 2003)

Several hadronic observables have been studied in central 158*A* GeV Pb+Pb collisions using data measured by the WA98 experiment at CERN: single π^- and K^- production, as well as two- and three-pion interferometry. The Wiedemann-Heinz hydrodynamical model has been fitted to the pion spectrum, giving an estimate of the temperature and transverse flow velocity. Bose-Einstein correlations between two identified π^- have been analyzed as a function of k_T, using two different parametrizations. The results indicate that the source does not have a strictly boost invariant expansion or spend time in a long-lived intermediate phase. A comparison between data and a hydrodynamical based simulation shows very good agreement for the radii parameters as a function of k_T. The pion phase-space density at freeze-out has been measured, and agrees well with the Tomášik-Heinz model. A large pion chemical potential close to the condensation limit of m_π seems to be excluded. The three-pion Bose-Einstein interferometry shows a substantial contribution of the genuine three-pion correlation, but not quite as large as expected for a fully chaotic and symmetric source.

I. INTRODUCTION

The study of single-particle distributions of particles produced in heavy-ion collisions gives access to the degree of thermal and chemical equilibrium at freeze-out, and allows the determination of the parameters of hydrodynamical expansion models of the source. The spatiotemporal extension of the interaction region created in such collisions is not

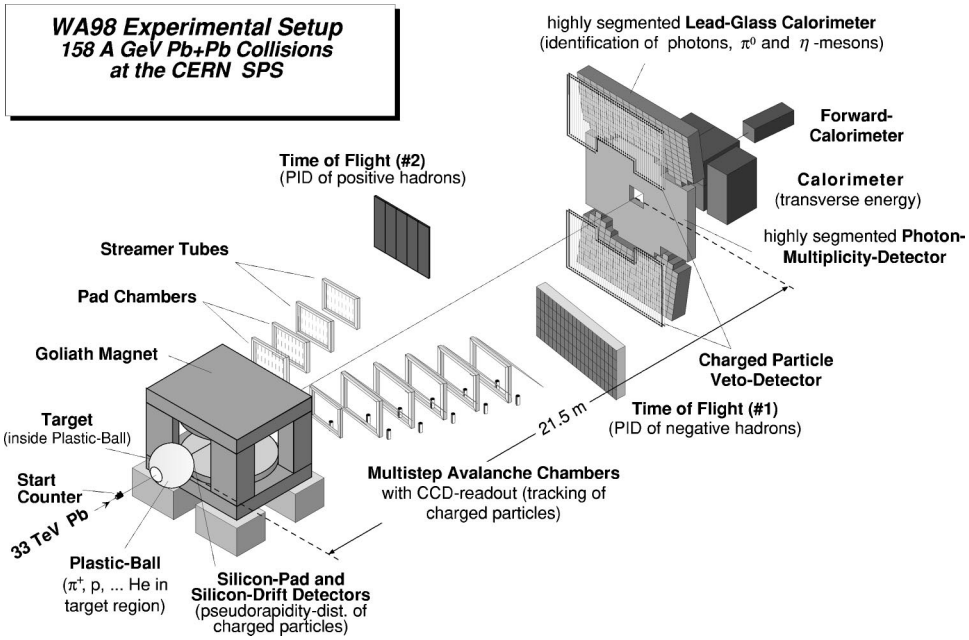

FIG. 1. The WA98 experimental setup.

directly observable, but the study of Bose-Einstein interferometry between identical particles provides information on the geometry and on the dynamical evolution of the particle emission sources. In particular, the correlations between produced pions give access to the size of the homogeneity region, to the duration of emission, and to various parameters characterizing the spatial extension of the fireball [1]. In addition, by combining information from the source size in momentum-space obtained by interferometry, and from the momentum-space density provided by the single-particle distributions, an average phase-space density at freeze-out can be calculated.

Compared to the two-particle correlation, the three-particle correlation can provide additional information on the chaoticity and asymmetry of the source emission [2–4]. In particular, the three-pion interference produced by a fully chaotic source is sensitive to the phase of the Fourier transform of the source emission function and, hence, to the asymmetry of the source.

In this paper, we present the analysis of single-particle production, and of two- and three-pion interferometry measured in the WA98 experiment for central 158*A* GeV ^{208}Pb+^{208}Pb collisions at the CERN SPS. In addition, estimates of hydrodynamical expansion model parameters, temperature and transverse flow velocity are extracted from these results.

II. EXPERIMENTAL SETUP AND DATA PROCESSING

The CERN SPS fixed target experiment WA98 [5] combined large acceptance photon detectors with a two arm charged particle tracking spectrometer. The experimental layout is shown in Fig. 1. The 158*A* GeV Pb beam interacted with a Pb target near the entrance of a large dipole magnet. The online trigger centrality selection used a forward calorimeter located at 0° and a midrapidity calorimeter measuring the total transverse energy in the pseudorapidity interval $3.2 \leqslant \eta \leqslant 5.4$. The results presented here have been obtained from an analysis of the complete data set. These data were taken with the most central triggers corresponding to about 10% of the minimum bias cross section of 6300 mb [6,7], with an average of 330 participating nucleons per collision. These quantities are estimated to have an overall systematic error of less than 10%. The charged particle spectrometer made use of a 1.6-Tm dipole magnet with a 2.4×1.6-m^2 air gap which deflected the charged particles in the horizontal plane into two tracking arms located downstream, one on each side of the beam axis. The results shown here are measurements of π^- and K^- observed in the negative particle tracking arm of the spectrometer. This tracking arm consisted of six multistep avalanche chambers with optical readout [8]. Inside the chambers, triethylamine photoemissive vapor produced UV photons along the path of charged particles, these photons being subsequently converted to visible light via wavelength shifter plates. On exit, the light was reflected by mirrors at 45° to CCD cameras equipped with two image intensifiers. The active area of the first chamber was 1.2×0.8 m^2 and that of the other five 1.6×1.2 m^2. Each CCD camera pixel viewed a region of about 3.1×3.1 mm^2 on the chambers. Downstream of the chambers, at a distance of 16.5 m from the target, a 4×1.9-m^2 time of flight wall allowed for particle identification with a time resolution of better than 120 ps. The resulting particle separation is shown in Fig. 2. The π^- rapidity acceptance ranged from $y=2.1$ to 3.1 with a rapidity average at 2.7, close to the midrapidity value of 2.9. The momentum resolution of the spectrometer was $\Delta p/p=0.005$ at $p=1.5$ GeV/c, resulting in an average precision of better than or equal to 10 MeV/c at vanishing p_T for all the Q variables used in the correlation analysis and defined in Secs. IV and VI: $\sigma(Q_{inv})=7$ MeV/c, $\sigma(Q_{TO})=10$ MeV/c, $\sigma(Q_{TS})=5$ MeV/c, $\sigma(Q_L)=3$ MeV/c, $\sigma(Q_T)=8$ MeV/c, $\sigma(Q_0)=5$ MeV/c, and $\sigma(Q_3)=7$ MeV/c. Severe track quality cuts were applied, resulting in a final sample of 7.9×10^6 π^-, providing 13.7×10^6 pairs

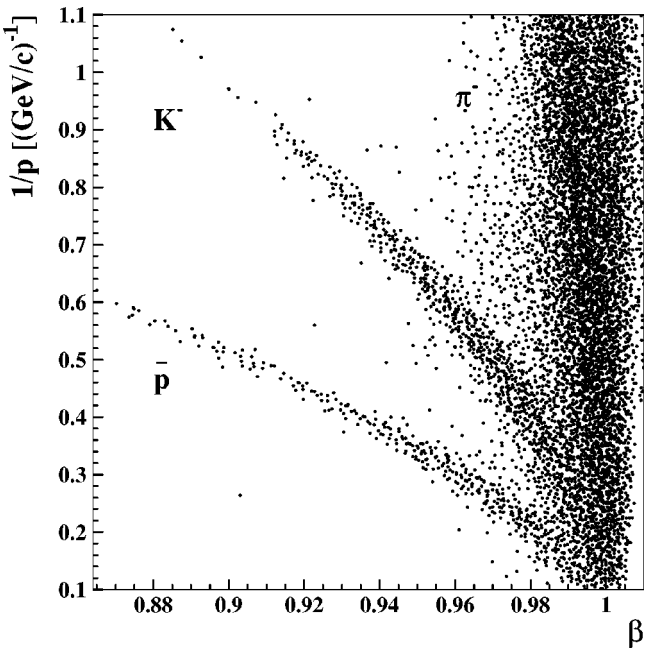

FIG. 2. Particle identification in the negative arm of the spectrometer.

and 13.1×10^6 triplets for the Bose-Einstein correlation analysis.

III. SINGLE-PARTICLE SPECTRA AND HYDRODYNAMICAL MODEL

The study of inclusive distributions of single particles produced in heavy-ion collisions can be interpreted in the context of models of the source using hydrodynamical expansion. Within the context of such models, which assume local thermal equilibration, parameters like the temperature and collective velocity at freeze-out can be determined. In the limit of a stationary fireball, the distribution takes the simple form [9]

$$E\frac{dN}{dp^3}\equiv\frac{dN}{m_T dm_T dy d\phi}\propto E\mathrm{e}^{-(E-\mu)/T}, \tag{1}$$

where p is the Cartesian particle momentum, $m_T \equiv\sqrt{p_T^2+m_0^2}$ is the transverse mass, p_T is the transverse momentum, m_0 is the rest mass, y is the rapidity, $E=m_T\cosh(y-y_{fireball})$, μ is the chemical potential, and T is the temperature.

In the limit where only a narrow rapidity interval close to $y_{fireball}$ is measured, the spectrum becomes

$$E\frac{dN}{dp^3}\sim m_T\mathrm{e}^{-m_T/T},$$

and, in the case of a rapidity-integrated spectrum,

$$\frac{dN}{m_T dm_T}\propto m_T K_1\left(\frac{m_T}{T}\right)\rightarrow\sim\sqrt{m_T}\mathrm{e}^{-m_T/T}$$

where K_1 is a modified Bessel function. The last approximation holds in the limit $m_T\gg T$. Plotted against m_T-m_0, all particles from a thermalized emitter should show the same universal exponential behavior. However, different additional features like transverse hydrodynamic expansion or particles originating from the decay of resonances will distort the shape of the spectrum. It was noted in Ref. [10] that for the popular fit with a simple exponential in m_T (without the m_T prefactor),

$$E\frac{dN}{dp^3}=C\mathrm{e}^{-m_T/T}, \tag{2}$$

an interpretation of the resulting slope parameter in terms of a temperature is not possible. However, since it is found to fit the measured spectrum better than the previous expressions, it is useful for obtaining an estimate of the inverse slope parameter T.

A. Data analysis

A detailed description of the analysis of the single particle spectra presented here can be found in Ref. [11]. The correction for detector acceptance and efficiency applied to the measured spectrum is based on a precise simulation of the detector, tuned in order to reproduce the measured detector response as accurately as possible using the VENUS [12] event generator as input. Multiple scattering, decays, and all other reactions within the detector material are taken into account. Efficiency maps depending on the hit position on each chamber, the particle momentum, and its identity are applied, together with position resolution and noise simulation. Simulated events are then reconstructed using the same code as for real data, ensuring that any software-induced systematics are also taken into account. The output is then matched to the VENUS input. This correction procedure ensures that the final result is little sensitive to remaining contamination, such as pions in a kaon sample. A detailed study of the systematic uncertainty has been performed and it is found to be small, especially as regards the slope of the spectrum ($\sim$3%). The absolute normalization, on the other hand, is more sensitive to detector instabilities which could not be perfectly simulated, and is found to have an estimated uncertainty of at most 20%.

Since the statistical uncertainty on the final m_T spectrum is negligible compared to the systematics, it is possible to apply very severe quality cuts on the reconstructed tracks and on the events used.

In contrast to the Bose-Einstein analysis, only a subset of all data is kept using only run periods where the detector operation remained particularly stable. The analysis is performed separately for identified π^- and K^-. The final data sample consists of 4.7×10^5 π^- tracks and 1.8×10^4 K^-

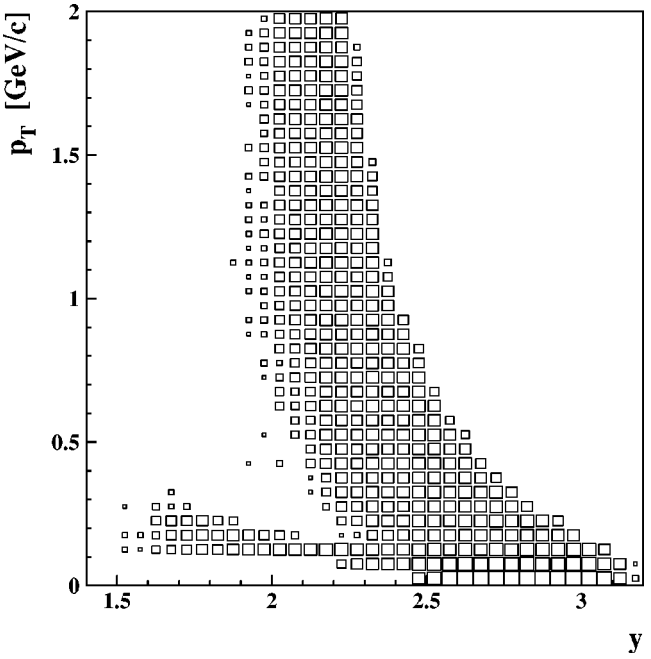

FIG. 3. Acceptance of tracking arm I in the (p_T, y) plane for pions.

drawn from 3.8×10^5 central events. Figures 3 and 4 show the detector acceptance for negative pions and kaons, respectively, obtained from the simulation. The π^-/π^+ ratio and the K^-/K^+ ratio of the number of detected pions and kaons have also been measured using two opposite magnetic field polarities. The results will be presented in a separate publication.

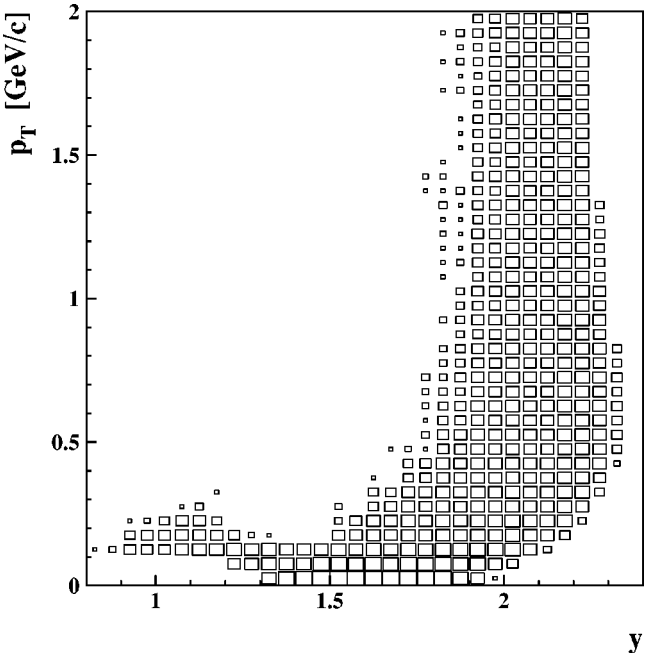

FIG. 4. Acceptance of tracking arm I in the (p_T, y) plane for kaons.

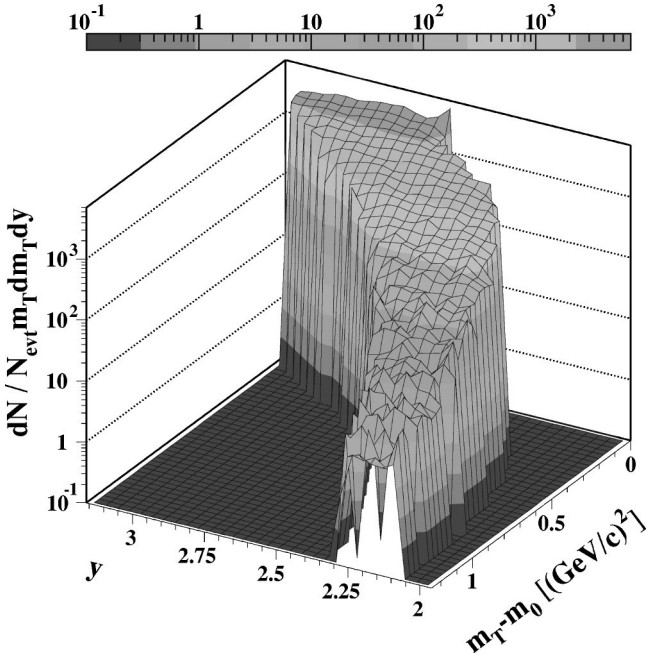

FIG. 5. Two-dimensional (fully corrected) single pion spectrum as a function of the two variables m_T and y.

B. Results

Figure 5 shows the final (fully corrected) single-particle spectrum for π^- plotted as a function of the two variables m_T and y. The form of the detector acceptance shown in Fig. 3 is clearly noticeable, except for the low p_T-low y lobe, which has been omitted here.

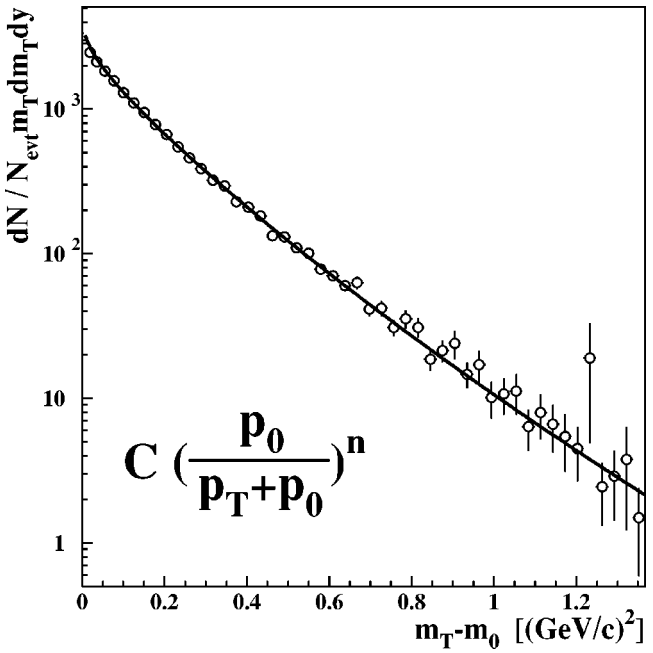

FIG. 6. One-dimensional (fully corrected) m_T spectrum for π^-. The errors are statistical. The power-law fit of Eq. (3) is superimposed on the data points. The fit interval is $m_T - m_0 = [0.05, 1.2]$ GeV/c^2.

Figure 6 shows the projection on the m_T axis (normalized to a unit rapidity interval using the VENUS profile) of the two-dimensional spectrum of Fig. 5. A fit to the exponential form of Eq. (2) over the interval $m_T - m_0 = [0.1,1.2]$ GeV/c^2 (not shown in Fig. 6) yields $C = 5220 \pm 80$ (stat.) $^{+1270}_{-200}$(syst.), and $T = 0.168 \pm 0.001$ (stat.) $^{+0.001}_{-0.005}$ (syst.) GeV, with a χ^2 per degree of freedom of 1.6. This result is in agreement with the NA49 result [13].

At high p_T, where perturbative QCD becomes applicable, the spectra are expected to attain a power-law behavior as observed in numerous high-energy pp measurements (see, for example, Ref. [14]). The heavy-ion data of this experiment seem to follow that trend even into the lower p_T range. Therefore, a parametrization originally inspired by QCD [15] and successfully applied already to *pp* data [14] and heavy-ion data [16] can be used to fit the spectrum,

$$E\frac{d^3\sigma}{dp^3} = C\left(\frac{p_0}{p_T + p_0}\right)^n, \tag{3}$$

with C, p_0, and n taken as free parameters. A link to the more familiar exponential slope parameter T is obtained from the derivative of this expression according to

$$T_{\text{power-law}} = -\frac{f(p_T)}{\dfrac{\partial f(p_T)}{\partial p_T}} = \frac{p_0}{n} + \frac{p_T}{n}.$$

Thus, p_0/n characterizes the slope of the transverse momentum spectrum in the limit $p_T \to 0$, while $1/n$ characterizes its gradient along p_T, i.e., the strength of the concave curvature. The extracted parameters are $C = 4150 \pm 70$, $p_0 = 4.80 \pm 1.04$ GeV/c and $n = 29.0 \pm 5.9$, which gives a slope parameter $T \equiv p_0/n = 0.166 \pm 0.005$ GeV. The χ^2 per degree of freedom is 1.0. The same fit performed on the π^0 spectrum, measured by the WA98 experiment [7,6,17,18], yields $C = 5120 \pm 140$, $p_0 = 5.08 \pm 0.18$ GeV/c, $n = 29.3 \pm 0.8$, and so $T = 0.173 \pm 0.002$ GeV. The acceptance for the π^0 measurement being different, it is interesting to note that fitting only the $p_T = [0.3,1.4]$ GeV/c common interval of both spectra yields $T = 0.169$ GeV for π^- and $T = 0.166$ GeV for π^0, showing that the result is stable with respect to the fit interval and that the spectra agree quite well.

It has also been shown that fluctuation of the parameter in an exponential distribution leads to a final distribution of the powerlike form [19]. This behavior can be interpreted in terms of a suitable application of the nonextensive statistics of Tsallis [20]. This interpretation is convenient to describe particle production at fluctuating T, as may occur near the phase transition. These fluctuations would exist in small parts of the hadronic system with respect to the whole system rather than between events. The average $\langle T \rangle$ around which the temperature fluctuates is given by $p_0/n = 0.166$ GeV, and the relative variance of $1/T$ is

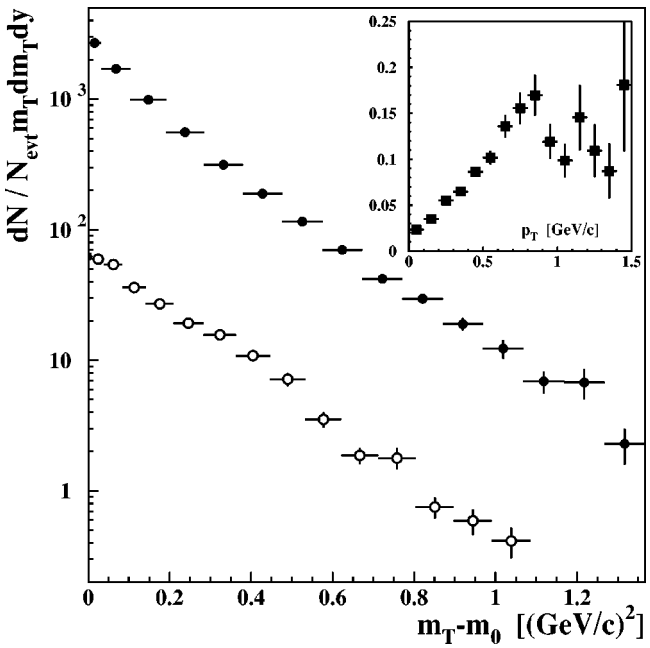

FIG. 7. π^- (black circles) and K^- (empty circles) single-particle spectra. The error bars are statistical only. Note that for the same transverse mass, p_T is different for pions and kaons. The inset shows the (bin by bin) ratio of the two p_T spectra.

$$\omega = \frac{\left\langle \left(\frac{1}{T}\right)^2 \right\rangle - \left\langle \frac{1}{T} \right\rangle^2}{\left\langle \frac{1}{T} \right\rangle^2} = \frac{1}{n} = 0.034,$$

both for π^- and π^0.

This corresponds to a nonextensivity parameter $q = 1 + \omega$ of 1.034. This result, interpreted in the spirit of Ref. [19], indicates a relative fluctuation $\Delta T/T$ of $18.4 \pm 1.9\%$ ($18.4 \pm 0.3\%$) for the π^- (π^0) measurement. However, this analysis neglects the contributions of resonance decays and flow velocity distributions. Both of these effects increase the curvature of the pion spectrum. Thus the value of $\Delta T/T = 18.4\%$ should be considered an upper limit on the temperature fluctuations.

The averaged negative pion yield per unit rapidity in the acceptance window is $1/N_{\text{evt}} dN/dy = 129 \pm 1$ (stat.) $^{+23}_{-5}$(syst.). Figure 7 shows the same plot as above for kaons. A fit to the exponential form 2 yields $C = 1000 \pm 120$ (stat.) $^{+260}_{-1}$ (syst.), and $T = 0.181 \pm 0.005$ (stat.) $^{+0.001}_{-0.009}$ (syst.) GeV. So the inverse slope T for kaons and pions are comparable. It should be noted that the rapidity acceptance is quite different for the two particle species, the π^- acceptance being much closer to midrapidity. An estimate of the effect induced by this difference in acceptance can be made using the term $\cosh(\Delta y)$ given below Eq. (1). The inverse slope for K^- would become of the order of 0.230 GeV. The K^-/π^- ratio at a common rapidity of 2.3 is 11.4 ± 0.4 (stat.) $^{+0.6}_{-2.7}$ (syst.)%, which is in agreement with the NA49 result [13].

C. Hydrodynamical source expansion model

The single pion spectrum has been fitted in the interval $0.05 < m_T - m_0 < 1.2$ GeV/c^2 with the Wiedemann-Heinz (W.-H.) model [21–26]. It relies on the following idea: the main characteristics of the particle phase-space distribution at freeze-out can be quantified by its widths in the spatial and temporal directions, a collective dynamical component (parametrized by a flow field) which determines the strength of the position-momentum correlations in the source, and a second, random dynamical component in momentum space (parametrized by a temperature). The model emission function contains seven parameters, but the shape of the single-particle transverse mass spectrum is fully determined by the temperature T and the transverse flow rapidity profile $\eta_T(r) = \eta_f(r/R)$ which is assumed to depend linearly on the transverse coordinate r, where η_f is the transverse flow rapidity strength, and R the Gaussian transverse spatial width. The mean transverse flow velocity $\langle \beta_T \rangle$ can be easily calculated as the mean value of $\tanh[\eta_T(r)]$ over the transverse source profile. The results will be given as a function of $\langle \beta_T \rangle$ rather than η_f, since its physical interpretation is more straightforward.

The three parameters that are allowed to vary freely during the fitting procedure are T, η_f, and an overall normalization factor. The result of the fit is $T = 0.084 \pm 0.003$ GeV and $\langle \beta_T \rangle = 0.50 \pm 0.02$, the χ^2/d.o.f. being 1.1. The resulting curve is not shown in Fig. 6 as it is hardly distinguishable from the power-law fit. The temperature and flow parameters are strongly correlated, so it is more interesting to consider a χ^2 contour plot of the fit to the measured single particle spectrum as a function of those two parameters. Figure 8 shows the result assuming a Gaussian transverse spatial profile, and Fig. 9 assuming a box profile of the same rms width as the Gaussian one. Only direct pions are considered in the model. Furthermore, only statistical errors are taken into account during the fit. The curves displayed represent different confidence levels for the $(T, \langle \beta_T \rangle)$ values.

The dependence of the χ^2/d.o.f. on the shape of the source is very small, the best χ^2/d.o.f. being slightly larger for the box profile (1.5). While the best fit temperature appears to be independent of the shape of the source, the best fit flow velocity is considerably smaller ($\langle \beta_T \rangle = 0.29$) for the box profile. Inclusion of the resonance decay contribution in the model calculation would be expected to reduce the extracted flow velocity parameters and increase the temperature parameters. The precise effects do however depend on details of the models used.

IV. TWO-PION CORRELATIONS

Bose-Einstein interferometry is most commonly used to study pairs of identical particles. The correlation function C_2 is defined, up to a proportionality factor $\mathcal{N}$, as the ratio of a two-particle spectrum $\mathcal{P}_2$ over the product of two single-particle spectra $\mathcal{P}_1$,

$$C_2(\vec{p}_1, \vec{p}_2) = \mathcal{N} \frac{\mathcal{P}_2(\vec{p}_1, \vec{p}_2)}{\mathcal{P}_1(\vec{p}_1) \cdot \mathcal{P}_1(\vec{p}_2)},$$

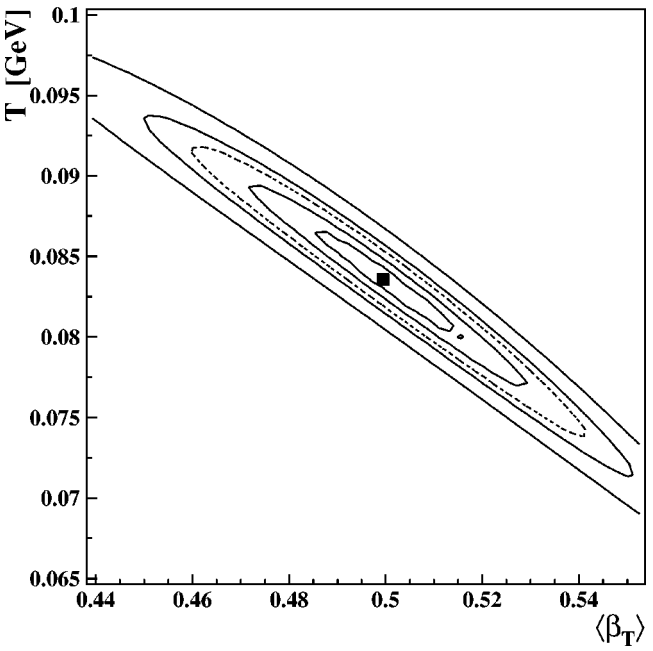

FIG. 8. χ^2 contour plot of the hydrodynamical model fit to the measured π^- single-particle spectrum of Fig. 6. A Gaussian profile is assumed for the transverse spatial profile of the source. The curves displayed represent successively (starting with the innermost one) contours at 50% C.L., 90% C.L., 99% C.L. (dashed line), and 99.9% C.L., and the last curve indicates a highly excluded region. The black square represents the best parameter values.

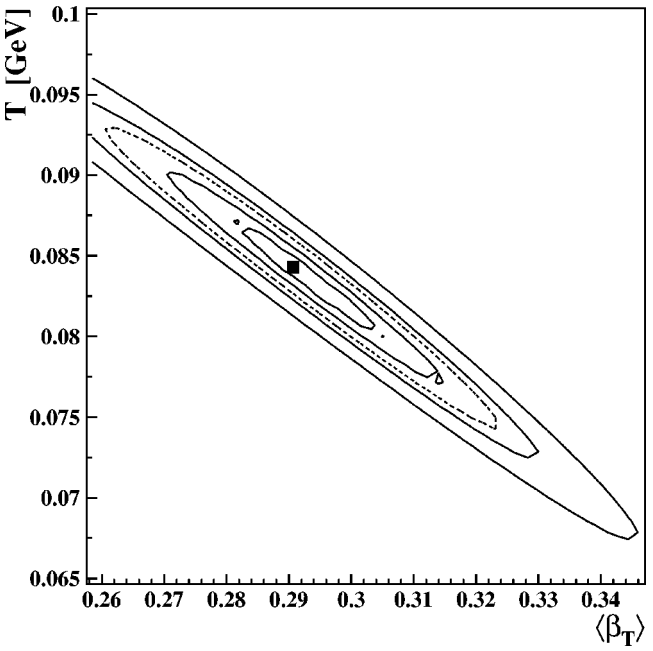

FIG. 9. Same plot as in Fig. 8, but assuming a box profile for the transverse spatial profile of the source.

with

$$\mathcal{P}_1(\vec{p}) = E\frac{dN}{dp^3}$$

and

$$\mathcal{P}_2(\vec{p}_1,\vec{p}_2) = E_1E_2\frac{dN}{dp_1^3 dp_2^3},$$

where E_i and $\vec{p}_i$ are the energy and momentum of particle i, respectively.

Experimentally, the product of one-particle distributions in the denominator is commonly obtained by a mixed event technique whereas the two-particle distribution in the numerator is constructed from all pair combinations of identical particles found in each event. C_2 is then normalized to unity far away from the interference region.

A fully chaotic source can be seen as a superposition of uncorrelated elementary sources, and one- and two-particle distributions may be expressed through the Wigner function of the source $S(x,k_{12})$ [1]. The correlation function is then written

$$C_2(\vec{p}_1,\vec{p}_2) = 1+\lambda\frac{\left|\int d^4x S(x,k_{12})\exp[iq_{12}x]\right|^2}{\left|\int d^4x S(x,k_{12})\right|^2}$$

with $q_{12}=p_1-p_2$ the four–momentum difference of the two particles, $k_{12}=(p_1+p_2)/2$, and $x=(x_1+x_2)/2$ the mean space-time coordinate of the pair emission point. The chaoticity parameter λ is inserted to take into account the possibility that the source may not be fully chaotic and also that any wrongly reconstructed tracks, or tracks originating from decays of long-lived resonances, will dilute the Bose-Einstein correlations in the data. A one-dimensional interferometry analysis is commonly made as a function of $Q_{inv} \equiv \sqrt{-q_{12}^2}$, whereas a multidimensional analysis uses a set of Q variables which are defined as various projections of q_{12}.

A. Data analysis and results

Two independent analyses were performed with the complete data set recorded in the negative tracking arm [11,27] totalling 13.7×10^6 pairs of identified π^-. These data were corrected for resolution and Coulomb effects in an iterative way [28]. The Gamow correction was not used as it overcorrects the data in the Q_{inv} range of 0.1–0.3 GeV/c. Because the finite resolution in the measurement of the Q variables leads to an underestimate of the radii and λ parameters, a correction has to be implemented in the fitting procedure. This is done by a convolution method, replacing the $C_2(\vec{Q})$ formula expressing the two-particle correlation function used to fit the data by

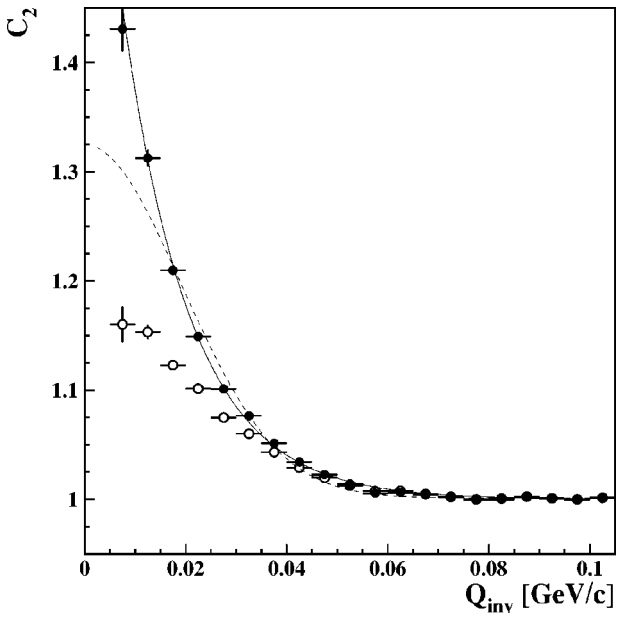

FIG. 10. The measured two-pion correlation function C_2 (full symbols), corrected for resolution and Coulomb effects, as a function of Q_{inv}. The full line is a fit to an exponential form, whereas the dashed curve is a fit to a Gaussian form. The empty symbols show the data before corrections.

$$C_2^{rc}(\vec{Q}) = \int\int\int r(\vec{Q},\vec{Q}')C_2(\vec{Q}')d\vec{Q}',$$

where $r(\vec{Q},\vec{Q}')$ is the resolution function which is chosen to be Gaussian:

$$r(\vec{Q},\vec{Q}') = 1/(2\pi)^{3/2}1/|V|^{1/2} \times\exp[-1/2(\vec{Q}-\vec{Q}')^T V^{-1}(\vec{Q}-\vec{Q}')].$$

The diagonal elements of the covariance matrix V are set equal to the square of the various Q resolutions, which are estimated by a full simulation of the experimental setup as a function of the $k_T=|\vec{p}_{T1}+\vec{p}_{T2}|/2$ of the pairs. The nondiagonal elements of V are neglected, as the resolution correction has a very small effect compared to the Coulomb correction. Figure 10 shows C_2, the measured $\pi^-\pi^-$ correlation function, plotted as a function of Q_{inv} before and after the resolution and Coulomb corrections. In the plot, the correction for resolution is obtained by multiplying each data point by $C_2^{rc}(Q_{inv})/C_2(Q_{inv})$. C_2 is clearly exponential [29]. The solid curve is a fit of the form $1+\lambda_e\exp[-2Q_{inv}R_{inv}]$ which gives $R_{inv}=7.33\pm0.08$ fm and $\lambda_e=0.788\pm0.009$ for $\langle k_T\rangle = 0.116$ GeV/c. This exponential behavior appears not to hold in the three-dimensional analysis, where projected slices are better represented by Gaussians.

The three-dimensional analysis of Bose-Einstein correlations has been done using two different parametrizations in the longitudinally comoving system (LCMS): the standard Pratt-Bertsch fit (PB) in the three-dimensional space of momentum differences Q_{TS} (perpendicular to the beam axis and

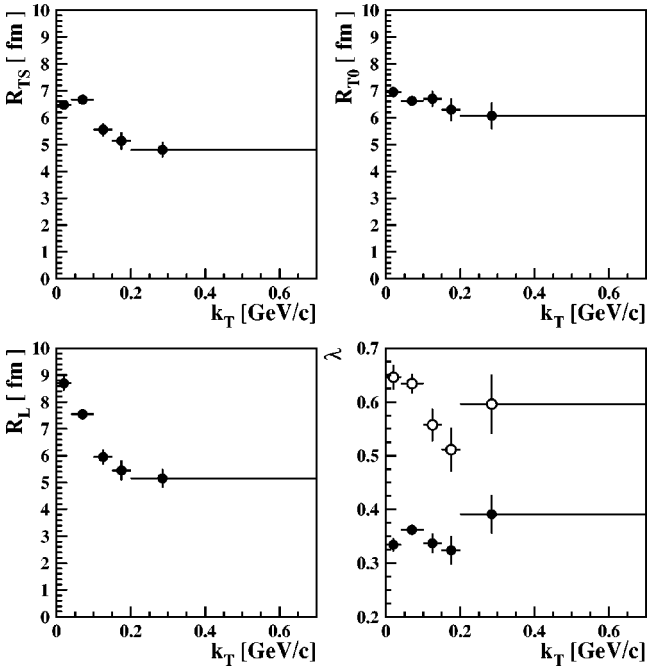

FIG. 11. The k_T dependence of the Pratt-Bertsch parameters. The points are plotted at the average k_T of the bin, and the horizontal bars indicate the bin width. The open symbols in the figure at bottom right show the λ parameter after correction for background from misidentified pions, as explained in Sec. V.

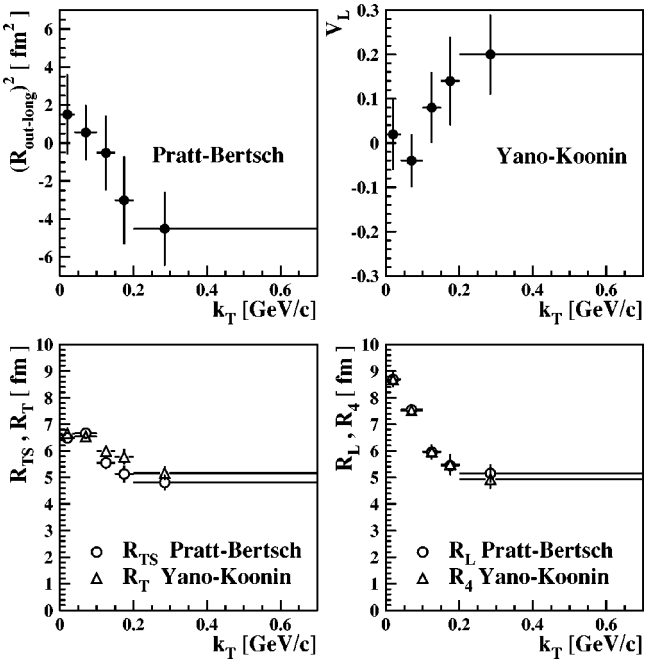

FIG. 12. Comparison between the PB and YKP fits in the LCMS. The cross term $R^2_{out\text{-}long}$ from the PB fit and v_L from the YKP fit both show a deviation from zero at large k_T when estimated in the LCMS. The R_{TS} and R_L parameters from the PB fit are in good agreement with, respectively, R_T and R_4 from the YKP fit.

to the transverse momentum of the pair), Q_{TO} (perpendicular to the beam axis and parallel to the transverse momentum of the pair), and Q_L (parallel to the beam axis) [30], including a cross term $R^2_{out\text{-}long}$ as predicted [31],

$$C_2 = 1 + \lambda \exp[-Q_{TS}^2 R_{TS}^2 - Q_{TO}^2 R_{TO}^2 - Q_L^2 R_L^2 - 2 Q_{TO} Q_L R^2_{out\text{-}long}],$$

and the Yano-Koonin-Podgoretskiĭ fit (YKP) [21] in the Q_0 (energy difference of the pair), Q_T, Q_L space,

$$C_2 = 1 + \lambda \exp[-Q_T^2 R_T^2 + (Q_0^2 - Q_L^2) R_4^2 - (Q \cdot U)^2 (R_0^2 + R_4^2)],$$

where $U = \gamma(1,0,0,v_L)$, $\gamma = 1/\sqrt{1 - v_L^2}$ with v_L in units of $c = 1$.

In the YKP parametrization the different radii are invariant under a longitudinal Lorentz boost, and the speed parameter v_L connects the local rest frame to the measurement frame (the LCMS in our case). The results as a function of the k_T of the pairs are shown in Figs. 11 and 12 and summarized in Table I. The λ parameters of the YKP fit (not shown in Table I) are found compatible with the λ parameters of the PB fit.

The systematic errors, not included in Figs. 11 and 12, and Table I, are estimated by varying the different analysis cuts, including the cuts used to identify the pion with the time of flight system. The systematic error on the Coulomb correction due to the error on the determination of the radius parameters is also taken into account. All these variations are added in quadrature. The total relative systematic errors on the radii $\Delta R/R$ amount to 0.8% for R_{inv}, 1.4% for R_{TS}, 3.5% for R_{TO}, 9.1% for R_L, 0.8% for R_T, and 9.7% for R_4. Systematic errors on $R^2_{out\text{-}long}$ and v_L are asymmetric and reach, respectively, $^{+2.2}_{-1.7}$ fm^2 and $^{+0.13}_{-0.08}$.

The R_{TS} and R_L parameters from the PB fit are in good agreement, respectively, with R_T and R_4 from the YKP fit. The cross term $R^2_{out\text{-}long}$ from the PB fit and v_L from the YKP fit deviate from zero.

In a source undergoing a boost invariant expansion the local rest frame coincides with the LCMS. Both the cross term and v_L expressed in the LCMS are then expected to vanish [21]. As this is not quite the case, it suggests that the source seen within the acceptance does not have a strictly boost invariant expansion. The strong decrease of the longitudinal radius R_L or R_4 with k_T compared to the transverse radii R_T, R_{TS}, and R_{TO} shows a longitudinal expansion which is larger than the transverse one. Finally, the R_0 parameter (not shown in the figures), which corresponds to the duration of emission of particles from the source, is compatible with zero for all k_T bins, excluding a long-lived intermediate phase. These results agree with the previously published WA98 results obtained using roughly half of the present data sample [29]. The WA98 analysis is compatible with the NA49 results obtained in a slightly different rapidity range ($\langle y \rangle = 3.2$) with unidentified negative particles [32]. The direct comparison with the NA44 results is not possible because NA44 and WA98 do not have the same rapidity range. The smaller R_{TO} measured by NA44 [33] can be explained by the larger rapidity range of its acceptance ($3.1 < y < 4.1$).

TABLE I. Three-dimensional analysis as a function of k_T for the PB and YKP fits. λ after correction for backgrounds from misidentified pions is also shown.

B. Comparison with a hydrodynamical model based simulation

The W.-H. model can be used to generate correlation functions which can be compared to the data. For that purpose, all necessary integrations are performed numerically [25] to get the value of C_2 in the PB parameterization for given values of Q_{TS}, Q_{TO}, Q_L, k_T, and the rapidity $Y=(y_1+y_2)/2$ of a pair. To simulate properly the acceptance of the negative tracking arm, the mean values of k_T and Y for each (Q_{TS},Q_{TO},Q_L) bin are calculated using real data, and then for each bin the mean values $(\langle Q_{TS}\rangle,\langle Q_{TO}\rangle,\langle Q_L\rangle,\langle k_T\rangle,\langle Y\rangle)$ are used as input for the hydrodynamical calculation. This procedure is repeated for all five k_T intervals used in the data analysis. The correlation functions are generated neglecting contribution from resonances, using $T=85$ MeV, $\eta_f=0.5$ (values extracted from the single-particle spectra analysis), $R=8$ fm, $\tau_0=11$ fm/c, $\Delta\tau=2$ fm/c, and $\Delta\eta=1.3$ (see Ref. [25] for definitions of the parameters). Figure 13 shows the Bose-Einstein radii extracted from fitting the simulated correlation functions with the PB formula. The error bars used to perform these fits are taken to be the same as the ones calculated for the real data in each (Q_{TS},Q_{TO},Q_L) bin. The measured results are shown on the same plot, and the agreement is found to be good. The shift in the the cross term $R^2_{out\text{-}long}$ between data and simulation is compatible with the systematic uncertainty.

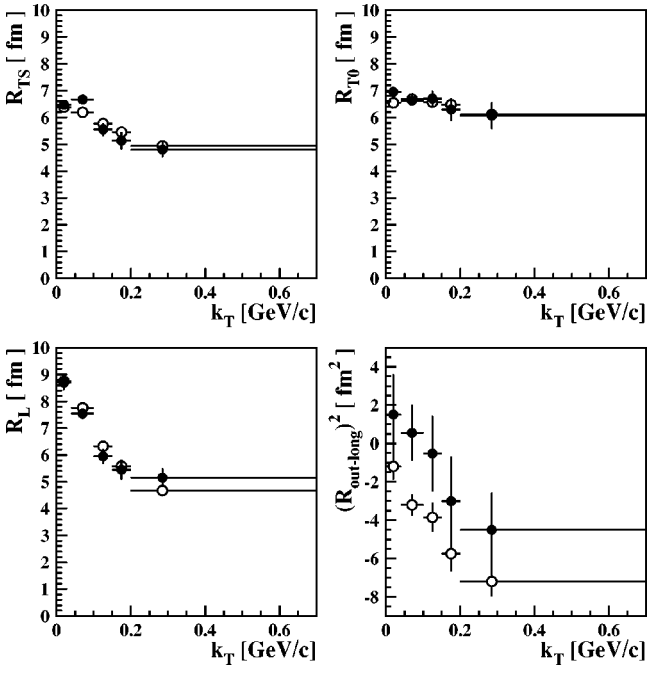

FIG. 13. Comparison between simulation and data as a function of k_T. The open symbols are the result of the fit of the PB formula to the correlation functions produced by the hydrodynamical model, whereas the full symbols are the result of the fit to the data.

V. AVERAGE PION PHASE-SPACE DENSITY AT FREEZE-OUT

As the m_T spectrum gives the momentum-space density at freeze-out and as the Bose-Einstein correlation radii provide information on the covariant volume for particles of momentum $\vec{p}$, it is possible, by combining these results, to extract the average phase-space density $\langle f\rangle(p_T,y)$ at freeze-out [34,35],

$$\langle f\rangle = \frac{\sqrt{\lambda}}{\left(\frac{E_\pi}{\pi^{3/2}}\right) R_{TS}\sqrt{R^2_{TO}R^2_L - R^4_{out\text{-}long}}} \frac{dn}{dy p_T dp_T d\phi}$$

with $E_\pi=\sqrt{m_\pi^2+p^2}=m_T\cosh y$. The radii and λ are functions of p_T and y. The factor λ, which comes from the two-pion correlation analysis, corrects for contributions of pions originating from long-lived resonances decaying close to the primary vertex. A difficulty of this method is to include only the contribution of the real pions in the determination of λ, excluding backgrounds from misidentified particles. This is achieved by applying to λ, separately for each k_T bin, a correction factor obtained from a full simulation of the experimental setup, taking into account geometrical acceptance, backgrounds and efficiency of the chamber-camera-time of flight system. The effects can be seen in Fig. 11, bottom right, where λ with and without correction is displayed.

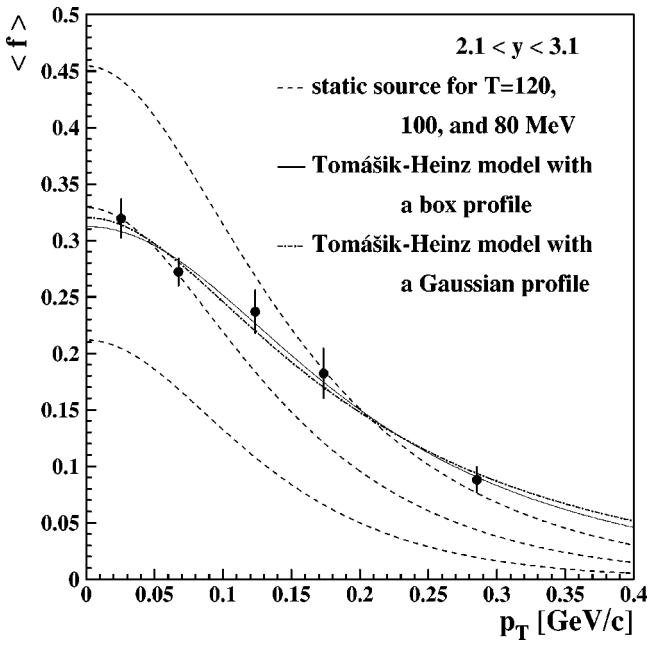

FIG. 14. Average pion phase-space density as a function of p_T compared to different models (see the text).

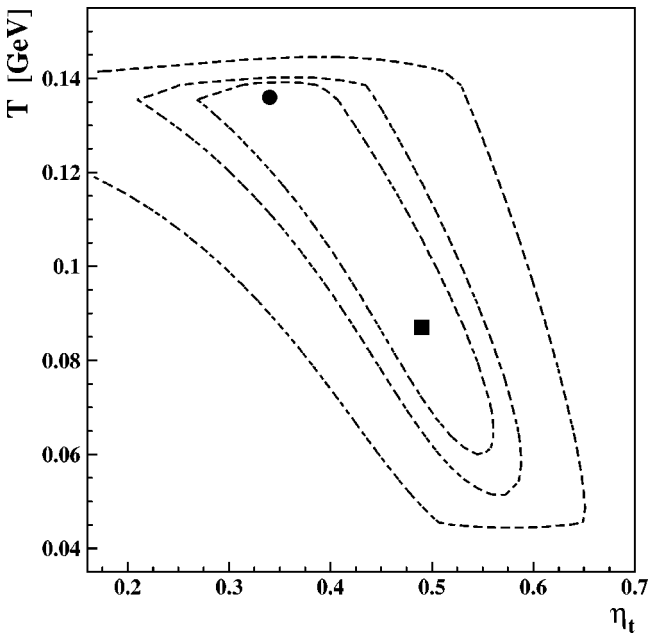

FIG. 15. χ^2 contour plot for the T.-H. model with a box profile. Starting from the center, the curves represent contours at 39%, 70%, and 99% confidence levels for T and η_t. The black square is the best fit ($\mu_0=57$ MeV). The full circle is the result with μ_0 excluded from the fit and set to zero.

Figure 14 and Table II show the results on the average phase-space density for π^- as a function of p_T. The error bars reflect the statistical errors only. The systematic uncertainties are dominated by the uncertainty of the correction on the λ parameter, which is estimated to be 20%, and by the systematic error on R_L, giving a total of 13.7% systematic error on $\langle f \rangle$. Within errors, all nuclear collision measurements at the SPS are found to be indistinguishable [36], and our result at mid-rapidity agrees well with these previous measurements. The dashed lines indicate Bose-Einstein density distributions $\langle f \rangle = [\exp(E_\pi/T)-1]^{-1}$ of static sources of pions ($E_\pi \approx m_T$) for three choices of the freeze-out temperature T: 80, 100, and 120 MeV, from the lower curve to the higher curve. The results are in rough agreement with the 100-MeV distribution at low p_T, but show a clear deviation from a Bose-Einstein distribution at high p_T. As pointed out in Ref. [37], this deviation is mainly due to the strong longitudinal expansion of the fireball which reduces the spatially averaged phase-space density and, to a lesser extent, due to the radial collective flow, which adds extra transverse momentum to the particles compared to particles emitted by a static source. Consequently, even in the absence of transverse flow, $\langle f \rangle$ will be reduced compared to a Bose-Einstein density distribution. This effect may necessitate a positive pion chemical potential in order to match the experimental observation. Such a positive potential can be related to the presence of pions from short-lived resonance decays. The Tomášik-Heinz (T.-H.) model [37] used to fit the data assumes a thermalized fireball with a longitudinally boost-invariant expansion and a transverse flow rapidity profile which depends linearly on the transverse coordinate. This model includes a pion chemical potential and has three free parameters, the freeze-out temperature T, the strength of the transverse flow rapidity profile η_t, and μ_0, the chemical potential value in the center of the fireball. In Fig. 14, the full line is a fit of the T.-H. model with a box transverse density profile, whereas the point-dashed line is a fit of the same model with a Gaussian transverse profile. Both fits agree well with the data with a χ^2/d.o.f. of 0.78 and 0.93 for, respectively, the box and Gaussian profiles, giving $T = 87^{+52}_{-27}$ MeV, $\eta_t = 0.49^{+0.07}_{-0.22}$, and $\mu_0 = 57^{+29}_{-125}$ MeV for the box profile. This η_t result corresponds to a mean transverse flow velocity $\langle \beta_T \rangle = 0.42^{+0.05}_{-0.18}$. Due to the lack of experimental points at large p_T, the T.-H. model with the Gaussian profile provides very loose estimates of these parameters, which are nevertheless compatible with those from the box profile. Figure 15 shows the χ^2 contour plot for the T.-H. model with the box profile for T and η_t. The curves represent (starting from the center) contours at 39%, 70% and 99% confidence level. The best fit is obtained for a pion chemical potential $\mu_0 = 57$ MeV (black square) but a solu-

$\langle f \rangle$	0.319 ± 0.018	0.272 ± 0.012	0.237 ± 0.019	0.182 ± 0.022	0.088 ± 0.012

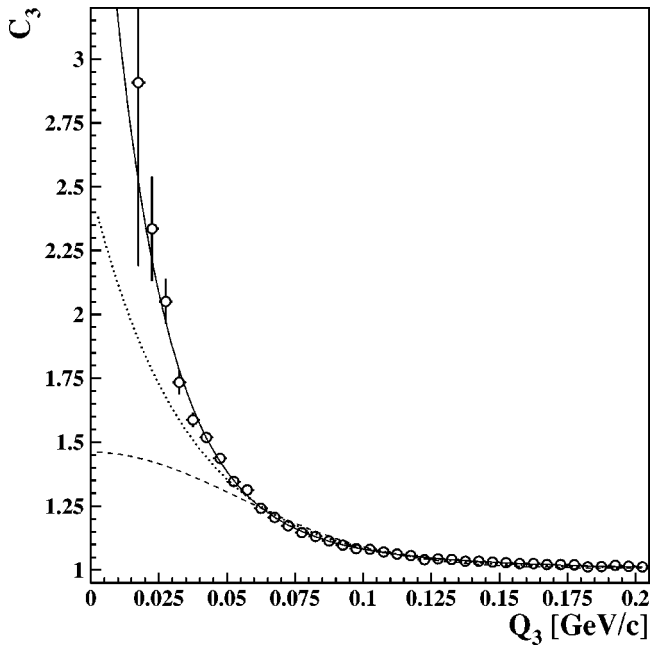

FIG. 16. The three-pion correlation function C_3 as a function of Q_3. The full line is a fit to a double exponential form (see the text). The dotted and dashed lines are fits, respectively, to a single exponential and a Gaussian form.

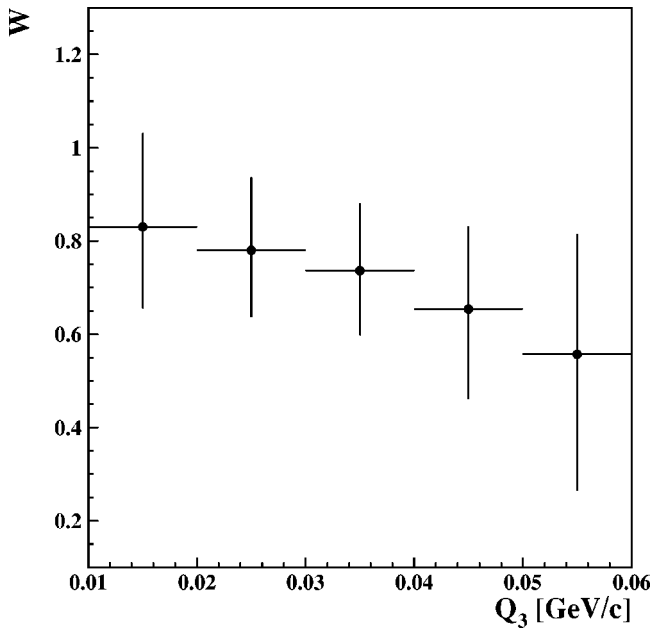

FIG. 17. The factor W as a function of Q_3. The error bars include statistical and systematic errors. The statistical errors alone are contained within the size of the symbols.

tion with $\mu_0=0$ MeV is also possible (full circle). On the other hand, a large pion chemical potential at freeze-out, close to the Bose condensation limit of $\mu_0=m_\pi$, as could be speculated given the rather low mass of the pion, seems to be excluded in view of the error bar on μ_0.

The results of the fit of the W.-H. model on the single π^- spectrum can be compared to the fit of the T.-H. model on the phase-space distribution. The agreement is good for T, and satisfactory for $\langle\beta_T\rangle$ when taking into account the systematic error. It should be noted that the constraint provided by the fit of the T.-H. model is weak compared to the one given by the W.-H. model because of the relatively small amount of experimental points in the phase-space distribution. Moreover the T.-H. model uses a pion chemical potential whereas the W.-H. model does not. Finally, as $\langle f\rangle$ is the pion occupation per six-dimensional position$\otimes$momentum cell, the obtained values do not provide striking evidence for the presence of an excess of pions or for the presence of large disoriented chiral condensates. This chiral condensate phenomena has been investigated by other means within WA98 [38,39].

VI. THREE-PION CORRELATIONS

In the hypothesis of a fully chaotic source of identical particles, the two-pion correlation function can be written $C_2=1+|F_{12}|^2$ where $|F_{12}|^2$ is the Fourier transform squared of the space-time source function. The three-pion correlation function is then $C_3=1+|F_{12}|^2+|F_{23}|^2+|F_{31}|^2+2\cdot\mathrm{Re}\{F_{12}\cdot F_{23}\cdot F_{31}\}$. The terms $|F_{ij}|^2$, which express the contribution of the three combinations of the two-pion correlations contained in the triplet (123), provide the largest contribution to C_3. The last term only represents the genuine three-body correlation. It can be written $2\cdot|F_{12}|\cdot|F_{23}|\cdot|F_{31}|\cdot W$, where F_{ij} is defined as $|F_{ij}|\exp[i\phi_{ij}]$ and $W\equiv\cos(\phi_{12}+\phi_{23}+\phi_{31})$. The simultaneous measurement of C_2 and C_3 provides information on W, the cosine of the sum of the three phases of the Fourier transforms. In contrast, the measurement of C_2 alone gives access only to the radii of the source and not to the phases. If the emission source is fully chaotic, W measures the asymmetry of the source. In the presence of not fully chaotic sources, which is likely to be the case, W, the strength of the true three-body correlation, is basically sensitive to the coherence. So, in the framework of the partially coherent model [40], W gives information on the de-

TABLE III. Weighted mean of the strength of the genuine three-pion correlations $\langle W\rangle$ as a function of Q_3.

Q_3 range	0.01–0.02 GeV/c	0.02–0.03 GeV/c	0.03–0.04 GeV/c	0.04–0.05 GeV/c	0.05–0.06 GeV/c
$\langle W\rangle$	$0.830^{+0.201}_{-0.175}$	$0.780^{+0.156}_{-0.143}$	$0.736^{+0.145}_{-0.138}$	$0.654^{+0.177}_{-0.193}$	$0.557^{+0.258}_{-0.293}$

gree of chaoticity of the emission source in a manner which is insensitive to backgrounds such as the contributions from resonances. The complete data set recorded with the negative tracking arm yielded a total of 13.1×10^6 triplets of π^-.

After correction for resolution and Coulomb effects,[1] a strong C_3 signal is observed (Fig. 16) as a function of $Q_3 \equiv \sqrt{Q_{12}^2+Q_{23}^2+Q_{31}^2}$ with $Q_{ij}\equiv\sqrt{-(p_i-p_j)^2}$, which can be fitted by a double exponential function

$$C_3 = 1+\lambda_1 \exp[-2Q_3R_1]+\lambda_2\exp[-2Q_3R_2],$$

with fitted parameters $R_1=5.08\pm0.26$ fm, $\lambda_1=3.12\pm0.27$, $R_2=1.66\pm0.08$ fm, $\lambda_2=0.341\pm0.046$, and χ^2/d.o.f. $=1.10$. Such a non-Gaussian behavior was in fact predicted by a final-state rescattering model [41]. After the measurement of C_2 and C_3, the data are analyzed again, and the experimental value of W is calculated using

$$W=\frac{\{C_3(Q_3)-1\}-\{C_2(Q_{12})-1\}-\{C_2(Q_{23})-1\}-\{C_2(Q_{31})-1\}}{2\cdot\sqrt{\{C_2(Q_{12})-1\}\{C_2(Q_{23})-1\}\{C_2(Q_{31})-1\}}}$$

individually for each triplet found, characterized by Q_3 and by the values Q_{12}, Q_{23}, and Q_{31} corresponding to the three pair combinations contained in the triplet.

As described earlier, the estimate of systematic errors is done by varying the different analysis cuts, both in the two- and three-pion correlation analysis. The effects on W of the statistical errors in the measurement of C_2 and C_3 are treated as systematic errors by changing C_2 (C_3) by $\pm\sigma_{C_2}$ ($\pm\sigma_{C_3}$). This last source of error dominates the other ones. All these variations are then added in quadrature.

Figure 17 and Table III show W as a function of Q_3 for $Q_3\leqslant 60$ MeV/c, beyond which the W significance is too low. The error bars include statistical and systematic errors. The statistical errors (not shown separately in Fig. 17) are by comparison negligible. In view of the errors, no significant Q_3 dependence is observed. The genuine three-pion correlation is found to be substantial with a weighted mean over the five bins $\langle W\rangle = 0.735\pm0.004(\text{stat.})\pm0.146(\text{syst.})$.[2]

This result is in agreement with the previously published WA98 result obtained using about half of the present data sample [42], where a more detailed description of the three-pion analysis method can also be found. More recently, the NA44 experiment [43] obtained with lower statistics a factor $\langle W\rangle$ which agrees with our results.

VII. CONCLUSIONS

We have studied m_T distributions for identified π^- and K^- produced in central Pb+Pb collisions at 158A GeV. The W.-H. hydrodynamical model has been fitted to the pion spectrum. The resulting fitted parameters favor a combination of a relatively low temperature $T\sim85$ MeV and an average transverse flow velocity $\langle\beta_T\rangle\sim0.50$. The shape of the π^- m_T distribution is in good agreement with the π^0 m_T distribution measured in the same experiment.

Bose-Einstein interferometry of π^- pairs gives fitted radii of typically 7 fm. This has to be compared to the equivalent rms radius of the initial Pb ion of 3.2 fm, indicating an expanded emission volume at freeze-out.

The analysis of two-pion correlations has been performed as a function of k_T using two different parametrizations in the LCMS. The results are consistent between the standard three-dimensional Pratt-Bertsch fit and the Yano-Koonin-Podgoretskiĭ fit.

A clear dependence of all radius parameters on k_T is observed, with a stronger dependence for the longitudinal radii, indicating a larger longitudinal than transverse expansion. Both the cross term $R^2_{out\text{-}long}$ from the PB fit and v_L from the YKP fit deviate from zero, which suggests that the source seen within the acceptance does not undergo a strictly boost invariant expansion. Moreover, the short duration of emission disfavors any long-lived intermediate phase.

A comparison of the data with a hydrodynamical simulation based on the Wiedemann-Heinz model, and taking into account acceptance and resolution effects has been made for the radii parameters as a function of k_T. The agreement is found to be very good.

The average pion phase-space density at freeze-out has been calculated from measured quantities as a function of p_T. The results indicate a clear deviation from a Bose-Einstein distribution at high p_T, but are very well fitted by the Tomášik-Heinz model. The pion chemical potential, which is included in the model, is found to be compatible with zero, while a large pion chemical potential close to the condensation limit of m_π, seems to be excluded.

Finally, we have studied the $\pi^-\pi^-\pi^-$ interference and found a substantial contribution of genuine three-pion correlations in central collisions. For $Q_3\leqslant60$ MeV/c a weighted mean of the strength of the genuine three-pion correlations $\langle W\rangle = 0.735\pm0.004(\text{stat.})\pm0.146(\text{syst.})$ was extracted. This

[1]The Coulomb correction applied to a particular triplet is the product of the Coulomb corrections used for the three pair combinations contained in that triplet.

[2]The weighted systematic error is obtained by calculating the weighted average over the five Q_3 bins separately for each kind of systematic error. These errors are then added in quadrature. On the other hand, adding quadratically the systematic errors of the five Q_3 bins, as done for weighted statistical errors, would give ±0.078 instead of ±0.146 for the systematic uncertainty.

is somewhat smaller than what is expected for a fully chaotic and symmetric source.

High p_T π^0 Production and Angular Correlations in 158 AGeV p+A and Pb+Pb Collisions

S. Bathe[a] for the WA98-Collaboration

[a]University of Münster, 48149 Münster, Germany

Recent results of the WA98 experiment with p and Pb induced reactions at 158 AGeV are presented. Azimuthal γ-γ correlations at high p_T were studied in search for a signal of jet-like structures. A clear indication for back-to-back correlations can be seen in p+A with a strong dependence on the p_T of the photons and the size of the system. In Pb+Pb collisions in plane elliptic flow has been observed. Results on transverse mass spectra of neutral pions measured at central rapidity are presented for impact parameter selected Pb+Pb collisions. In going from peripheral to medium central collisions there is a nuclear enhancement increasing with transverse mass similar to the Cronin effect, while for very central collisions this enhancement appears to be weaker than expected.

1. Introduction

The CERN experiment WA98 [1,2] consisted of large acceptance photon and hadron spectrometers together with several other large acceptance devices which allow to measure various global variables on an event-by-event basis. The results presented here were obtained from an analysis of the data taken with p and Pb beams in 1995 and 1996 at 158 AGeV. The Pb-induced reactions have been subdivided into samples of different centrality using the transverse energy E_T measured in the MIRAC calorimeter. Photons are measured with the WA98 lead-glass photon detector, LEDA, which consisted of 10,080 individual modules with photomultiplier readout. The detector was located at a distance of 21.5 m from the target and covered the pseudorapidity interval $2.2 < \eta < 2.9$. Details about the photon measurement can be found in [2].

2. Azimuthal γ-γ-Correlations

We attempt to use azimuthal correlations of photons, which mainly originate from decays of neutral hadrons, π^0 or η, to gain information on the relative fraction of produced particles which still carry memory of the primary production process. Particles produced in a primary two-body collision of incoming nucleons must be correlated in transverse momentum due to local momentum conservation. Dominantly, especially if their individual transverse momenta are large, the particles will be anti-correlated in azimuthal angle. This is of course reminiscent of jet structure in the particle emission in high-energy physics. In fact, there is expected to be a smooth transition of this purely kinematical effect to mini-jet or jet production. At high enough transverse momenta, such an analysis

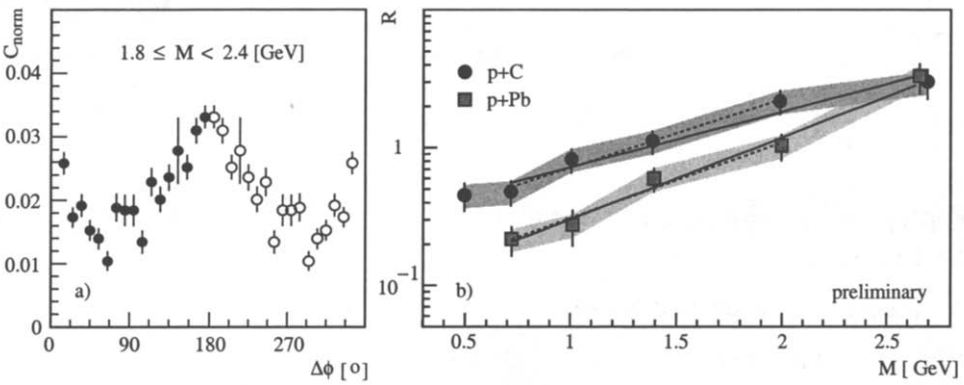

Figure 1. a) Exemplary $C(\Delta\phi)$ for p+C reactions. b) Ratio R of correlated to uncorrelated pairs at $\Delta\phi = 180°$ as function of the pseudo-mass M for p+C and p+Pb.

should allow to study minijet or jet production and eventually allow to investigate effects such as jet quenching. If the particles undergo secondary and further rescatterings, as in an equilibrated system, the memory of the correlation discussed above will be lost. Of course, anti-correlation of particle pairs will also be generated by collective effects like hydrodynamical elliptic flow. One therefore has to check how much the measured effects might be altered by flow phenomena. The γ-pairs are characterized by the difference of their azimuthal angle $\Delta\phi$ and the so-called pseudo-mass $M = p_{T1} + p_{T2}$. The correlation function $C(\Delta\phi)$ is introduced:

$$C(\Delta\phi) = \left.\frac{d^2N}{d\varphi_1 d\varphi_2}\right|_{p_{T1}+p_{T2}} \Big/ \left.\left(\frac{dN}{d\varphi_1}\frac{dN}{d\varphi_2}\right)\right|_{p_{T1}+p_{T2}}$$

The combinatorial background of uncorrelated pairs is obtained by event mixing taking into account different centrality and multiplicity classes. A clear correlation around $\Delta\phi = 180°$ can be seen for p+C (Fig 1a) and p+Pb reactions. It is assumed that the correlation originates from the direct production of π^0's in single binary collisions and that its strength therefore contains information about the ratio of directly produced to rescattered particles. The correlation function for the p+A data can be described by a Gaussian distribution, with the ratio R of correlated to uncorrelated pairs at $\Delta\phi = 180°$ increasing exponentially with the pseudo-mass M as shown in Figure 1b. Peripheral Pb+Pb data show a similar behaviour. Semi-peripheral and semi-central Pb+Pb data show a correlation function that is dominated by elliptic flow. The flow effects are evaluated by means of a Fourier expansion [3,4].

$$\frac{1}{N}\frac{dN}{d(\Delta\phi)} = 1 + 2v_1^2\cos\Delta\phi + 2v_2^2\cos 2\Delta\phi, \qquad (1)$$

The Fourier coefficient v_1 quantifies the directed flow, whereas v_2 quantifies the elliptic flow. The Fourier coefficients $v_n (n = 1, 2)$ can be extracted from the correlation function without determination of the reaction plane, and hence no event plane resolution correction has to be applied. Figure 2a shows v_2 for different cut-offs on the pseudo-mass as

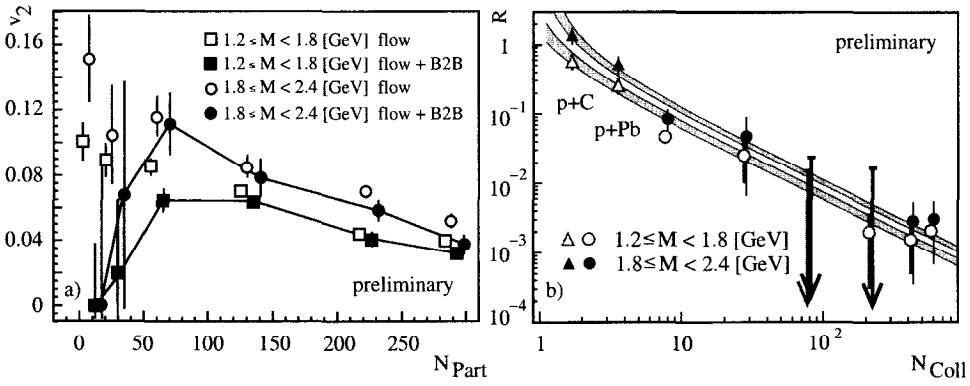

Figure 2. a) v_2 in Pb+Pb as function of the number of participants with and without consideration of back-to-back effects. b) Strength of back-to-back correlations in p+A and Pb+Pb reactions.

a function of different centralities in Pb+Pb with and without consideration of back-to-back effects. Especially in the more peripheral samples, elliptic flow does not describe the correlation completely. To compare the strength of an additional Gaussian-like correlation for different systems the ratio R of correlated to uncorrelated pairs at $\Delta\phi = 180°$ is shown in Figure 2b as a function of the number of binary collisions. A parametrisation of the p+A data points with $R(N_{Coll}) = 1/(aN_{Coll} - 1)$ is extrapolated to the Pb+Pb data, which represents scaling of the number of correlated pairs with N_{Coll}. No deviation from this scaling is observed.

3. Centrality Dependence of π^0-Production

Already from the experimentally determined shape of transverse mass spectra of hadrons it is evident that heavy ion reactions are not merely a superposition of nucleon-nucleon collisions [5]. In p+A collisions the flattening of the transverse mass spectra compared to p+p (Cronin effect [6]) has been attributed to initial state multiple scattering of partons [7]. In the analysis of central reactions of Pb+Pb at 158 AGeV, however, it is seen that both predictions of perturbative QCD [8] and hydrodynamical parameterizations [9] can describe the measured neutral pion spectra reasonably well. The understanding of the relative contributions of the various soft and hard processes in particle production is especially important in view of the recent interest in the energy loss of partons in dense matter [10,11], generally referred to as *jet quenching*, as a possible probe for the quark gluon plasma. Since one of the suggested experimental hints of jet quenching is the suppression of particle production at high transverse momenta, it is important to understand other possible nuclear modifications of particle production in detail.

More information in this respect may be gathered from the variation of the particle spectra for different reaction systems or different centralities [12]. Here we study the variations in absolute multiplicities. Especially at high transverse momentum one naïvely expects an increase of the multiplicity proportional to the number of collisions due to the

importance of hard scattering. In fact, it was already observed in p+A collisions at beam energies of 200 – 400 GeV [6] that the increase in cross section at high transverse momenta is even stronger than the increase in the target mass. The ratios of the measured pion multiplicity distributions for two different samples (labeled X and Y) normalized to the number of collisions

$$R_{XY}(m_T) \equiv \frac{\left(E\frac{d^3N}{dp^3}(m_T)/N_{coll}\right)_X}{\left(E\frac{d^3N}{dp^3}(m_T)/N_{coll}\right)_Y} \tag{2}$$

is introduced.

The ratio of peripheral Pb+Pb collisions to p+p increases strongly with increasing transverse mass – this is in line with the Cronin effect discussed above. A similar trend is observed when going from peripheral to medium-central data. In addition, the pion production is seen to increase roughly proportional to the number of collisions even at low transverse mass. Going from medium central to central the trend is reversed: the ratio decreases with increasing transverse mass and the pion multiplicities increase more weakly than the number of collisions. The ratio of very central to central collisions shows an indication of a similar effect although not very significant.

Neither results of HIJING[13] calculations nor a more refined pQCD calculation [14] can reproduce the experimental data. Here the ratios are all ≥ 1 and thus do not explain the centrality dependence observed.

Abstract

PHENIX has measured the centrality dependence of charged hadron p_T spectra from Au+Au collisions at $\sqrt{s_{\mathrm{NN}}} = 130$ GeV. The truncated mean p_T decreases with centrality for $p_T > 2$ GeV/c, indicating an apparent reduction of the contribution from hard scattering to high p_T hadron production. For central collisions the yield at high p_T is shown to be suppressed compared to binary nucleon–nucleon collision scaling of p + p data. This suppression is monotonically increasing with centrality, but most of the change occurs below 30% centrality, i.e., for collisions with less than ~ 140 participating nucleons. The observed p_T and centrality dependence is consistent with the particle production predicted by models including hard scattering and subsequent energy loss of the scattered partons in the dense matter created in the collisions.

1. Introduction

Particle production at large transverse momentum (p_T) provides a new tool to study hot and dense nuclear matter created in high energy nuclear collisions. In nucleon–nucleon collisions, hadrons with $p_T \geqslant 2$ GeV/c are believed to originate mostly from the jet fragmentation of constituent partons, quarks and gluons, that were scattered with large momentum transfer Q^2 [1]. In nuclear collision these hard scattering processes between constituent partons occur early compared to the lifetime of the strongly interacting matter. Thus the hard scattered partons may traverse

the highest energy density matter produced. Theoretical studies of the propagation of partons in high density matter suggest that they lose a significant fraction of their energy through gluon bremsstrahlung [2] and that the energy lost reflects the density of color charges in the matter through which they pass [3]. The energy loss reduces the momenta of the partons, which results in a corresponding reduction of the momenta of the fragmentation products [4], observable as a reduced yield of high p_T hadrons.

The first measurements of hadron spectra at the Brookhaven National Laboratory Relativistic Heavy Ion Collider (RHIC) facility indicate a suppression of high-p_T hadron production in central Au + Au collisions relative to a binary collision scaling of p + p and $\bar{\text{p}}$ + p data [5,6]. No suppression is found for peripheral Au + Au collisions. So far no unique explanation of this apparent absence of the expected jet contribution to the p_T spectrum above 2 GeV/c has been identified.

Models of parton energy loss can reproduce the observed suppression in central Au + Au collisions [7–9]. Other final state effects such as rescattering of hadrons originally produced via the jet fragmentation have been proposed to explain the suppression [10]. It should be noted that models invoking thermal hadron production combined with collective transverse expansion of the reaction volume successfully describe the transverse momentum distributions of identified hadrons up to 3 GeV/c [11,12]. However, the mechanism of equilibration, which requires a reduction of the high p_T particle yield, is not specified in these models.

Alternatively, the initial state may be modified such that the number of hard scatterings is reduced. It is well known that nuclear modifications of the parton distributions exist [13]. These modifications cannot explain the suppression, since in the kinematic range of the measurements anti-shadowing enhances the parton distributions in nuclei [14–16]. However, models using a classical QCD picture of a highly relativistic nucleus [17,18] suggest that gluon distributions are saturated for momenta below a scale Q_s and thus reduced compared to expectations based on perturbative QCD [19]. As a consequence, a considerable suppression of hadron production might be expected even well above Q_s [20].

In this Letter we present the centrality dependence of the suppression of the high-p_T hadron yield to provide new experimental constraints on theoretical descriptions. These data are complementary to the previous study of the absolute yields [5] and have different systematic errors.

2. Experimental setup and data analysis

The results are obtained from 1.4×10^6 minimum bias Au + Au collisions at $\sqrt{s_{\text{NN}}} = 130$ GeV recorded by the PHENIX experiment during the Run-1 operation of RHIC (August–September 2000). Details on the PHENIX detector and its configuration in Run-1 operation can be found in [5,21].

In PHENIX semi-inclusive charged hadron spectra are measured over the range $0.5 < p_T < 5.0$ GeV/c in the east central arm spectrometer using data from a drift chamber (DC) and two segmented cathode pad chambers (PC1 and PC3), located outside of an axial magnetic field at a radial distance of 2.2, 2.5 and 5 m from the beam axis. The detectors cover an azimuthal acceptance of 90° and a pseudo-rapidity range of $|\eta| < 0.35$. In this analysis an additional fiducial cut $|\eta| < 0.18$ is applied to guarantee homogeneous track acceptance for collisions within $|z_{\text{vtx}}| < 30$ cm of the nominal interaction point. About $\sim 25\%$ of the azimuthal acceptance is covered by a time-of-flight system which allows proton identification out to 3.5 GeV/c, where the measurement is limited by statistics [22].

A pair of beam–beam counters provides the vertex position along the beam direction (z). Each charged track is reconstructed from the DC measurements of its projection into the bend plane of the magnetic field and two space points provided by PC1 and PC3. The unphysical background, resulting from false associations of drift chamber projections with pad chamber points, is estimated and subtracted by forming artificial events with the locations of pad chamber points inverted around the symmetry axis of the spectrometer. Physical background from decays in flight and photon conversions close to the DC, which only partially traverse the field and thus mimic high momentum tracks, are removed by requiring the track to point back to the event vertex within $|z_{\text{vtx}}| < 2.5$ cm. The remaining background level is negligible below 4 GeV/c and less than 40% at 5 GeV/c; this upper estimate is included in the systematic errors.

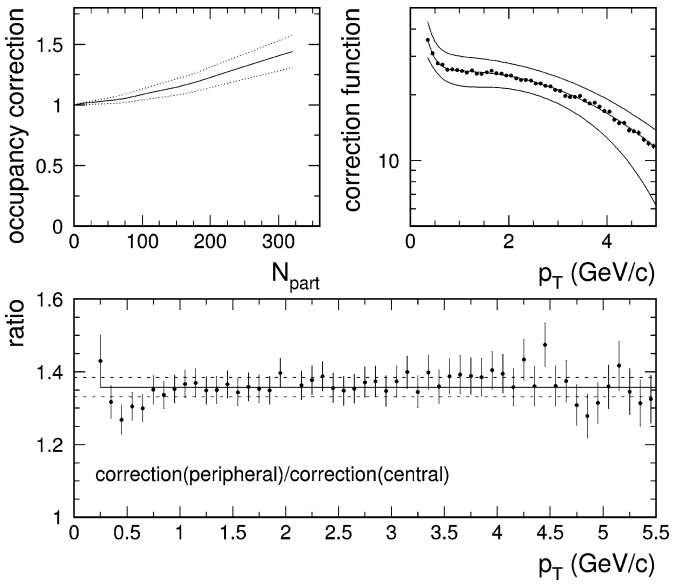

Fig. 1. Functions used to correct the charged particle p_T spectra. Upper left panel shows the centrality dependent correction $c(N_{\text{part}})$ and the right panel shows the p_T dependent correction $c(p_T)$. The systematic uncertainties are indicated by the dashed lines. The two corrections factorize, so that for any centrality the full correction function is given by $c(p_T) \times c(N_{\text{part}})$. The accuracy of this factorization is demonstrated in the lower panel. The ratio of the full correction for central collisions (top 5%) to the correction for single particle events varies by less than 2% above 1 GeV/c.

Corrections of the data are determined by tracing individual particles through a full GEANT simulation, simulating the detector response, then merging this response with that of all particles from a real event and passing the composite event through the PHENIX reconstruction software. The average track reconstruction efficiency in the active detector area is larger than 98% in peripheral collisions and decreases to $68 \pm 6\%$ for central collisions. The corresponding correction is shown on the upper left-hand side of Fig. 1. The full correction also depends on p_T. It is plotted for peripheral collision on the upper right-hand side of the figure. Between 0.8 and 2.5 GeV/c the correction factor varies slowly with p_T. Its value of ~ 25 corrects for geometrical acceptance ($\Delta\phi = \pi/4$; $\Delta\eta = 0.36$), dead areas of the detectors (45% DC, 5% PCs), and losses due to 2σ track matching cuts. At lower p_T the correction increases reflecting the gradual loss of acceptance. At higher p_T the observed particle yield is artificially increased because of the finite momentum resolution ($\delta p/p \simeq 0.6\% \oplus 3.6\% p$ (GeV/c)) and therefore the correction function decreases. Since this correction depends on the spectral shape of the true p_T distribution it was determined iteratively. At 5 GeV/c the correction is reduced by a factor of ~ 2. The systematic uncertainties are indicate by the dashed lines; they are also tabulated in Table 1. As shown in the lower part of Fig. 1 correction factorizes into functions of centrality (i.e., detector occupancy) and p_T within 2% systematic uncertainty in the range from 2 to 5 GeV/c.

Events are selected according to centrality following the procedure described in [5]. Six exclusive centrality bins are established using the energy measured in two zero-degree calorimeters and the number of charged-particles detected in the two beam–beam counters. A Monte Carlo simulation using measured nucleon density distributions calculated in the Glauber eikonal approximation was used to estimate the average number of binary nucleon–nucleon collisions (N_{coll}) and the corresponding average number of participating nucleons (N_{part}) for each bin. The results are quoted in Table 2.

3. Results

Fig. 2 presents charged hadron p_T spectra for the six centrality bins. For peripheral collisions the spectra

Table 1
Upper bounds of the systematic error on the p_T dependent single particle correction function

p_T (GeV/c)	δ_{track} (%)	δ_{decay} (%)	δ_{reso} (%)	δ_{bgr} (%)	Total
1	±13.5	+10	±0	0	−13.5+16.4
2	±13.5	+5	±1	0	−13.7+14.4
3	±13.5	+2.5	±4	−1.6	−14.2+14.2
4	±13.5	+1.25	±9	−11.5	−20 + 16
5	±13.5	+0.6	±15	−40	−45 + 16

Here δ_{track} includes the uncertainties of the acceptance, dead areas, track matching cuts and the track reconstruction efficiency. The δ_{decay} term accounts for the uncertainty of the decay correction. The effect of the momentum resolution contributes with δ_{reso} to the systematic error. Uncertainties due to potentially unsubtracted background are quantified by δ_{bgr}. The total systematic error given in the last column is calculated as quadrature sum of the individual contributions. It is calculated separately for positive and negative errors.

Table 2
Number of participants and binary collisions and their systematic errors for the individual centrality selections used in this analysis

Bin	Relative fraction (%)	N_{part}	N_{coll}	$N_{\text{coll}}^{\text{central}}/N_{\text{coll}}$	$2N_{\text{coll}}/N_{\text{part}}$
1	80–92	5.5±2.6	4.1±1.7	246 ± 98	1.5 ± 0.5
2	60–80	19.5±3.5	20 ± 6	50.4 ± 13	2.1 ± 0.5
3	30–60	79 ± 4.6	131 ± 23	7.68 ± 1.1	3.4 ± 0.6
4	15–30	180 ± 6.6	406 ± 46	2.49±0.13	4.5 ± 0.5
5	5–15	271 ± 9	712 ± 72	1.41±0.03	5.2 ± 0.6
6	0–5	348 ± 10	1009 ± 101	1	5.8 ± 0.6

Also given is the ratio of the number of binary collisions for the most central sample relative to the one for each sample. The last column quantifies the ratio of binary collisions to participant pairs.

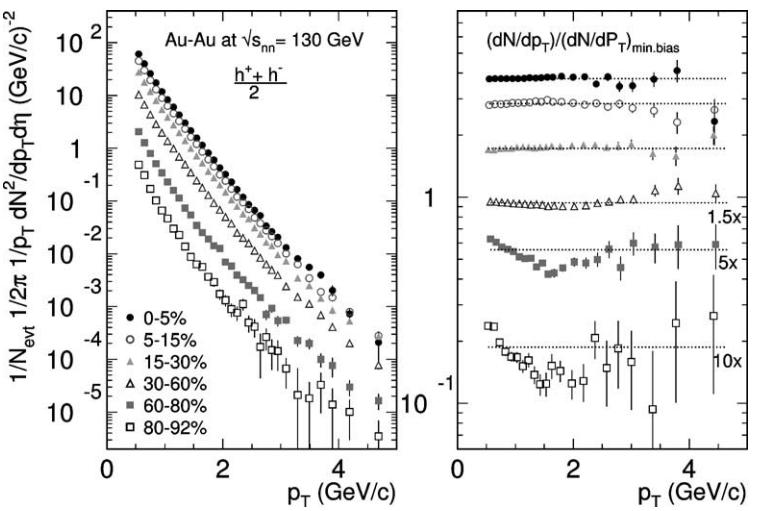

Fig. 2. The left panel shows p_T spectra of charged hadrons from six Au + Au centrality selections. Error bars indicate statistical errors only. The p_T dependent systematic errors are independent of centrality and not shown, they are given in Table 1. The centrality dependent errors are less than 10% and small compared to the symbol size. The right panel shows the ratio of each of the centrality selected p_T spectra to the minimum bias spectrum. Ratios for peripheral selections are scaled for clarity. Dotted lines indicate the average ratios for each centrality selection.

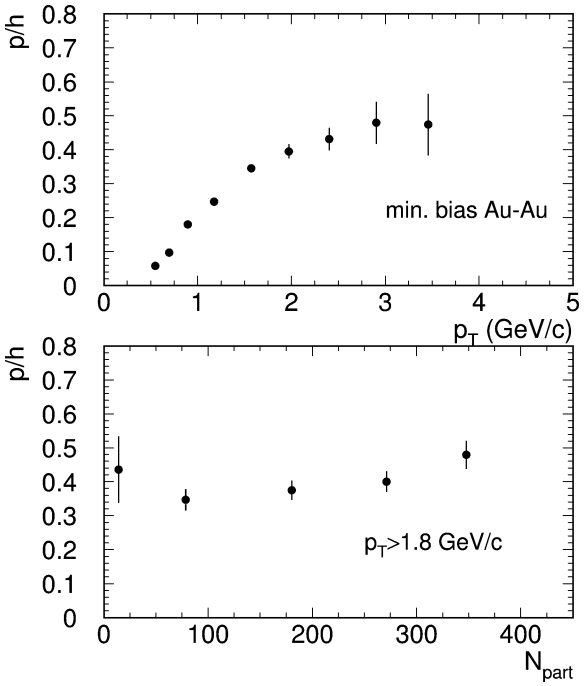

Fig. 3. The ratio p/h represents the proton plus anti-proton yield relative to the total charged hadron multiplicity. The top panel shows the p_T dependence of p/h for minimum bias events. In the bottom panel we show the centrality dependence of p/h for $p_T > 1.8$ GeV/c. Only statistical errors are shown.

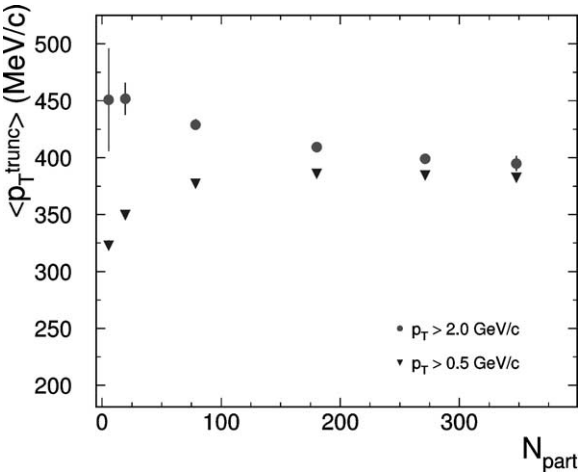

Fig. 4. Centrality dependence of $\langle p_T^{\text{trunc}} \rangle$, the average p_T of charged particles with p_T above a threshold p_T^{min} minus the threshold p_T^{min}. Shown are values for two p_T^{min} cuts, one at $p_T > 0.5$ GeV/c representing all data presented in Fig. 2 and the other one at $p_T > 2$ GeV/c. Only statistical errors are shown; see the text following Eq. (1) for a discussion of the systematic errors.

are more concave than those for central collisions. This shape difference is seen more clearly by taking the ratio of the spectrum for each centrality bin to the minimum-bias spectrum, as shown on the right-hand side of Fig. 2. In these ratios most systematic errors cancel or affect the overall scale only. The ratios for the central bins are almost independent of p_T since central collisions dominate the minimum bias yields. The peripheral bins show a decreasing ratio between 0.5 and 1.5 GeV/c thus in peripheral collisions the yield in this region decreases more rapidly with increasing p_T than in central collisions. For p_T above 1.5 GeV/c this trend is inverted.

Before analyzing the centrality dependence in more detail we demonstrate that the observed suppression of the yield at high p_T does not result from a reduced yield of protons and anti-protons [22]. To evaluate the effect of the (anti-)protons, we plot in the top panel of Fig. 3 the p_T dependence of p/h, the ratio of proton plus anti-proton yields to the total charged hadron yield for minimum bias collisions, which increases steadily. Above 1.5 GeV/c the ratio seem to saturate reaching a value of ~ 0.5 around 3 GeV/c. In the bottom panel of Fig. 3 we show p/h for p_T above 1.8 GeV/c as a function of centrality. Since there is clearly no significant decrease of the p/h ratio with either centrality or p_T, the observed hadron suppression is not due to a larger suppression of the (anti-)proton component than that of the mesons. On the contrary, within the range of the presented measurement the apparent slight increase in p/h with N_{part} could indicate a larger suppression of the meson component relative to all charged hadrons.

To evaluate the change of the hadron spectra more quantitatively we calculate the truncated average p_T:

$$\langle p_T^{\text{trunc}} \rangle \equiv \frac{\int_{p_T^{\text{min}}}^{\infty} p_T \, dN/dp_T}{\int_{p_T^{\text{min}}}^{\infty} dN/dp_T} - p_T^{\text{min}} \tag{1}$$

for $p_T^{\text{min}} = 0.5$ GeV/c and for $p_T^{\text{min}} = 2.0$ GeV/c for each centrality selection.[3] In Fig. 4 $\langle p_T^{\text{trunc}} \rangle$ is plotted as a function of N_{part}. The value of $\langle p_T^{\text{trunc}} \rangle$ is

[3] The value of $\langle p_T^{\text{trunc}} \rangle$ is closely related to the local inverse slope which is slightly smaller. The conversion to local slope depends on the spectral shape and also on p_T^{min}. For an exponential spectrum

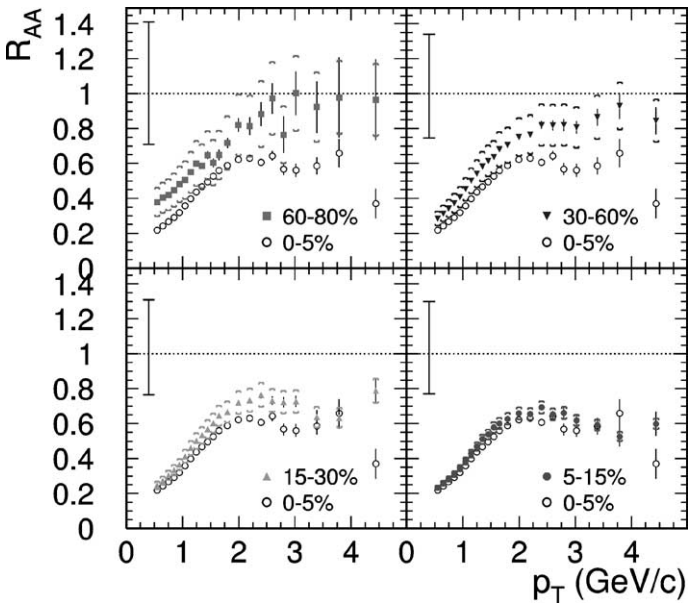

Fig. 5. Nuclear modification factor (R_{AA}) for the 60–80%, 30–60%, 15–30%, and 5–15% centrality selections compared to the one for the most central sample (0–5%). Due to insufficient statistics R_{AA} is not shown for the 80–92% sample. The solid error bars on each data point are statistical. The systematic error between the more peripheral and the central sample are given as brackets for the more peripheral data points. The error bar on the left-hand side of each panel indicates the overall systematic error on the R_{AA} scale.

insensitive to the normalization of the spectra. Systematic uncertainties of $\sim 20(50)$ MeV/c for $p_T^{\min} = 0.5(2.0)$ GeV/c result from an 1–2% uncertainty on the momentum scale and the p_T dependent uncertainties on the correction function. Since the centrality and p_T dependence of the correction factorize the error on $\langle p_T^{\text{trunc}} \rangle$ is independent of centrality to better than 2 MeV/c.

The $\langle p_T^{\text{trunc}} \rangle$ for $p_T^{\min} = 0.5$ GeV/c increases with N_{part} similar to the average p_T of identified charged hadrons [22]. For higher $p_T^{\min} = 2.0$ GeV/c the $\langle p_T^{\text{trunc}} \rangle$ drops by ~ 60 MeV/c with N_{part}, distinctly different from the expected increased role of hard particle production in the more central collisions. Absent any collective effects, the hard scattering contribution should increase relative to soft production by the factor $N_{\text{coll}}/N_{\text{part}}$ which grows from 1.5 to ~ 6 from peripheral to central collisions. Since the relative contribution of the hard component to the spectrum increases with p_T, this should lead to a rise of $\langle p_T^{\text{trunc}} \rangle$ for sufficiently large $p_T^{\min}$. The drop of $\langle p_T \rangle$ therefore indicates the suppression of the high p_T relative to the low p_T hadron yield independent of systematic errors associated with the absolute normalization of the spectra or any nucleon–nucleon reference distribution.

Changes of the hadron spectra at high p_T are often presented in terms of the nuclear modification factor R_{AA}. This measure relies on the absolute normalization and a reference and therefore has intrinsically larger systematic uncertainties, but it allows to quantify the suppression. We have calculated R_{AA} for each centrality bin as:

$$R_{AA}(p_T, \eta) = \left(\frac{1}{N_{\text{evt}}} \frac{d^2 N^{A+A}}{dp_T\, d\eta} \right) \times \left(\frac{\langle N_{\text{coll}} \rangle}{\sigma_{\text{inel}}^{\text{N+N}}} \frac{d^2 \sigma^{\text{N+N}}}{dp_T\, d\eta} \right)^{-1}. \quad (2)$$

For the N + N charged hadron cross section we use a power-law parameterization $1/\pi\ d^2\sigma/dp_T^2 = A/(1 + p_T/p_0)^n$, with $A = 330$ mb/(GeV/c)^2, $p_0 = 1.72$ GeV/c, and $n = 12.4$. The parameters were obtained by interpolating p + p and $\bar{\text{p}}$ + p data to $\sqrt{s} = 130$ GeV as described in [5]. In Fig. 5 the $R_{AA}(p_T)$

with an inverse slope of 350 MeV/c the conversion is approximately $-80(-60)$ MeV/c for $p_T^{\min} = 0.5(2.0)$ GeV/c.

values for all centrality bins excluding the most peripheral one are compared to the central (0–5%) bin. The systematic uncertainties in the normalization of the data, in $N_{\rm coll}$, and in the N + N reference (20%) result in overall systematic errors of about 41%, 34%, 31%, 31% and 30% for centrality bins 2–6, respectively. The errors are quoted for the range from 1 to 3.5 GeV/c; they increase somewhat towards higher p_T. Comparing R_{AA} for a given centrality bin to the most central bin, the systematic errors reduce to $\sim 6\%$ for bin 5 (5–15%) and nearly 27% for bin 2(60–80%). They are dominated the uncertainty in $N_{\rm coll}$ listed in Table 2.

For the 60–80% centrality bin, R_{AA} increases with p_T and reaches unity at high p_T. In comparison to the 60–80% bin, the R_{AA} values for the most central bin remain significantly below unity at a value of 0.55 for $p_T > 2$ GeV/c. At high p_T approximately constant R_{AA} values are detected in all centrality bins. The high p_T values decrease monotonically with centrality, clearly indicating that the magnitude of the suppression of high p_T hadrons increases with centrality. This is shown clearly in the upper part of Fig. 6, which presents R_{AA} obtained for the three p_T bins 1.6 to 2.6 GeV/c, 2.6 to 3.6 GeV/c, and above 3.6 GeV/c as a function of centrality. For central collisions we observe a suppression of about a factor of 2 ± 0.6 compared to binary collision scaling. Relative to peripheral collisions the suppression factor in central collisions increases with p_T from 1.25 ± 0.2 to 1.5 ± 0.2 to 1.8 ± 0.3 for the three p_T bins, respectively.

We note that for peripheral collisions the data do not indicate a significant increase of R_{AA} above unity, unlike data at lower energies [23]. However, such an increase, attributed to initial state scattering, the Cronin effect [24], may well be consistent with the peripheral data due to the large systematic uncertainty of the R_{AA} scale. While the relative difference between the peripheral and central spectra increases with p_T, the roughly constant nuclear modification factor at large p_T suggests an approximately p_T independent suppression of hard scattering contributions over the range $2 < p_T < 4.5$ GeV/c.

The physics that controls the production of high-p_T particles or the suppression of the hard scattering yields in the measured p_T range may not depend directly on $N_{\rm coll}$. Thus, we have calculated a different

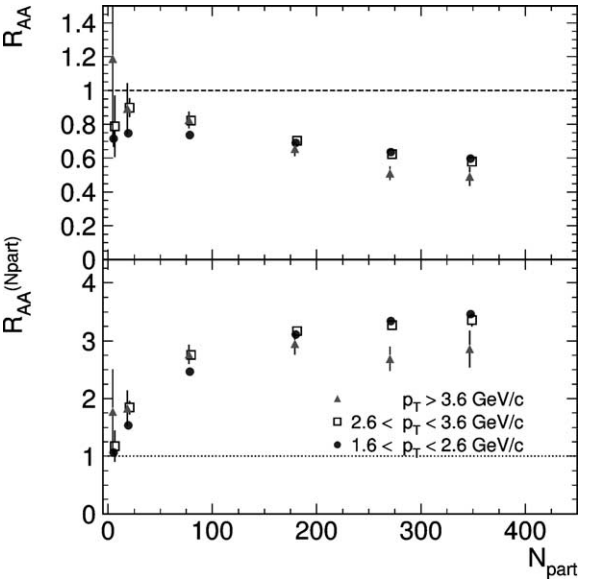

Fig. 6. The top panel gives the nuclear modification factor R_{AA} for three exclusive p_T regions as a function of the centrality of the collision. The lower panel shows essentially the same quantity but normalized to the number of participant pairs rather than to the number of binary collisions. The dotted line indicates the expectation for scaling with the number of binary collisions (top) or with the number of participants (bottom). Only statistical errors are shown. The systematic error on the scale and the centrality dependence are identical to the errors shown in Fig. 5. These errors are correlated, i.e., take their maximum or minimum value simultaneously for all centrality and p_T selections. In addition, there are also p_T dependent systematic errors, which are given in Table 1. The systematic errors do not alter the trends in the data.

ratio, $R_{AA}^{\rm part}$, defined similarly to R_{AA} but with $N_{\rm coll}$ replaced by the number of participant pairs, $N_{\rm part}/2$. If particle production increases proportional to the number of participants, $R_{AA}^{\rm part} = 1$.

The obtained $R_{AA}^{\rm part}$ values are shown in Fig. 6 (bottom) for the three p_T bins used above. The values of $R_{AA}^{\rm part}$ are larger than R_{AA} by a factor equal to $2N_{\rm coll}/N_{\rm part}$ the average number of nucleon–nucleon collisions suffered by each participant. For all p_T bins the yield per participant is consistent with unity for peripheral collisions as expected since peripheral collisions should closely resemble N + N collisions. For central collisions $R_{AA}^{\rm part}$ increases to approximately three. Most of this change occurs in the range of $N_{\rm part}$ from 40 to 140. For larger $N_{\rm part}$ the yield in the highest p_T bin is approximately constant while in both lower p_T bins it increases by 20 to 30%.

4. Concluding discussion

In this Letter we have presented the centrality dependence of charged hadron p_T spectra focusing on the behavior of the spectra at high p_T. A striking change of the spectral shape is observed when comparing spectra from different centrality selections. For peripheral collisions the spectrum exhibits a pronounced concave shape which is modified towards a more exponential spectrum as the centrality increases. The observed lack of variation with centrality in the proton to charged ratio at large transverse momenta indicates that the modification is not due to a change in the relative yields of protons.

We observe a decrease of $\langle p_T^{\text{trunc}} \rangle$ for $p_T > 2$ GeV/c with increasing centrality, which is distinctly different from the increase of $\langle p_T \rangle$ and demonstrates the suppression of the high p_T hadron yield independent of systematic errors associated with the absolute normalization of the spectra. The data are not consistent with binary collision scaling of hard scattering processes, which would results in an increase of $\langle p_T^{\text{trunc}} \rangle$. If the p_T spectra above 2 GeV/c are strongly affected by collective motion of matter before freeze-out, we would also expect an increase $\langle p_T^{\text{trunc}} \rangle$ since the corresponding flow velocities should increase in more central collisions [25]. Similarly, if gluon saturation is important for particle production in the p_T range above 2 GeV/c, $\langle p_T^{\text{trunc}} \rangle$ should increase with increasing N_{part} due to the predicted logarithmic increase of Q_s [26]. In contrast, the data are consistent with models assuming energy loss of hard scattered partons, which results in an increasing reduction of the hard scattering contribution to the hadron spectrum with increasing centrality of the collisions [7–9]. It remains to be seen whether this explanation is unique.

Comparing the measured differential yields in five centrality bins to an N_{coll} scaling of the N + N reference yields we see a suppression of the yields in central collisions at high p_T, consistent with the results in [5,6]. In the 0–30% centrality range (bins 1–3) the suppression is approximately independent of p_T for $2 < p_T < 5$ GeV/c at a value of $R_{AA} \sim 0.6$ and simultaneously nearly independent within 20% of centrality. The suppression sets in gradually with the largest change occurring over the 30–60% centrality range. This centrality bin covers a broad range of collision geometries. Whether the change is continuous or exhibits a threshold behavior, as predicted in [27], cannot be judged from the present data. The observed suppression is consistent with parton energy loss scenarios. In these models, the value of R_{AA} and its p_T dependence are very sensitive to the actual energy loss prescription. Due to the large systematic errors on the R_{AA} scale, the contribution from the protons and the limited p_T reach of the data presented here, we cannot distinguish between the different energy loss prescriptions on the basis of R_{AA}.

In summary, a detailed analysis of the centrality dependence of charged particle data from Au–Au collisions at $\sqrt{s_{\text{NN}}} = 130$ GeV measured by PHENIX reveals interesting features of the observed high p_T hadron suppression. The decrease of the average p_T with increasing centrality seems to favor models of particle production that consider energy loss effects, rather than saturation- or hydrodynamics-based approaches for this p_T range. The suppression sets in gradually with the largest changes occurring for peripheral collisions with less than about 140 participating nucleons. From there on it does not change substantially towards more central collisions.

Note added in proof

After submission of our manuscript, data from Au–Au collisions at $\sqrt{s_{\text{NN}}} = 200$ GeV were presented by the PHOBOS Collaboration [28,29], with an emphasis on the lack of variation in the scaled yields with N_{part} for $N_{\text{part}} > 65$. Keeping in mind that results from different energies are not directly comparable, we note that the broader range in N_{part} presented here shows that this effect does not apply over the entire range of centralities, and that when normalized with the appropriate p–p yields, is simply an aspect of the smooth variation of R_{AA}^{part} visible in Fig. 6.

(Received 25 June 2002; published 2 April 2003)

Results on the study of localized fluctuations in the multiplicity of charged particles and photons produced in 158*A* GeV/*c* Pb+Pb collisions are presented for varying centralities. The charged versus neutral particle multiplicity correlations in common phase space regions of varying azimuthal sizes are analyzed by two different methods. Various types of mixed events are constructed to probe fluctuations arising from different sources. The measured results are compared to those from simulations and from mixed events. The comparison indicates the presence of nonstatistical fluctuations in both the charged particle and photon multiplicities in limited azimuthal regions. However, no correlated charged-neutral fluctuations, a possible signature of formation of disoriented chiral condensates, are observed. An upper limit on the production of disoriented chiral condensates is set.

I. INTRODUCTION

The large number of particles produced in relativistic heavy-ion collisions at the Super Proton Synchrotron (SPS) and the Relativistic Heavy-Ion Collider provide an opportunity to analyze and study, on an event-by-event basis, fluctuations in physical observables, such as particle multiplicities, transverse momenta, and their correlations. These studies provide information on the dynamics of multiparticle production and may help us to reveal the phase transition from hadronic matter to quark-gluon plasma [1,2]. The formation of hot and dense matter in high energy heavy-ion collisions also has the possibility to create matter in a chiral symmetry restored phase in the laboratory. After the initial stage of the collision, the system cools and expands, returning to the normal QCD vacuum in which the chiral symmetry is spontaneously broken. During this process, a metastable state may be formed in which the chiral condensate is disoriented from the true vacuum direction. This transient state would subsequently decay by emitting pions coherently within finite subvolumes or domains of the collision region. The possibility of formation of disoriented chiral condensate (DCC) has been discussed extensively in recent years [3–11]. The detection and study of the DCC state would provide valuable information about the chiral phase transition and the vacuum structure of strong interactions.

Theoretical studies [5–7] suggest that isospin fluctuations caused by the formation of a DCC would produce clusters of coherent pions in localized phase space domains. The formation of DCC domains would be associated with large event-by-event fluctuations in the ratio of neutral to charged pions. The probability distribution of the neutral pion fraction f in such a DCC domain has been shown [3] to follow the relation

$$P(f)=\frac{1}{2\sqrt{f}}, \quad \text{where} \quad f=N_{\pi^0}/N_{\pi}, \tag{1}$$

which is quite different from that of the normal pion production mechanism. For the normal pion production, where the production of π^0, π^+, and π^- are equally probable, the f distribution is binomial, peaking at 1/3.

In the experimental search for localized domains of DCC, a practical approach is to search for events with large and localized fluctuations (localized in pseudorapidity η and azimuthal angle ϕ) in the ratio of the number of photons to charged particles, which would directly reflect fluctuations in the neutral to charged pion ratio. Typical event structures would be similar to the Centauro and anti-Centauro events reported by the JACEE Collaboration [12]. Results from other cosmic ray experiments have not ruled out the possibility of the DCC formation mechanism [13]. The accelerator based studies carried out in p-$\bar{p}$ [14] and heavy-ion [15,16] reactions have investigated particle production over extended regions of phase space. These analyses were not sensitive to the presence of small domains of DCC localized in phase space. The first search for evidence of localized domains of DCC has been carried out at the SPS by the WA98 experiment in a detailed study of central Pb+Pb events [17]. The analysis showed the presence of localized nonstatistical fluctuations in the multiplicity of both photons and charged particles. However, the charged-neutral fluctuations were found not to be correlated event by event, as would be expected for a DCC production mechanism. An upper limit on the frequency of DCC formation in central Pb+Pb collisions was set. Recently, there have been theoretical suggestions to look for DCC formation in events for intermediate centralities [18]. In this paper we present first results on the centrality dependence of localized charged-neutral multiplicity fluctuations. It is based on an analysis of event-by-event fluctuation in the relative number of charged particles and photons detected within the common acceptance of the photon and charged particle multiplicity detectors of the WA98 experiment [19].

The paper is organized in the following manner: In the following section we describe the detectors used for the present analysis; the centrality selection criteria, the data reduction, and simulation. Section III deals with the analysis techniques where two analysis methods are presented, one based on the correlation of photons and charged particles, and the other based on a discrete wavelet transformation analysis. In Sec. IV, we present in detail the construction of mixed events used for this study. Section V discusses the ability of the mixed events to probe specific fluctuations. The final results and discussion are given in Sec. VI. A summary is presented in Sec. VII.

II. EXPERIMENTAL SETUP AND DATA REDUCTION

In the WA98 experiment at CERN [19], the main emphasis has been on high precision, simultaneous detection of both hadrons and photons. The experimental setup consisted of large acceptance hadron and photon spectrometers, detectors for charged particle and photon multiplicity measurements, and calorimeters for transverse and forward energy measurements. The present study makes use of the data from the photon multiplicity detector (PMD), the silicon pad multiplicity detector (SPMD), and the midrapidity calorimeter (MIRAC).

A. Centrality selection

The centrality of the interaction was determined from the total transverse energy (E_{T}) measured by the MIRAC [20]. The MIRAC measures both the transverse electromagnetic (E_{T}^{em}) and hadronic (E_{T}^{had}) energies in the interval $3.5 \leqslant \eta \leqslant 5.5$ with a resolution of $17.9\%/\sqrt{E}$ and $46.1\%/\sqrt{E}$, respectively, where E is expressed in GeV. The centrality, or impact parameter of the collision, has a strong correlation with the amount of E_{T} produced. Events with large E_{T} production correspond to the most central, small impact parameter, collisions [21].

The centralities are expressed as fractions of the minimum bias cross section as a function of the measured total E_{T}. For the present analysis we have used data selections in four centrality bins, the top 5% (henceforth referred to as centrality-1), 5–10 % (centrality-2), 15–30 % (centrality-3),

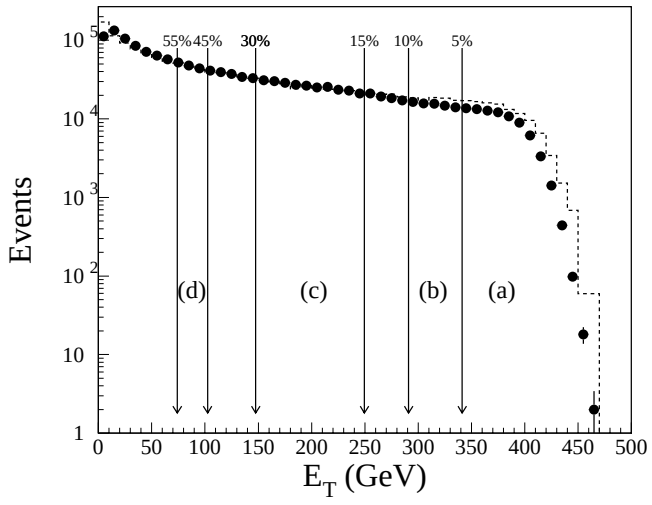

FIG. 1. The total E_{T} distribution (solid dots) measured in $3.5 \leqslant \eta \leqslant 5.5$ for Pb+Pb collision at 158*A* GeV/c. The total E_T distribution as obtained from VENUS is also shown as dashed histogram. The E_{T} values corresponding to the different centrality bins used in the analysis are shown. (a) Centrality-1 (0–5 %), (b) centrality-2 (5–10 %), (c) centrality-3 (15–30 %), and (d) centrality-4 (45–55 %) of the minimum bias cross section as determined by selection on the measured transverse energy distribution.

and 45–55 % (centrality-4) of the minimum bias cross section. The minimum bias distribution of the total E_{T} is shown in Fig. 1. The centrality bins used in this analysis are marked in the figure.

B. Photon multiplicity detector

The photon multiplicity is measured using the preshower PMD located at a distance of 21.5 m from the target. The PMD consists of three radiation length (X_0) thick lead converter plates in front of an array of square scintillator pads of four sizes, varying from 15×15 mm^2 to 25×25 mm^2, placed in 28 box modules. Each box module consists of a matrix of 38×50 scintillator pads read out using an image intensifier plus charged coupled device (CCD) camera system. The scintillation light is transmitted to the readout device via a short wavelength shifting fiber spliced to a long extramural absorber coated clear fiber. The total light amplification of the readout system is $\sim$40 000. Digitization of the CCD pixel charge is done by a set of custom built fast-bus modules employing an 8-bit, 20-MHz flash analog-to-digital converter (ADC) system. Details of the design and characteristics of the PMD may be found in Refs. [22,23]. The results presented here make use of the data from the central 22 box modules covering the pseudorapidity range of $2.9 \leqslant \eta \leqslant 4.2$. The clusters of hit pads, having total ADC content above a hadron rejection threshold are identified as photon-like, the multiplicity being denoted by $N_{\gamma\text{-like}}$. If the number of incident photons is denoted by N_γ^{inc} and the number of photons detected above the hadron rejection threshold as N_γ^{th}, then the photon counting efficiency ϵ_γ and purity of photon sample (f_p) are defined as $\epsilon_\gamma = N_\gamma^{th}/N_\gamma^{inc}$ and $f_p = N_\gamma^{th}/N_{\gamma\text{-like}}$, respectively. These are estimated from detector simulations [22,23]. The photon counting efficiencies for the central to peripheral cases varies from 68% to 73%. The purity of the photon sample in the two cases varies from 65% to 54% [22,23]. The acceptance in terms of transverse momentum p_T extends down to about 30 MeV/c, however, the PMD energy resolution is not sufficient for particle-by-particle p_T measurement.

C. Silicon pad multiplicity detector

The charged particle multiplicity N_{ch} is measured using the circular SPMD located 32.8 cm from the target and having full azimuthal coverage in the region $2.35 < \eta < 3.75$, corresponding to the central rapidity region at SPS energies (where $\eta_{CMS} = 2.92$). The detector consists of four overlapping quadrants, each fabricated from a single 300-μm-thick silicon wafer. The active area of each quadrant is divided into 1012 pads forming 46 azimuthal wedges and 22 radial bins, with the pad size increasing with increasing radius to provide equal sized pseudorapidity bins. The efficiency for detection of a charged particle in the active area has been determined in test beam measurements to be better than 99%. Conversely, the detector is transparent to high energy photons, since only about 0.2% are expected to interact in the silicon. During the data recording, 95% of the pads worked properly and are used in this analysis. Details of the characteristics of the SPMD can be found in Refs. [15,24]. The SPMD does not provide p_T measurement, but provides the multiplicity measurement integrated over transverse momentum p_T with a threshold which extends down to about 20 MeV/c.

D. Data reduction

The data presented here were taken in 1996 at the CERN SPS with the 158*A* GeV Pb ion beam on a Pb target of thickness 213 μm. The WA98 Goliath magnet was switched off during these runs. Events with beam pileup, downstream interactions, and pileup in the CCD camera system were rejected in the off-line analysis [15,23]. The data have been analyzed for the region of common η ($2.9 < \eta < 3.75$) and ϕ coverage of the SPMD charged particle and PMD photon multiplicity detectors. The $N_{\gamma\text{-like}}$ and the N_{ch} distributions for the four centrality bins are shown in Figs. 2 and 3. The number of events analyzed, the mean number of photons and charged particles, along with the root mean square deviations are shown in the figures. The PMD and SPMD detectors provide momentum integrated multiplicity measurements with very low thresholds. Since pions from DCC domains are expected to have small p_T values, below the pion mass, the momentum integration will dilute the DCC signal. On the other hand, the large coverage of the PMD and SPMD are important to overcome the limitations of small number fluctuations.

The various sources of systematic errors associated with the $N_{\gamma\text{-like}}$ and N_{ch} distributions have been investigated and described in detail previously [23,25]. These include the following.

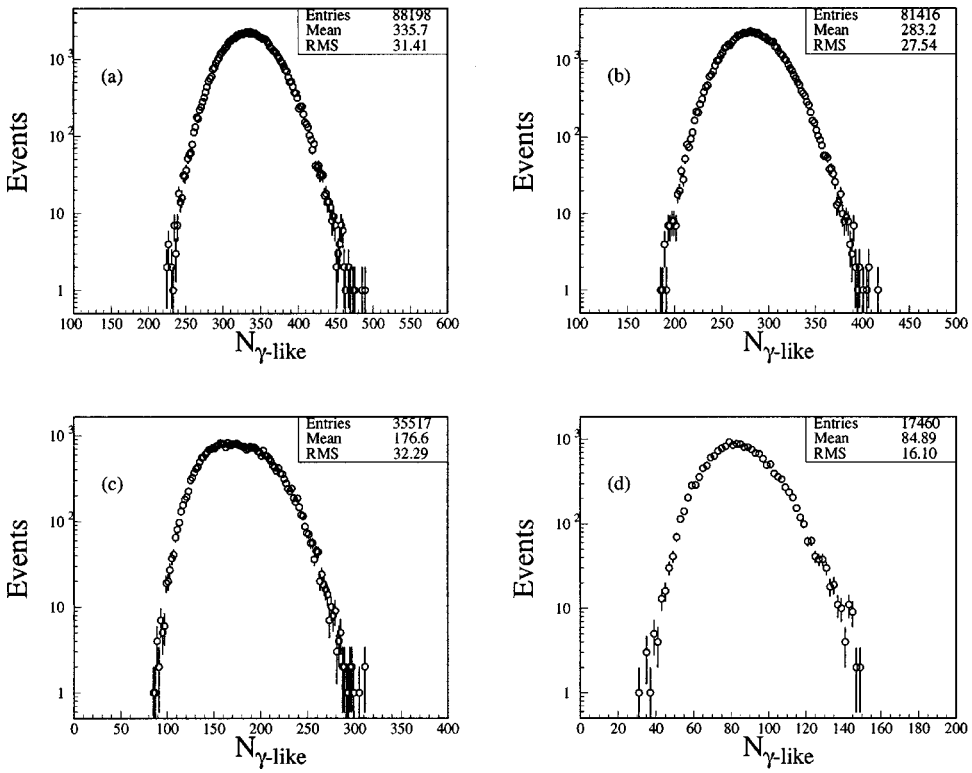

FIG. 2. The $N_{\gamma\text{-like}}$ multiplicity distributions for the four centrality selections for Pb+Pb collision at 158*A* GeV/*c*. (a) Centrality-1 (0–5 %), (b) centrality-2 (5–10 %), (c) centrality-3 (15–30 %), and (d) centrality-4 (45–55 %).

(a) The uncertainty in the energy calibration and the associated uncertainty in the energy threshold for hadron rejection in the PMD leads to an error in the efficiency for $N_{\gamma\text{-like}}$ clusters. The nominal hadron rejection threshold was set at three times the minimum ionizing particle (MIP) peak. The value of the threshold was reduced by 10% [23] in order to estimate the systematic error. The associated error in $N_{\gamma\text{-like}}$ is 2.5%.

(b) The error due to the effect of clustering of pad signals in the PMD is a major source of error in $N_{\gamma\text{-like}}$. This error is determined from GEANT [26] simulation by comparing the number of known photon tracks on the PMD with the total

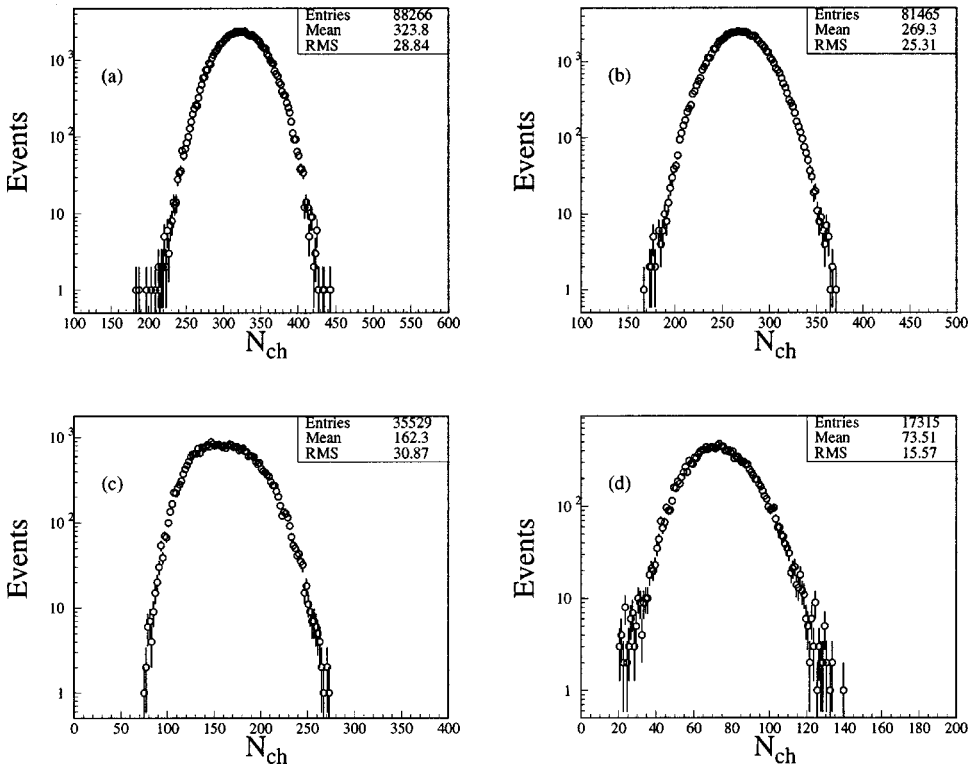

FIG. 3. The N_{ch} multiplicity distributions for the four centrality selections for Pb+Pb collision at 158*A* GeV/*c*. (a) Centrality-1 (0–5 %), (b) centrality-2 (5–10 %), (c) centrality-3 (15–30 %), and (d) centrality-4 (45–55 %).

number of reconstructed photonlike clusters. It is found that the number of clusters exceeds the number of tracks by 3% in the case of peripheral events and by 7% for high multiplicity central events.

(c) The error due to the variation in pad-to-pad gains of the scintillators in PMD was found to be less than 1%.

(d) The uncertainty in the $N_{\rm ch}$ determination with the SPMD has been estimated to be about 4% [15].

(e) The error due to the finite resolution in the measurement of the total transverse energy E_T in MIRAC [23] translates into an uncertainty in the centrality selection. The effect of this systematic error has been determined by performing the analysis with varying centrality cut within the MIRAC resolution.

The contribution of each of these various systematic errors to the final results is discussed in the following sections.

E. Simulated events

Simulated events were generated using the VENUS 4.12 event generator [27] with the default parameter values. The output was processed through a detector simulation package in the GEANT 3.21 [26] framework. This simulation includes the full WA98 experimental setup and includes experimental effects such as photon conversions, downstream interactions, hadron backgrounds in the PMD, etc., which might dilute or enhance the observed fluctuations. The effect of Landau fluctuations in the energy loss of charged particles in silicon was included in the SPMD simulation [15]. For the PMD simulation, the GEANT results in terms of energy deposition in pads were converted to the pad ADC values using the MeV-ADC calibration relation. After this the ADC distribution is convoluted with a Gaussian function of proper width taken from the readout resolution curve. If the energy deposition is less than three MIP, a Landau distribution is used for convolution. The details of the PMD simulations taking into account the detector and readout effects can be found in Ref. [22]. The centrality selection with the simulated data has been made in a manner identical to the data, determined from the simulated total transverse energy in MIRAC. The minimum bias total $E_{\rm T}$ distribution predicted by VENUS is shown by the dashed histogram in Fig. 1. The agreement with the data is seen to be quite reasonable. A total of 60 K VENUS events with simulated detector response were generated for the present study. These simulated events (henceforth referred to simply as VENUS events unless otherwise specified) were then processed with the same analysis codes as used for the analysis of the experimental data.

III. ANALYSIS TECHNIQUES

Two different analysis methods have been used in the present study. In the first analysis method, the magnitude of the $N_{\gamma\text{-like}}$ versus $N_{\rm ch}$ multiplicity fluctuations is obtained in decreasing phase space regions. The second method employed the discrete wavelet transformation technique to investigate the relative magnitude of the $N_{\gamma\text{-like}}$ versus $N_{\rm ch}$ fluctuations in adjacent phase space regions. The results from these methods of analysis applied to data, VENUS, and various sets of mixed events (to be discussed later) are compared to draw proper conclusions.

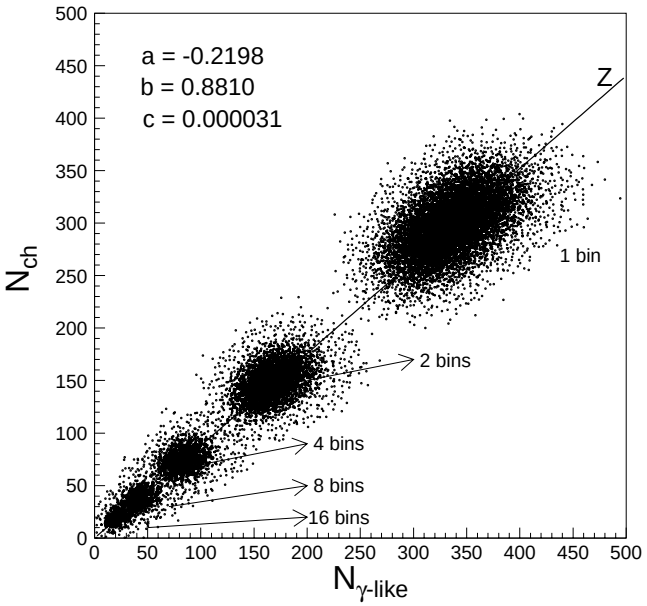

FIG. 4. The event-by-event correlation between $N_{\rm ch}$ and $N_{\gamma\text{-like}}$ for centrality bin 1. Overlaid on the plot is the common correlation axis (Z axis) obtained for the full distribution by fitting the $N_{\gamma\text{-like}}$ and $N_{\rm ch}$ correlations with a second-order polynomial. The values in the upper left are the coefficients of the polynomial of the form $N_{\rm ch}=a+bN_{\gamma\text{-like}}+cN^2_{\gamma\text{-like}}$. For the other three centrality classes, the plots are qualitatively similar.

A. N_γ versus $N_{\rm ch}$ correlations

In order to search for localized fluctuations in the photon and charged particle multiplicities, which may have non-statistical origin, the correlation between $N_{\gamma\text{-like}}$ and $N_{\rm ch}$ is investigated at various scales in ϕ.

The event-by-event correlation between $N_{\gamma\text{-like}}$ and $N_{\rm ch}$ has been studied in various ϕ intervals by dividing the entire ϕ space into 2, 4, 8, and 16 bins. The method of analysis is similar to that described in Refs. [15,17]. Figure 4 shows a scatter plot of the correlation between $N_{\gamma\text{-like}}$ and $N_{\rm ch}$ for the top centrality bin. The correlation plots for each ϕ interval size, including the case of the full interval with no segmentation, are shown. The distributions for the other three centrality bins are qualitatively similar. A common correlation axis Z has been obtained for the full distribution by fitting the $N_{\gamma\text{-like}}$ and $N_{\rm ch}$ correlation with a second-order polynomial. The correlation axis with fit parameters is shown in the figure. The distance of separation (D_Z) between a data point and the correlation axis has been calculated with the convention that D_Z is positive for points below the Z axis. The distribution of D_Z represents the relative fluctuations of $N_{\gamma\text{-like}}$ and $N_{\rm ch}$ from the correlation axis for any chosen ϕ bin size. In order to compare the fluctuations for different ϕ bins on a similar footing, a scaled variable $S_Z=D_Z/s(D_Z)$ is used, where $s(D_Z)$ represents the rms deviation of the D_Z distribution for VENUS events analyzed in the same manner. The D_Z distributions of data, mixed events, and the simu-

lated events for a given centrality and ϕ bin size are all scaled by the same $s(D_Z)$ corresponding to the VENUS events for the respective centrality and azimuthal bin size. The presence of events with localized fluctuations in $N_{\gamma\text{-like}}$ and N_{ch}, at a given ϕ bin, is expected to result in a broader distribution of S_Z compared to those for normal events. Comparing the rms deviations of the S_Z distributions of data, mixed events (to be discussed later), and VENUS events may allow us to infer the presence of nonstatistical localized fluctuations.

B. Multiresolution DWT analysis

A multiresolution analysis using discrete wavelet transform (DWT) [28] has been shown to be quite powerful in the search for localized domains of DCC [29–31]. The significance of the DWT technique lies in its power to analyze a spectrum at different resolutions, with the ability to identify fluctuations present at any scale. This method has been utilized very successfully in many fields including image processing, data compression, turbulence, human vision, radar, and earthquake prediction [28]. It should be noted that the DWT analysis provides information different from the moment analysis of the preceding section. It analyzes the event-by-event distribution in ϕ space to characterize the bin-to-bin fluctuations relative to the average behavior.

For the present DWT analysis, the full azimuthal region is divided into smaller bins in ϕ, the number of bins at a given scale j being 2^j. The input to the analysis is a spectrum of the sample function at the smallest bin in ϕ corresponding to the highest resolution scale j_{max}. In the present case the sample function is chosen to be the photon fraction, given by

$$f'(\phi)=N_{\gamma\text{-like}}(\phi)/[N_{\gamma\text{-like}}(\phi)+N_{\text{ch}}(\phi)]. \tag{2}$$

A multiresolution analysis has been carried out using the D-4 wavelet basis on the above sample function starting with $j_{max}=5$. It may be mentioned that there are several families of wavelet bases distinguished by the number of coefficients and the level of iteration; we have used the frequently employed D-4 wavelet basis [32]. The output of the DWT consists of a set of wavelet or father function coefficients (FFCs) at each scale, from $j=1,\ldots,(j_{max}-1)$. The coefficients obtained at a given scale j are derived from the distribution of the sample function at one higher scale, $j+1$. The FFCs quantify the bin-to-bin fluctuations in the sample function at that higher scale relative to the average behavior. The presence of localized nonstatistical fluctuations will increase the rms deviation of the distribution of FFCs and may result in non-Gaussian tails [29,31]. The DWT technique as used in this analysis has been demonstrated in our earlier publication [17]. Once again, comparing the rms deviations of the FFC distributions of data, mixed events, and VENUS events may allow us to infer the presence of localized fluctuations. The utility of the mixed events and the response of the analysis technique are demonstrated in Sec. V.

IV. CONSTRUCTION OF MIXED EVENTS

It is possible to search for nonstatistical fluctuations in the experimental data in a model independent way by comparison of the data with mixed events generated from the data itself. Furthermore, it is necessary to isolate the various contributions to the fluctuations and to understand all detector related effects in the data. This has been done by generating different types of mixed events which preserve the global multiplicity correlation between $N_{\gamma\text{-like}}$ and N_{ch}. Fluctuations in the ratio of N_γ to N_{ch} can arise due to fluctuations in N_γ only, fluctuations in N_{ch} only, or fluctuation in both N_γ and N_{ch}. Furthermore, the fluctuations in N_γ and N_{ch} may be correlated event by event, as nominally expected in the case of DCC formation. Each of these possibilities is investigated through the construction of four different kinds of mixed events. The method of construction of these mixed events and the type of fluctuations they probe are described next.

A. Maximally mixed events

The first set of mixed events, referred to as $M1$ events, are constructed to remove all correlations to the greatest extent possible to provide a base line for comparison to the real event data. They were generated by mixing hits in both the photon and charged particle detectors separately, but still satisfying the global $N_{\gamma\text{-like}}$-N_{ch} correlation of the real event in the full acceptance. This means that on an event-by-event basis, the total photon multiplicity and charged particle multiplicity of the mixed event were identical to those of the real event to which it corresponds. Thus, the scatter plot of the mixed events is identical to the real events for the single-bin case shown in Fig. 4. The idea is to constrain the mixed events to be identical to real events globally, and then compare them to the real data in localized regions of phase space to search for indications of nonstatistical localized fluctuations in the data.

The $M1$ type of mixed events was constructed from the pool of all photonlike and charged particle hits, in which the hit position (η and ϕ) and event information (event number and total multiplicity) were kept for both the photonlike and charged particle hits. For a given real event measured to have multiplicities $N_{\gamma\text{-like}}$ and N_{ch} in the full acceptance region, a mixed event was constructed by randomly selecting $N_{\gamma\text{-like}}$ photonlike hits from the pool of photonlike hits and N_{ch} charged particle hits from the pool of charged particle hits. This procedure was repeated for each real event. Care was taken such that no two hits from the same real event were used in the construction of a mixed event. Also, for the mixed events, hits within either the SPMD or PMD detector were not allowed to lie within the two-track resolution of that detector. In brief, the $M1$ mixed events randomly distribute the hits in each individual detector but keep the global correlation between the $N_{\gamma\text{-like}}$ and N_{ch} multiplicity. They provide a maximally randomized sample of PMD and SPMD hits. Comparisons of such mixed events to real events will be most sensitive to the presence of localized fluctuations. However, in themselves they would not isolate the source of fluctuations as being due to N_γ and/or N_{ch}, or correlations between N_γ and N_{ch}.

B. Minimally mixed events

A second type of mixed events, referred to as $M2$ mixed events, was constructed to investigate the presence of correlated event-by-event fluctuations between N_γ and $N_{\rm ch}$. These mixed events had a minimal amount of randomization since they were generated by mixing the photon hits taken unaltered from one event, with the charged particle hits taken unmodified from another event. As with the $M1$ mixed events, the global $N_{\gamma\text{-like}}$-$N_{\rm ch}$ multiplicity correlation was maintained to be exactly the same as the data. To construct such mixed events, for a given real event measured to have multiplicities $N_{\gamma\text{-like}}$ and $N_{\rm ch}$ in the full acceptance region, a mixed event was constructed by keeping the PMD $N_{\gamma\text{-like}}$ portion of the event intact, but combining it with the unaltered SPMD portion of a different randomly selected event, but constrained to have almost the same charged particle multiplicity $N_{\rm ch}$. This procedure was repeated for each real event. In brief, this type of mixed event keeps the event-by-event hit structure in each detector identical to that in real events. Thus, such mixed events keep the individual localized fluctuations present in N_γ or $N_{\rm ch}$, but remove the event-by-event localized correlated fluctuations between them. Comparison of such mixed events to real events may reveal the presence of correlated localized fluctuations between N_γ and $N_{\rm ch}$.

C. Partially mixed events

The intermediates between the $M1$ and $M2$ types of mixed events are third and fourth type of partially mixed events, referred to as $M3$-γ and $M1$-ch mixed events. These were constructed to provide information regarding the contribution to the localized fluctuations in the N_γ to $N_{\rm ch}$ ratio from the individual observables (N_γ and $N_{\rm ch}$). They were generated from real events by mixing hits in one of the detectors (following the procedure for construction of $M1$ mixed events) and keeping the hit structure of the event in the other detector intact. $M3$-γ mixed events correspond to the case where the hits within the photon detector are unaltered while the hits in the charged particle detector are mixed. Similarly, in $M3$-ch mixed events the hits in the charged particle detector were unaltered and the hits in the photon detector were mixed. In each type of mixed event, the global $N_{\gamma\text{-like}}$-$N_{\rm ch}$ correlation is maintained as in the real event. The two-track resolution in the detectors where the hits are mixed is kept identical to that in real events. The total number of mixed events is the same as the number of real events. Comparison of such mixed events to real events and the other types of mixed events will reveal the presence of localized fluctuations in N_γ or $N_{\rm ch}$ separately.

A summary of the different sources of fluctuations in the ratio of N_γ to $N_{\rm ch}$ probed by each of the types of mixed events is given in Table I.

TABLE I. Type of fluctuations preserved by various mixed events.

Fluctuation	Mixed Event			
	$M1$	$M2$	$M3$-ch	$M3$-γ
N_γ only	No	Yes	No	Yes
$N_{\rm ch}$ only	No	Yes	Yes	No
Correlated N_γ-$N_{\rm ch}$	No	No	No	No

V. DEMONSTRATION OF ANALYSIS METHOD

In this section we wish to demonstrate the analysis method and illustrate how the relationship of the measured result to that obtained with the various mixed events can be used to provide an essentially model-independent signature of DCC formation. To demonstrate the analysis method and the potential to observe DCC event formation, we have applied the DWT analysis to a simple DCC-like model. The analysis is applied to ''real'' DCC events from the model as well as the various types of mixed events described in the preceding section constructed from the model DCC events. Since event generators which include DCC formation do not exist, we have implemented a simple DCC model in which localized nonstatistical N_γ-N_{ch} fluctuations have been introduced by modification of the output of the VENUS event generator. To implement the fluctuations, the final state pions within a localized $\eta-\phi$ region from VENUS are interchanged pairwise ($\pi^+\pi^- \leftrightarrow \pi^0\pi^0$) according to the DCC probability distribution $P(f)=1/2\sqrt{f}$. The fluctuations were generated over a localized region of $\eta=3-4$ and a $\Delta\phi$ interval of 90°. The π^0's were then allowed to decay. The resulting events were then passed through the WA98 detector response simulation. The DCC events in the simple model used here give rise to an anticorrelation between N_γ and $N_{\rm ch}$. It also results in nonrand'om fluctuations in both N_γ and $N_{\rm ch}$ individually. Since the probability to produce events with localized charged-neutral fluctuations is unknown, ensembles of events, here referred to as ''nDCC events,'' were produced as a mixture of normal VENUS events and events with localized fluctuations. The fraction of events with localized DCC-like fluctuations in each nDCC sample was varied as a parameter to be studied.

By using VENUS events as the basis to introduce the DCC effect, it is ensured that the general features of the event, including the multiplicity, composition, and momenta of the produced particles, as well as correlations in the particle multiplicities due to impact parameter variation, are reasonably well described. Also the GEANT simulation of the detector response to these events ensures that other effects such as photon conversions and the response of the PMD to hadrons, which might affect the observed multiplicities and the observed correlations, are also taken into account. While the assumption of a 100% DCC contribution over an interval of fixed size in $\eta-\phi$ is certainly a gross simplification, it provides a well-defined reference to gauge the potential for DCC observation. Other assumptions, such as a varying fraction, which might also be momentum dependent (since DCCs are expected to be low-p_T phenomena), and different or varying sizes might be more realistic. However, without clear theoretical guidance, we have chosen this very simple model as a reasonable and well-defined reference.

The DWT analysis was carried out on an ensemble of nDCC events and their corresponding mixed event sets cre-

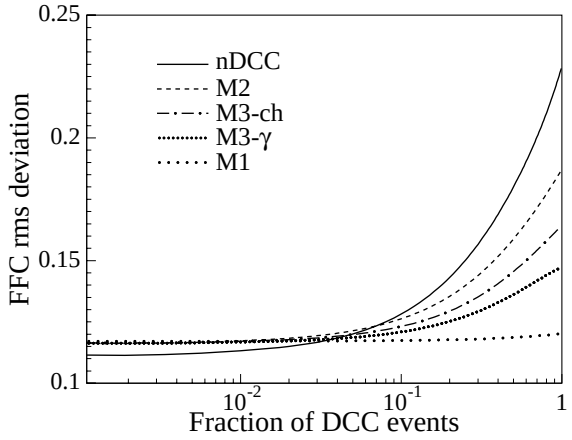

FIG. 5. The rms deviations of the FFC distributions for simulated VENUS events containing a variable fraction of localized DCC-like events with DCC extent $\Delta\phi_{DCC}=90°$, as a function of that fraction. Results are also shown for various mixed events constructed from those events.

ated from each set of nDCC events. By ensemble of nDCC events we mean sets of events having different percentages of events with localized fluctuations. The percentage varied from zero, that is, normal VENUS events with no localized fluctuations, to an event set where all events had localized charged-neutral fluctuations. For every nDCC event set, the four sets of mixed events ($M1$, $M2$, $M3$-γ, and $M3$-ch) were constructed from the nDCC events and analyzed. The rms deviations of the FFC distributions for each set of nDCC events and corresponding mixed event sets were obtained. The results for scale $j=1$ are plotted in Fig. 5 as a function of the percentage of localized DCC-type events in the nDCC event set.

It is seen that the rms deviations of the FFC distributions of the nDCC events increase as the percentage of events with localized fluctuations in N_γ-$N_{\rm ch}$ increases. This is the expected behavior and demonstrates the linear response of the DWT to the DCC events when the frequency of events with fluctuations increases. On the other hand, the rms deviations of the FFC distributions of the $M1$-type mixed events created from the nDCC events are found to be independent of the percentage of events having localized fluctuations. This is also the expected behavior and demonstrates that the $M1$ mixed events can be used as a base line from which to deduce the presence of fluctuations in a model-independent manner. However, the deviation of the real events from the $M1$ mixed events does not inform about the relative contributions of the individual N_γ and $N_{\rm ch}$ fluctuations. The rms deviations of the FFC distributions of the $M3$ mixed events are found to be intermediate to those obtained for nDCC events and $M1$ mixed events. They indicate the separate contributions of the N_γ or $N_{\rm ch}$ fluctuations alone to the ratio. The rms deviations of the $M2$ mixed events are higher than those of $M1$ and $M3$ mixed events. That is because the $M2$ mixed events keep the separate contributions of both the N_γ and $N_{\rm ch}$ fluctuations. However, the rms deviations of the $M2$ mixed events are consistently below those for the nDCC events. This is because the $M2$ events randomize the correlations between N_γ and $N_{\rm ch}$. The difference between the $M2$ mixed events and the nDCC events indicates the presence of the DCC-like correlated N_γ-$N_{\rm ch}$ fluctuations. The relative pattern of rms values for the real events and the various mixed events constructed from those real events seen in Fig. 5 provides a rather unambiguous model-independent signature for DCC-like fluctuations. Similar relative patterns of the rms deviations of the S_Z distributions for mixed events and simulated events were also observed for N_γ-$N_{\rm ch}$ correlation analysis. In particular, the observation of fluctuations in real events that are greater than the $M2$ mixed events would constitute what might be called ''smoking gun'' evidence for DCC formation. Conversely, the lack of a difference between real events and $M2$ mixed events would indicate the lack of DCC-like correlated charged-neutral fluctuations.

Figure 5 also demonstrates an effect which must be taken into account when comparing the measured result to the mixed events. For nDCC events with vanishing fraction of events with fluctuations, which is to say for normal VENUS events, it is seen that the rms deviations of the FFC distributions for all types of mixed events are higher than those for the nDCC events. In the VENUS simulations this is due to the presence of correlations between $N_{\rm ch}$ and $N_{\gamma\text{-like}}$. These are primarily due to residual impact parameter correlations (see Fig. 4) as well as due to the charged particle contamination in the $N_{\gamma\text{-like}}$ data sample whereby the charged particles register in both the PMD and SPMD (see Sec. II C) [33]. These correlations are removed by the event mixing procedure that results in a larger rms deviations for the mixed events. The real data are presumed to have similar residual correlations as observed in the VENUS simulations. In order to correct for the effects of these non-DCC correlations, all mixed event rms values constructed from real events have been rescaled by the percentage difference between the rms deviations of the VENUS distributions and those of the corresponding VENUS mixed events, as also discussed in Ref. [17].

For nDCC events with larger percentages of DCC-like events, the anticorrelation between $N_{\rm ch}$ and $N_{\gamma\text{-like}}$ overcomes the correlations between $N_{\rm ch}$ and $N_{\gamma\text{-like}}$, and hence the rms deviations of the FFC distributions of nDCC events become greater than those of the mixed events, despite the other correlation effects.

VI. RESULTS AND DISCUSSION

In the analysis of experimental data, the results from the measured data are compared with simulated and mixed events. Below we discuss the results obtained from such a comparison using two different analysis methods discussed earlier.

A. N_γ versus $N_{\rm ch}$ correlation results

The S_Z distributions calculated for different ϕ bin sizes are shown in Fig. 6 for data, $M1$, and VENUS events, for the four different centrality selections. The distributions for the other types of mixed events are not shown for clarity of presentation. The small differences in the S_Z distributions have been quantified in terms of the corresponding rms de-

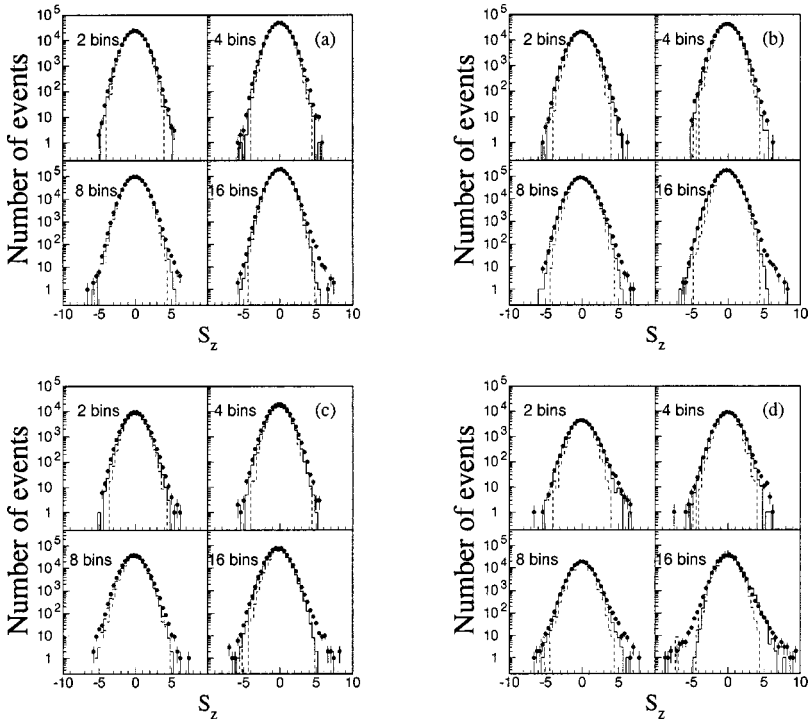

FIG. 6. The S_Z distributions for data (solid circles), mixed events (solid histogram), and simulated events (dashed histogram) for the four centrality bins. (a) Centrality-1 (0–5 %), (b) centrality-2 (5–10 %), (c) centrality-3 (15–30 %), and (d) centrality-4 (45–55 %).

viations; these rms distributions are shown in Fig. 7. The statistical errors on the values are small and are within the size of the symbols. The bars represent statistical and systematic errors added in quadrature. The various sources of systematic error have been discussed in an earlier section. An additional systematic error from the fit errors associated with the determination of the correlation axis Z is also included. In general, the width of the S_Z distribution increases from the most central to less central event selections, and decreases with decreasing bin size.

The rms deviations of the S_Z distribution for the VENUS simulated events are 1 (by definition) for all centrality and all bins in azimuth by definition of S_Z, and are significantly different from the measured results. This is primarily because the global particle multiplicity as predicted by VENUS and those measured in the experiment within the coverage of the detectors are not same.

As seen in Fig. 7, the widths of the S_Z distributions for mixed events closely follow those of the data. The mixed events have been constructed such that the global $N_{\gamma\text{-like}}$ versus $N_{\rm ch}$ multiplicity correlations are maintained. Therefore the rms deviations of the data and the mixed event reference are the same in the first ϕ bin of Fig. 7 by construction. Some correlations between $N_{\rm ch}$ and $N_{\gamma\text{-like}}$ are expected, mostly as a result of the charged particle contamination in the $N_{\gamma\text{-like}}$ data sample, but are removed by the event mixing

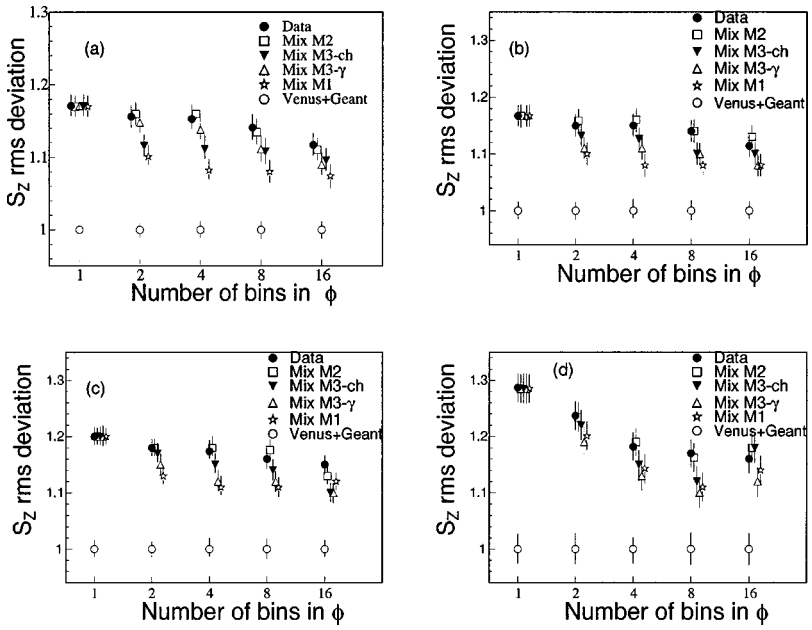

FIG. 7. The rms deviations of the S_Z distributions for data, various mixed events, and simulated events for the four centrality bins. (a) Centrality-1 (0–5 %), (b) centrality-2 (5–10 %), (c) centrality-3 (15–30 %), and (d) centrality-4 (45–55 %).

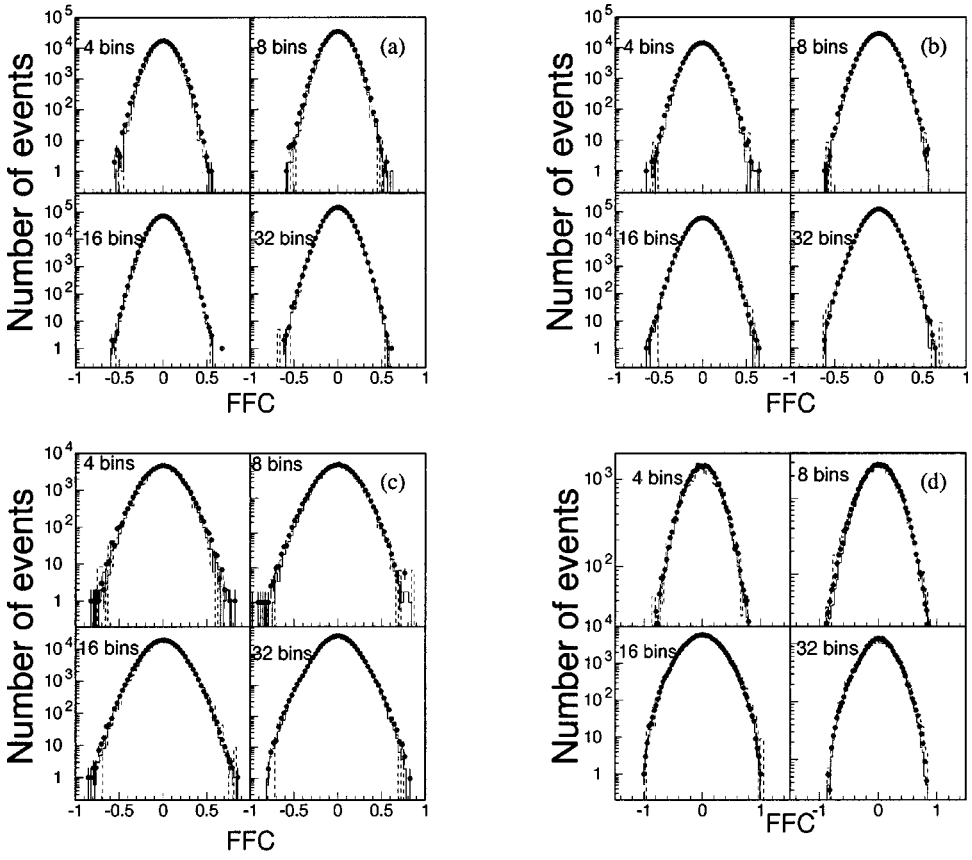

FIG. 8. The FFC distributions for data (solid circles), mixed events (solid histogram), and simulation (dashed histogram) for the four centrality bins. (a) Centrality-1 (0–5 %), (b) centrality-2 (5–10 %), (c) centrality-3 (15–30 %), and (d) centrality-4 (45–55 %).

procedure, and thereby result in a small difference between the real and mixed events, as seen in the analysis of the VENUS events discussed earlier. All of the mixed event S_Z distribution rms values (Fig. 7) have therefore been rescaled by the percentage difference between the rms deviations of the VENUS distributions and those of the corresponding VENUS mixed events for each centrality class (Ref. [17]).

The rms deviations of S_Z distributions of the $M2$ mixed events are found to agree with those of the experimental data within errors for all four centrality classes and for all azimuthal bin sizes. This indicates the absence of event-by-event localized correlated fluctuations in $N_{\gamma\text{-like}}$ and N_{ch}, as expected for DCC-like fluctuations. On the other hand, the rms deviations of the $M1$ mixed events are found to be sys-

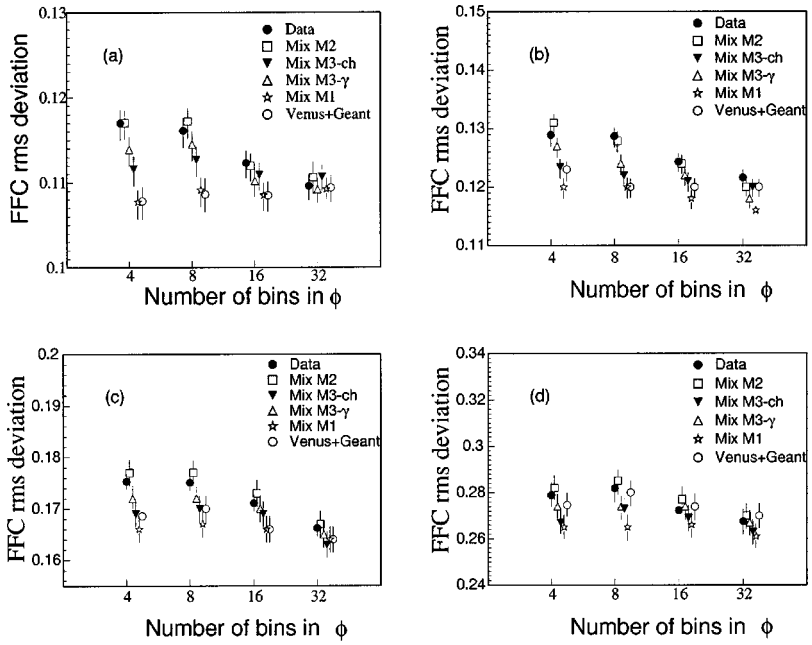

FIG. 9. The rms deviations of the FFC distributions for data, various mixed events, and simulation for the four centrality bins. (a) Centrality-1 (0–5 %), (b) centrality-2 (5–10 %), (c) centrality-3 (15–30 %), and (d) centrality-4 (45–55 %).

tematically lower than those of the data for 2, 4, and 8 bins in ϕ for centrality bins 1, 2, and 3. The results for both types of $M3$ mixed events are found to be intermediate between those of the data and the $M1$ mixed events. The results indicate the presence of localized fluctuations in the data in both the photon and charged particle multiplicities. For the case of the most peripheral centrality selection (centrality-4), the rms deviations of the S_Z distributions of data and the various mixed events are found to be in close agreement to each other within the quoted errors.

B. Multiresolution DWT analysis results

The FFC distributions at scales $j=1-4$, corresponding to 4–32 bins in azimuthal angle, are shown in Fig. 8 for data, $M1$, and VENUS events for the four centrality classes. The results for other types of mixed events are not shown for clarity of presentation. The widths of the FFC distributions are found to increase in going from the most central to most peripheral centrality class. The rms deviations of these FFC distributions are summarized in Fig. 9. Similar to the case for the S_Z distributions discussed above, the rms deviations of the mixed events have been rescaled by the percentage difference between the rms deviations of the VENUS FFC distributions and those of the VENUS mixed events for each centrality class. The statistical errors are small and are within the size of the symbols. The bars represent statistical and systematic errors added in quadrature.

The rms deviations of the FFC distributions for the data, VENUS, and mixed events are found to be close to each other (within quoted errors) for the case of 32 bins in ϕ for all of the four centrality classes. The rms deviations for the FFC distribution of $M2$ mixed events are found to closely follow those of the data for all centrality classes and all bins in ϕ, while the rms deviations for the $M3$ mixed events lie between those of the data and $M1$ mixed events. These results are consistent with those obtained from the analysis of the S_Z distributions. These observations indicate the absence of event-by-event localized correlated fluctuations (DCC-like) between $N_{\gamma\text{-like}}$ and N_{ch}. They also suggest the presence of localized fluctuations in both photons and charged particle multiplicities for intermediate bin sizes in azimuth. The rms values of the FFC distributions for VENUS events are close to those of the $M1$ mixed events for centrality classes 1, 2, and 3. However, they are slightly higher for the most peripheral centrality class (centrality-4).

C. Discussion

The results from the two independent methods of analysis are consistent and indicate the absence of event-by-event correlated DCC-like fluctuations in the photon and charged particle multiplicities. However, they do suggest the presence of uncorrelated fluctuations in both the photon and charged particle multiplicities for intermediate bin sizes in ϕ. The data have been compared to various kinds of mixed events and to simulated events which take into account many detector related effects. Still it is worthwhile to explore the extent of other possible experimental effects that might affect the observed rms deviations of the S_Z and FFC distributions. As discussed extensively in Refs. [15,22,23], care has been taken during the data taking and during the data processing to closely monitor the performance of the PMD and SPMD. The detector uniformity of the PMD was studied in detail by using the minimum ionizing particle (MIP) signal from the data for all pads of the 22 boxes. The fluctuations of the pad-to-pad relative gains were approximately 10%. The gain corrections were made for each pad. Corrections for gain variations during the data taking period were made periodically for both the PMD and SPMD. This reduces the possibility of abrupt gain or threshold changes during the run period. Events with obvious detector readout effects, such as missing or dead regions, were carefully removed from the data sample. It should be recalled that most detector effects are reflected in the mixed events.

The effect of local fluctuations in the performance of the PMD has been studied using simulated VENUS events. In one test, the gain of a group of pads corresponding to one or more PMD cameras was randomly varied. A 30% change of gain in one camera for all events resulted in an increase of 0.7% in the rms deviations. Changing the gains of three cameras by 30% for all events resulted in an increase of the rms deviations by 1.7%. Since the camera gains were closely monitored on-line and during the processing of the data, this is considered to be a highly unlikely scenario. Still, these changes are within the quoted errors of Figs. 7 and 9, which indicates that local gain and threshold variations would not account for the observed differences between the data and the $M1$ mixed events.

Several checks were performed to verify the quality of the data obtained with the SPMD. One of the differences between the previous analysis [15] and the present one is that while in the previous case the analysis was performed using the total charged particle multiplicity of the detector deduced from the magnitude of the measured SPMD signals, here we simply used the total number of hit SPMD pads. The reason for using hit pads is that the correction in going from deposited charge to hits for each event and small $\eta-\phi$ segments is nontrivial. Also, the effects of two-track resolution and possible shifts of the beam position on the target during the spill were studied in detail. However, all of these produced small effects that could not account for the differences observed between the data and $M1$ mixed events.

D. Strength of localized fluctuations

In order to quantify the strength of the $N_{\gamma\text{-like}}$ and N_{ch} fluctuations for various bins in ϕ and for different centrality classes, we define a quantity χ as

$$\chi=\frac{\sqrt{(s^2-s_1^2)}}{s_1}, \tag{3}$$

where s_1 and s correspond to the rms deviations of the FFC distributions of the $M1$ mixed events and real data, respectively. The results are shown in Fig. 10 as a function of the number of bins in ϕ for the four different centrality classes. Qualitatively similar results are obtained when χ is calculated using the rms deviations of the S_Z distributions. The

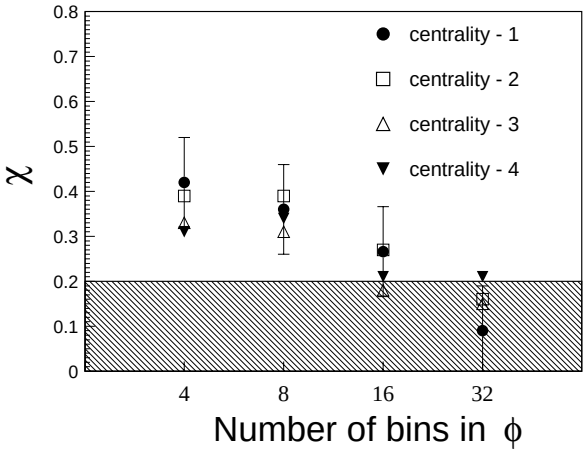

FIG. 10. The fluctuation strength parameter for the four centrality classes. Centrality-1 corresponds to the 5% most central, centrality-2 corresponds to 5–10 %, centrality-3 corresponds to 15–30 %, and centrality-4 corresponds to 45–55 % of the minimum bias cross section as determined by selection on the measured transverse energy distribution. The error bars are shown only on the centrality-1 selection for clarity of presentation. The errors are similar for the other centralities. The shaded portion represents the limit above which a signal is detectable (see text for details).

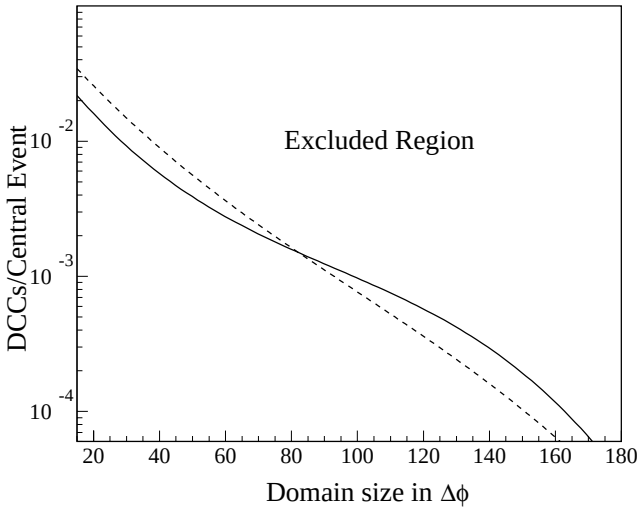

FIG. 11. The 90% confidence level upper limit on DCC production for central Pb+Pb collision at 158*A* GeV/*c*, as a function of the DCC domain size in azimuthal angle within the context of a simple DCC model and the measured photon and charged particle multiplicities in the interval $2.9<\eta<3.75$. The solid line corresponds to data from the top 5% and dashed line to top 5–10 % of the minimum bias cross section as determined by selection on the measured transverse energy distribution.

shaded portion indicates the region of χ where s is one σ greater than the rms deviation FFC distributions for $M1$ events, where σ is the total error on the $M1$ event rms deviation. It represents the limit above which a signal is detectable. Since χ is calculated from the rms deviations of the FFC distributions for data and $M1$ mixed events, it gives the combined strength of localized fluctuations in both the photon and charged particle multiplicities. We do not present χ values calculated using $M3$-type mixed events. However, it is clear from the rms deviation figures (Figs. 7 and 9) that both photons and charged particles contribute to the observed fluctuations. The result shows that the strength of the fluctuations decreases as the number of bins in ϕ increases, with a strength that decreases to below the detectable level (within the quoted errors) for 16 and 32 bins. There is an indication that the strength of the signal decreases with decreasing centrality for 4 and 8 bins in azimuthal angle, although the tendency is not very strong.

E. Upper limit on DCC production

It has been shown that the rms deviations of the S_Z and FFC distributions for data are very close to those of the $M2$ mixed events, within the quoted errors. If the DCC-like correlated fluctuations in $N_{\gamma\text{-like}}$ versus N_{ch} were large, the rms deviations (Figs. 7 and 9) of data would have been larger compared to those of the $M2$ mixed events. Since this is not the case, we may extract an upper limit on the production of DCCs at the 90% confidence level following the standard procedure as discussed in Ref. [34].

The errors are assumed to have Gaussian distribution, although they are asymmetric. The larger of the asymmetric errors is conservatively used for the limit calculation. The 90% C.L. upper limit contour has been calculated as $\chi + 1.28e_\chi$, where χ is calculated using Eq. (3). Here s_1 and s correspond to the rms deviations of the FFC (or S_Z) distributions for $M2$ mixed events and real data, respectively, and e_χ is the error in χ from the FFC (or S_Z) analysis. If the difference between the rms deviation of the FFC distributions for $M2$ mixed events and real data is negative, we take the value of χ to be zero. It may be mentioned that for the calculation of the upper limits we have assumed that the total difference in the rms values of data and $M2$ mixed events is due to DCC-like fluctuations only.

To relate the measured upper limit on the size of the fluctuations to a limit on DCC domain size and frequency of occurrence, we proceed as follows. Within the context of the simple simulated DCC model described earlier, we obtain the rms deviations of the FFC distributions with various domain sizes in azimuthal angle (15°,30°, . . . ,180°) and for each domain size also for different frequencies of occurrence of DCC (0–100 %). The $M2$ mixed events are then constructed for each of these sets of simulated events. For each set of DCC-type events of a given domain size and frequency of occurrence, the value of χ is calculated using Eq. (3), from the difference in rms deviations of the FFC distribution of the DCC event (s) and its corresponding $M2$ mixed event distribution ($s1$). The upper limit is set at that value of frequency of occurrence for a fixed DCC domain size at which the χ value from the DCC model matches with that of the $\chi+1.28e_\chi$ upper limit from the experimental data. This is used to set the upper limit contour in terms of domain size and frequency of occurrence of the DCC. The results for centrality classes 1 and 2 are shown in Fig. 11. It may be mentioned that the upper limit contour set by a similar analysis of the rms values of the S_Z distributions is very similar to

that from the FFC analysis. Also, from Fig. 10 it is seen that the total fluctuation is similar or weaker for centrality classes 3 and 4; hence the upper limit for these two classes would be similar or weaker than those shown in Fig. 11 for centrality classes 1 and 2.

VII. SUMMARY

A detailed event-by-event analysis of the $\eta-\phi$ phase space distributions of the multiplicity of charged particles and photons in Pb+Pb collisions at 158*A* GeV has been carried out using two different analysis methods for four different centrality classes. The results from the two analysis methods were found to be consistent with each other. The first analysis method studied the magnitude of the $N_{\gamma\text{-like}}$ versus N_{ch} multiplicity fluctuations in decreasing phase space regions. The second analysis employed the discrete wavelet transformation technique to investigate the relative magnitude of the $N_{\gamma\text{-like}}$ versus N_{ch} fluctuations in adjacent phase space regions. The results were compared to pure VENUS +GEANT simulation events and to various types of mixed events to search for and identify the source of nonstatistical fluctuations. Both analysis methods indicated fluctuations beyond those observed in simulated and fully mixed events for ϕ intervals of greater than 45° and which increased weakly in strength with increasing centrality. The additional fluctuations were found to be due to uncorrelated fluctuations in both $N_{\gamma\text{-like}}$ and N_{ch}. No significant correlated fluctuations in $N_{\gamma\text{-like}}$ versus N_{ch}, a likely signature of the formation of disoriented chiral condensates, were observed in all of the four centrality classes studied. Using the results from the data, mixed events, and within the limitations of a simple model of DCC formation, an upper limit on DCC production in 158 A GeV Pb+Pb collisions has been set.

ACKNOWLEDGMENTS

We wish to express our gratitude to the CERN accelerator division for the excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians, and support staff who participated in the construction of this experiment. This work was supported jointly by the German BMBF and DFG, the U.S. Department of Energy, the Swedish NFR and FRN, the Dutch Stichting FOM, the Polish KBN under Contract No. 621/E-78/SPUB-M/CERN/P-03/DZ211, the Grant Agency of the Czech Republic under Contract No. 202/95/0217, the Department of Atomic Energy, the Department of Science and Technology, the Council of Scientific and Industrial Research, the University Grants Commission of the Government of India, the Indo-FRG Exchange Program, the PPE division of CERN, the Swiss National Fund, the INTAS under Contract No. INTAS-97-0158, the ORISE, a Grant-in-Aid for Scientific Research (specially promoted research and international scientific research) of the Ministry of Education, Science and Culture, the University of Tsukuba Special Research Projects, and the financial support of the JSPS. ORNL is managed by UT-Battelle, LLC, for the U.S. Department of Energy under Contract No. DE-AC05-00OR22725. The MIT group has been supported by the U.S. Department of Energy under the cooperative agreement under Grant No. DE-FC02-94ER40818.

(Received 17 April 2002; published 12 August 2002)

We present results on the measurement of Λ and $\bar{\Lambda}$ production in Au + Au collisions at $\sqrt{s_{NN}} =$ 130 GeV with the PHENIX detector at the Relativistic Heavy Ion Collider. The transverse momentum spectra were measured for minimum bias and for the 5% most central events. The $\bar{\Lambda}/\Lambda$ ratios are constant as a function of p_T and the number of participants. The measured net Λ density is significantly larger than predicted by models based on hadronic strings (e.g., HIJING) but in approximate agreement with models which include the gluon-junction mechanism.

DOI: 10.1103/PhysRevLett.89.092302 PACS numbers: 25.75.Dw

In this Letter we report on the measurement by the PHENIX experiment at the Relativistic Heavy Ion Collider (RHIC) of the production of Λ and $\bar{\Lambda}$ particles and the ratio $\bar{\Lambda}/\Lambda$ as a function of transverse momentum p_T and centrality in Au + Au collisions at $\sqrt{s_{NN}} =$ 130 GeV. The production of strange baryons and of strange particles in general has been extensively studied in heavy ion collisions at the Alternating Gradient Synchrotron (AGS) and at the Super Proton Synchrotron (SPS) [1] to investigate the flavor composition of nuclear matter at high density and temperature. Furthermore, antibaryon-to-baryon ratios, or alternatively, a net baryon number such as $(\Lambda - \bar{\Lambda})$ at midrapidity provide insight into the baryon transport mechanism in these collisions [2–5]. The systematic study of baryon stopping (transport of baryon number in rapidity space) and hyperon production in proton-proton, proton-nucleus, and nucleus-nucleus collisions has been done over the past decade at the AGS [6,7] and CERN SPS [8–10]. The results have shown a high degree of baryon stopping and enhanced hyperon production in heavy nucleus-nucleus collisions. Clearly the measurement of these quantities at RHIC, at the highest energies so far available in the laboratory, is of great importance for our understanding of the sources of these processes.

The results reported here were obtained using the west arm of the PHENIX spectrometer [11] which covers an angular range of $\Delta\phi = \pi/4$ (during its first year of running) and a pseudorapidity range of $|\eta| < 0.35$. The detectors used were the drift chamber (DC), a set of multiwire proportional chambers with pixel-pad readout (PC1) [12], and a lead-scintillator electromagnetic calorimeter (EMCal) [13]. Signals from two sets of beam-beam counters (BBC) and two zero-degree calorimeters (ZDC) provided a trigger sensitive to $92\% \pm 4\%$ of the 6.8 b total Au + Au cross section [14]. The centrality selection was done using the correlation between the analog responses of the ZDC and BBC [14].

The present analysis is based on 1.3 M minimum-bias events with a vertex position of $|z| < 20$ cm. To reconstruct the Λ and $\bar{\Lambda}$ particles, their weak decays $\Lambda \rightarrow p\pi^-$ and $\bar{\Lambda} \rightarrow \bar{p}\pi^+$ are used. The tracks of the charged particles from the decay of Λ and $\bar{\Lambda}$ are reconstructed using DC and PC1, and their momentum is determined by the DC with a resolution of $\delta p/p \simeq 0.6\% \oplus 3.6\% p$ (GeV/c). Although these tracks do not point back to the primary vertex position (the mean distance of the Λ decay vertex to interaction vertex is $\sim$3.5 cm), their momentum is calculated assuming that they come from the interaction point, hence there is, in general, a shift in the momentum of the reconstructed Λ and $\bar{\Lambda}$ particles. A Monte Carlo (MC) study shows that the difference is of the order 1%–2% over the measured momentum range, within the measured momentum resolution, and thus neglected in the present study. The absolute momentum scale is known to better than 2% [15]. In order to reduce background the tracks are confirmed by requiring a matching hit in the EMCal within $\pm 3\sigma$. For the particle identification of the daughter charged particles the time-of-flight signal of the EMCal with a timing resolution of $\sim$700 ps is used. Using the momentum measured by the DC and the flight time, the particle mass is calculated and a 2σ momentum-dependent cut is applied to the mass-squared distribution to identify protons, antiprotons, and pions. An upper momentum cut of 0.6 and 1.4 GeV/c for pions and protons, respectively, provides clean particle separation. Then each proton is combined with each pion in the same event and the invariant mass is calculated. If Λ or $\bar{\Lambda}$ are produced, a peak appears in the mass distribution on top of a background from random combinations of particles and short lived resonances (Δ and N^*). In order to determine the number of Λ's and $\bar{\Lambda}$'s from such a distribution, an estimation of the background is essential. For this, the mass distribution with combinations of protons and pions from different events with the same centrality class (event mixing) is used. In order to reduce the background, the decay proton energy is required to be within $E_p^{\min} < E_p < E_p^{\max}$, where $E_p^{\min}$ and $E_p^{\max}$ are calculated from the two-body decay kinematics in the Λ center-of-mass system. A similar cut is used for the pions. This cut is particularly effective in reducing the contributions from short-lived resonances and gives an improvement of the signal-to-background ratio by a factor of 2 without affecting the Λ line shape and results in the final value of $S/B = 1/2$ for both Λ and $\bar{\Lambda}$. We obtain $\sim$12000 Λ and $\sim$9000 $\bar{\Lambda}$ particles in the mass range $1.05 < m_{p\pi} < 1.20$ GeV/c^2 with mass resolution $\delta m/m \simeq 2\%$ obtained from a Gaussian fit. The Λ ($\bar{\Lambda}$) peaks vary by less than the mass resolution over the measured p_T range.

Figure 1 shows the invariant mass spectra for the $\Lambda \rightarrow p\pi^-$ and $\bar{\Lambda} \rightarrow \bar{p}\pi^+$. The results represent the primary Λ and $\bar{\Lambda}$ and contributions from the feed-down from heavier hyperons (mainly Σ^0 and Ξ). The reconstructed number of Λ and $\bar{\Lambda}$ particles is corrected for acceptance, pion decay-in-flight, momentum resolution, and reconstruction efficiency. For this, single-particle MC events were generated over the full azimuth ϕ ($0 < \phi < 2\pi$) and one unit of rapidity y ($-0.5 < y < 0.5$). The simulated particles were passed through the entire PHENIX GEANT [16] simulation. The correction function is defined as the ratio of the input (generated) transverse momentum distribution to the p_T distribution of the particles reconstructed in the spectrometer. However, this correction does not take into account the decreasing track reconstruction efficiency due to the high multiplicity environment in more central events. A well-established method to obtain this efficiency drop is the embedding procedure [15]. We use single-particle MC tracks embedded into real events and analyze the merged events with the same analysis code as used for the reconstruction of the data set. The track reconstruction efficiency decreases from 90% for minimum bias to 70%

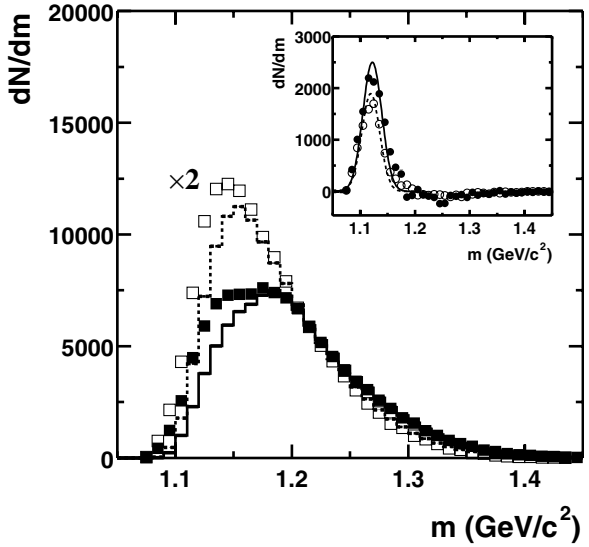

FIG. 1. Invariant mass spectra of $p\pi^-$ (solid squares) and $\bar{p}\pi^+$ (open squares) pairs. The histograms show the background for $p\pi^-$ (solid line) and $\bar{p}\pi^+$ (dashed line). For clarity the $\bar{p}\pi^+$ data are scaled up by a factor of 2. The inset shows the background-subtracted spectra of Λ (solid circles) and $\bar{\Lambda}$ (open circles). The lines are Gaussian fits to the Λ (solid line) and $\bar{\Lambda}$ (dashed line) mass spectra.

for central events, independently of the track p_T. The Σ^0 and Ξ hyperons decay to Λ with a branching ratio of essentially 100%. We have verified, using HIJING, that the kinematic properties (p_T and y distributions) of primary Λ and those produced by Σ^0 and Ξ decay are the same (within a few percent). We conclude that the correction function determined for primary Λ is valid for all Λ. Since there are no reliable data available for the yields of those hyperons at RHIC energies, we cannot quantitatively state the contributions from those heavier hyperons to our Λ production. Therefore, our data include the primordial Λ and $\bar{\Lambda}$, as well as the feed-down from the heavier hyperons.

Using the correction function determined from single-particle MC and multiplicity-dependent track reconstruction efficiency derived from the embedding procedure, we correct the transverse momentum distributions of Λ and $\bar{\Lambda}$. The invariant yields as a function of the transverse momentum p_T for Λ and $\bar{\Lambda}$ are shown in Fig. 2 for minimum-bias events (circles). Over the measured transverse momentum range ($0.4 < p_T < 1.8$ GeV/c), both the Λ and $\bar{\Lambda}$ spectra can be described by a distribution of the form $dN/dp_T^2 \propto p_T e^{-p_T/T}$ as shown in Fig. 2 by the solid line. The total yield dN/dy is obtained by integrating the functional fit from zero to infinity. The fraction of the extrapolated yield is 29%. In the same Fig. 2 we show the invariant yield for the 5% most central events (squares). In Table I the total yields dN/dy together with the average transverse momentum $\langle p_T \rangle$ and the slope parameters T are listed for both minimum bias and for the 5% most central events.

There are several sources which contribute to the systematic uncertainties of the total yield dN/dy and average transverse momentum $\langle p_T \rangle$ determination. One of the sources, the uncertainty in the correction function determination, is found to be 13%. By changing the fitting function used for the yield extrapolation to a pure exponential, we derive a systematic error of $\pm 9\%$. There is also an additional contribution to the systematic error which originates from the combinatorial background subtraction which is 3%. Combining the above uncertainties in quadrature gives a total systematic error in the yield of 16% (see Table I).

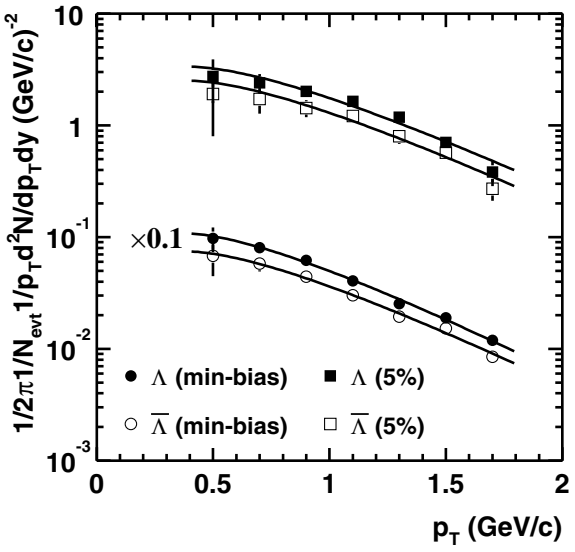

FIG. 2. Transverse momentum spectra of Λ and $\bar{\Lambda}$ for minimum bias and for the 5% most central events. For clarity of presentation the data points for minimum bias are scaled down by a factor of 10.

The $\bar{\Lambda}/\Lambda$ yield ratio determined in the mass window defined above versus p_T is shown in Fig. 3 (top panel). The ratio is constant over the whole p_T range $0.4 < p_T < 1.8$ GeV/c. There is also no significant variation of the $\bar{\Lambda}/\Lambda$ ratio as a function of the number of participants (bottom panel) which is calculated using a Glauber model together with a simulation of the ZDC and BBC responses [14]. The average $\bar{\Lambda}/\Lambda$ ratio is $0.75 \pm 0.09(\text{stat}) \pm 0.17(\text{syst})$. Both the p_T dependence and the integral $\bar{\Lambda}/\Lambda$ ratio are consistent with statistical thermal model calculations [17] at RHIC energies.

The present measurement of the total yield of Λ and $\bar{\Lambda}$ enables us to take the previously reported inclusive p and $\bar{p}$ spectra [18] and construct a feed-down correction for Λ decays. As the Σ yield has not been measured, we do

TABLE I. Inclusive Λ and feed-down corrected proton yields, average transverse momentum (in GeV/c), and slope parameters (in MeV/c) for minimum bias (MB) and for the 5% most central events. The errors listed are statistical. The systematic errors are 17% for the protons and 16% for the Λ.

		Λ	$\bar{\Lambda}$	p	$\bar{p}$
dN/dy	(MB)	4.8 ± 0.3	3.5 ± 0.3	5.4 ± 0.2	3.7 ± 0.2
	(5%)	17.3 ± 1.8	12.7 ± 1.8	19.3 ± 0.6	13.7 ± 0.7
$\langle p_T \rangle$	(MB)	1.06 ± 0.08	1.10 ± 0.12	0.88 ± 0.04	0.91 ± 0.06
	(5%)	1.15 ± 0.15	1.14 ± 0.21	0.95 ± 0.07	1.04 ± 0.12
T	(MB)	355 ± 11	366 ± 13	292 ± 21	304 ± 23
	(5%)	384 ± 16	380 ± 19	319 ± 31	327 ± 34

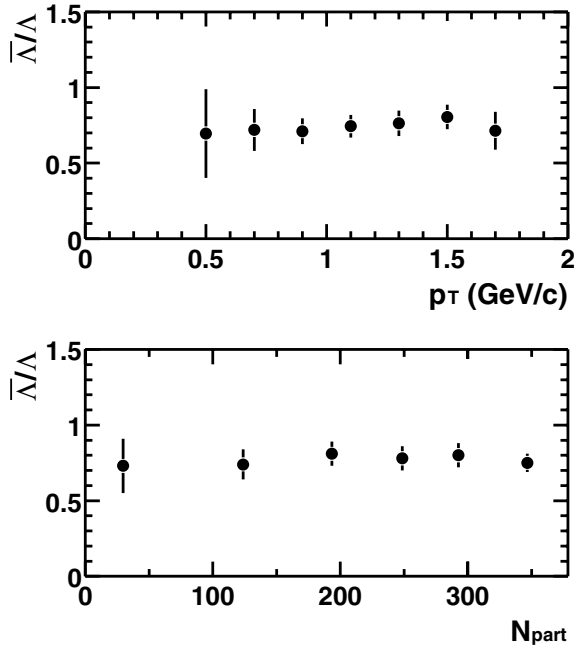

FIG. 3. The ratio $\bar{\Lambda}/\Lambda$ as a function of p_T (top) and as a function of the number of participants (bottom).

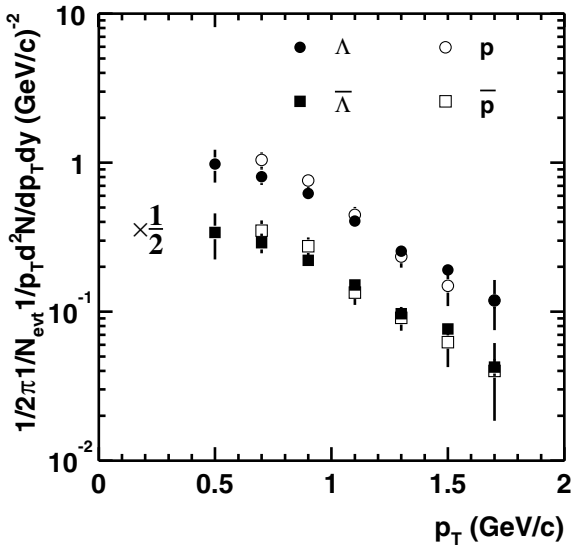

FIG. 4. Spectra of inclusive Λ ($\bar{\Lambda}$) and feed-down corrected protons (antiprotons) for minimum-bias events. The data points for antiprotons and $\bar{\Lambda}$ are scaled down by a factor of 2.

not include feed-down from $\Sigma^{\pm}$ decays, but this is expected to be $<5\%$, based on HIJING calculations. The feed-down corrections were done bin by bin on the proton (antiproton) p_T spectrum by the following method:

$$\frac{dN^p}{dydp_T}(i) = \frac{dN^m}{dydp_T}(i) - \sum_{j=1}^{N_{\text{bins}}} \frac{dN^{\Lambda}}{dydp_T}(j) \times BR \times w(j,i), \tag{1}$$

where $dN^p/dydp_T$ is the total yield of the primary protons, $dN^m/dydp_T$ is the total yield of the measured protons, $dN^{\Lambda}/dydp_T$ is the total yield of the measured Λ, BR is the branching ratio of the Λ decay $\Lambda \rightarrow p\pi^-$, i is the p_T bin number, N_{bins} is the number of bins, and $w(j,i)$ is the fraction of protons from Λ decay from bin number j which fall into the proton bin number i. These fractions were extracted from MC. The feed-down corrected proton and antiproton p_T spectra are shown in Fig. 4. We calculated the total yield, dN/dy, for protons and antiprotons by fitting them to the same distribution as used for the Λ and integrating from zero to infinity. The results for the total yields dN/dy, the average transverse momentum $\langle p_T \rangle$, and the slope parameters T for minimum bias and for the 5% most central events are also listed in Table I. The measured Λ/p and $\bar{\Lambda}/\bar{p}$ ratios after feed-down corrections are found to be $0.89 \pm 0.07(\text{stat}) \pm 0.21(\text{syst})$ and $0.95 \pm 0.09(\text{stat}) \pm 0.22(\text{syst})$.

The net baryon numbers are indicative of the baryon transport mechanism in relativistic heavy ion (RHI) collisions. In Table II we compare our results for minimum bias and for the 5% most central events with the predictions of the HIJING [19] model which assumes that the primary mechanism for baryon transport in RHI is due to quark-diquark hadronic strings. Vance *et al.* [4] implemented a nonperturbative gluon-junction mechanism in a new version of HIJING (called HIJING/B) to explain the enhanced baryon stopping at CERN SPS energies. The predictions of this model are also shown in Table II. For a valid comparison with the experimental data, the HIJING and HIJING/B results for Λ and $\bar{\Lambda}$ also include the feed-down from the heavier hyperons and the results for protons and antiprotons the feed-down from $\Sigma^{\pm}$. Table II shows a clear difference (by a factor of $\sim$4) between HIJING and HIJING/B for the net Λ number, with the HIJING/B predictions in much better agreement, in particular, for the minimum-bias data, where the experimental errors are relatively small. Moreover, HIJING/B rapidity densities for both Λ and $\bar{\Lambda}$ are closer to the experimental values though still below them. The difference between the two models for the net proton number is less obvious and, although the data seem

TABLE II. Total measured and predicted baryon yields for minimum bias (MB) and for the 5% most central events. The errors listed are statistical. The proton yields are corrected for feed-down. The systematic errors are 24% for the protons and 23% for the Λ.

Net baryon number	PHENIX	HIJING	HIJING/B
$(\Lambda - \bar{\Lambda})$ (MB)	1.3 ± 0.4	0.2	0.8
$(p - \bar{p})$ (MB)	1.7 ± 0.3	1.1	1.7
$(\Lambda - \bar{\Lambda})$ (5%)	4.6 ± 2.5	0.8	3.2
$(p - \bar{p})$ (5%)	5.6 ± 0.9	4.7	7.1

to favor HIJING/B, the present accuracy does not allow for a clear preference between the two models.

In conclusion, we have measured the transverse momentum spectra of Λ and $\bar{\Lambda}$ particles in the p_T range $0.4 < p_T < 1.8$ GeV/c in minimum bias and the 5% most central Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV at RHIC with the PHENIX experiment. The absolute yields of dN/dy, at midrapidity, of Λ hyperons are determined by extrapolating to all values of p_T. The average $\bar{\Lambda}/\Lambda$ ratio is found to be $0.75 \pm 0.09 \pm 0.17$. The ratio is constant over the whole p_T range and there is also no significant variation of the $\bar{\Lambda}/\Lambda$ ratio as a function of the number of participants. Using the measured Λ and $\bar{\Lambda}$ yields, the p and $\bar{p}$ yields corrected for feed-down from Λ decays are determined. The Λ/p and $\bar{\Lambda}/\bar{p}$ ratios after feed-down corrections are found to be $0.89 \pm 0.07 \pm 0.21$ and $0.95 \pm 0.09 \pm 0.22$. The measured net Λ number is substantially larger than predicted by HIJING as already seen at CERN SPS and which may indicate enhanced baryon stopping at RHI energies. The newly available high statistics data at $\sqrt{s_{NN}} = 200$ GeV will allow us to further study baryon transport and strangeness production in RHI collisions.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 11 April 2002; published 30 October 2002)

Two-particle azimuthal correlation functions are presented for charged hadrons produced in Au + Au collisions at the Relativistic Heavy Ion Collider ($\sqrt{s_{NN}} = 130$ GeV). The measurements permit determination of elliptic flow without event-by-event estimation of the reaction plane. The extracted elliptic flow values (v_2) show significant sensitivity to both the collision centrality and the transverse momenta of emitted hadrons, suggesting rapid thermalization and relatively strong velocity fields. When scaled by the eccentricity of the collision zone ε, the scaled elliptic flow shows little or no dependence on centrality for charged hadrons with relatively low p_T. A breakdown of this ε scaling is observed for charged hadrons with $p_T > 1.0$ GeV/c.

DOI: 10.1103/PhysRevLett.89.212301 PACS numbers: 25.75.Ld

The primary goal of current relativistic heavy ion research is the creation and study of nuclear matter at high energy densities [1–7]. Open questions include the detailed properties of such excited matter, as well as the existence of a transition to the quark-gluon plasma (QGP) phase. Such a phase of deconfined quarks and gluons has been predicted to survive for $\approx$ 3–10 fm/c in Au + Au collisions at the Relativistic Heavy Ion Collider (RHIC) [8], and several experimental probes have been proposed for its possible detection and study [1]. Elliptic flow constitutes an important observable [9–16] because it is thought to be driven by pressure built up early in the collision and, therefore, can reflect conditions existing in the first few fm/c. Elliptic flow leads to an anisotropy in the azimuthal distribution of emitted particles. A Fourier decomposition of this distribution [17,18],

$$\frac{dN}{d(\phi - \Phi_R)} \propto \left(1 + \sum_{n=1}^{\infty} 2v_n \cos[n(\phi - \Phi_R)]\right), \qquad (1)$$

provides a characterization of the elliptic flow via the second Fourier coefficient v_2. Here, ϕ is the azimuthal angle of an emitted particle and Φ_R is the azimuth of the reaction plane, defined by the beam direction and the impact-parameter vector [19]. The apparent reaction plane is determined from the azimuthal correlations between emitted particles, and its dispersion correction from the azimuthal correlations between two "subevents" [19–21]. An alternative technique for elliptic flow analysis is the Fourier decomposition of the pairwise distribution in the azimuthal angle difference ($\Delta\phi = \phi_1 - \phi_2$) between pairs of emitted particles [22–24]:

$$\frac{dN}{d\Delta\phi} \propto \left(1 + \sum_{n=1}^{\infty} 2v_n^2 \cos(n\Delta\phi)\right). \quad (2)$$

In this case the magnitude of the elliptic flow is characterized by the square of the second Fourier coefficient in Eq. (1), i.e., v_2^2. These methods of analysis can be taken as equivalent since (i) the correlation between every particle and the reaction plane induces correlations among the particles, and (ii) correlating two subevents amounts to summing two-particle correlations [18]. The results in this Letter have several advantages over elliptic flow measurements obtained via the reaction plane method at the same beam energy by the STAR [5] and PHOBOS [6] Collaborations. First, two-particle correlations circumvent the need for full azimuthal detector acceptance. Second, it allows the determination of elliptic flow without event-by-event estimation of the reaction plane and the associated corrections for its dispersion. Third, the correlation method can provide insights on nonflow correlations and minimize many important systematic uncertainties (detector acceptance, efficiency, etc.) important to the accuracy of elliptic flow measurements [22,23,25] .

Elliptic flow is predicted and found to be negative for beam energies $\lesssim 4A$ GeV and positive for higher beam energies in Au + Au collisions [9,13–16]. Recent theoretical investigations have made predictions for the centrality dependence of the scaled elliptic flow $A_2 \equiv v_2/\varepsilon$ [26,27], where ε is the eccentricity or initial spatial anisotropy of the "participant" nucleons in the collision zone. The eccentricity ε shows an essentially linear variation with impact parameter b, for $0.2b_{\max} \lesssim b \lesssim 0.8b_{\max}$ [9] in Au + Au collisions ($b_{\max} \approx 14$ fm). For central collisions ($b \lesssim 5$–6 fm), it is predicted that higher energy densities are produced and rapid kinetic equilibration in the QGP phase leads to a characteristic rise in A_2 [26,27]. In addition, elliptic flow for high p_T particles has been proposed as an observable sensitive to the energy loss of scattered partons in a QGP phase [28].

The colliding Au beams ($\sqrt{s_{NN}} = 130$ GeV) used in these measurements have been provided by the Relativistic Heavy Ion Collider at Brookhaven National Laboratory (BNL). Charged reaction products were detected in the east and west central arms of the PHENIX detector [2,29]. Each of these arms subtends 90° in azimuth ϕ, and ± 0.35 units of pseudorapidity η. The axially symmetric magnetic field of PHENIX (0.5 T) allowed for the tracking of particles with $p_T \geq 200$ MeV/c in the fiducial volume of both arms. The drift chamber (DC) and a layer of pad chambers (PC1) located at radii of 2 m and 2.5 m, respectively, in each arm, served as the primary tracking detector for these measurements. A second layer of pad chambers (PC3), positioned at 5 m in the east arm, was employed to confirm the trajectory of charged particles which traversed both the DC and PC1. The zero degree calorimeters (ZDC) were used in conjunction with the beam-beam counters (BBC) to provide the position of the vertex along the beam direction as well as a trigger for a wide range of centrality selections.

The present data analysis uses two-particle azimuthal correlation functions to measure the distribution of the azimuthal angle difference ($\Delta\phi = \phi_1 - \phi_2$) between pairs of charged hadrons. Following an approach commonly exploited in interferometry studies, a two-particle azimuthal correlation function can be defined as follows [22–24]:

$$C(\Delta\phi) = \frac{N_{\text{cor}}(\Delta\phi)}{N_{\text{uncor}}(\Delta\phi)}, \quad (3)$$

where $N_{\text{cor}}(\Delta\phi)$ is the observed $\Delta\phi$ distribution for charged particle pairs selected from the same event, and $N_{\text{uncor}}(\Delta\phi)$ is the $\Delta\phi$ distribution for particle pairs selected from mixed events. Events were selected with a collision vertex position, $-20 < z < 20$ cm, along the beam axis. Mixed events were obtained by randomly selecting each member of a particle pair from different events having similar multiplicity and vertex position. In order to suppress an overefficiency in finding two tracks at close angles, hadron pairs within 1 cm of each other in the DC were removed from both the $N_{\text{cor}}(\Delta\phi)$ and $N_{\text{uncor}}(\Delta\phi)$ distributions. Event centralities were obtained via a series of cuts in the space of BBC versus ZDC analog response [2]; they reflect percentile selections of the total interaction cross section of 6.8 b [2]. Estimates for the impact parameter and the eccentricity, $\varepsilon \equiv (\langle y^2\rangle - \langle x^2\rangle)/(\langle y^2\rangle + \langle x^2\rangle)$, were also made for each of these selections following the model detailed in Ref. [2]. Here, $\langle \ldots \rangle$ represents the spatial average (weighted by the density) of participant nucleons over the transverse plane of the collision zone [11]. Systematic uncertainties associated with the determination of ε are estimated to be $\sim$7%. This estimate includes the variation of all of the inputs to the Glauber model within reasonable limits.

Correlation functions were obtained via two separate methods. In the first, charged hadron pairs were formed by selecting each particle from a common p_T range (fixed-p_T method). In the second hadron pairs were formed by selecting one member from a fixed p_T range

and the other from outside this range (assorted-p_T method). Within statistical errors, both methods of analysis yield similar results for the p_T range presented below, as would be expected for a system dominated by collective motion.

An important prerequisite for reliable flow extraction from PHENIX data is to establish whether or not the $\sim 180^o$ azimuthal coverage of the detector results in significant distortions to the correlation function. To this end, detailed simulations of the detector response, acceptance, and efficiency, have been performed for simulated data incorporating specific amounts of flow (parametrized by v_2). The results from these simulations indicated no significant distortion to the correlation functions due to the PHENIX acceptance. On the other hand, small distortions to the correlation function (for $\Delta\phi \lesssim 25^o$) as well as an incomplete recovery of v_2 could be attributed to background contributions from particle decay and interactions in detector material.

These background contributions principally affect the extraction of v_2 from the correlation function in two ways. The distortion to the correlation function at small relative angle introduces a small systematic distortion when fit with a Fourier function [cf. Eq. (2)]. A good representation of the data was obtained with the fit function $C(\Delta\phi) = \lambda \exp[-0.5(\Delta\phi/\sigma)^2] + a_1[1 + 2v_2^2 \cos(2\Delta\phi)]$, where the Gaussian term is used to characterize the background distortion at small angles. In addition, there is an isotropic background of false tracks which are predominantly misidentified as high p_T particles. These contributions can be efficiently suppressed in the east central arm of PHENIX, by requiring a relatively stringent association between tracks found in the DC and their associated hits in PC3. Using such a procedure, the fraction of background tracks has been evaluated as a function of p_T and used to correct v_2. Corrections range from $\sim 10\%$ at low p_T to $\sim 25\%$ at 2 GeV/c with a systematic uncertainty of 5%. The current analysis is restricted to the range $0.3 < p_t \leq 2.5$ GeV/c to maintain this relatively small systematic uncertainty.

Figures 1(a)–1(d) show representative $\Delta\phi$ correlation functions obtained for charged hadrons detected in the pseudorapidity range $-0.35 < \eta < 0.35$. Correlation functions for relatively central events (centrality = 20%–25%, $b \sim 7.0$ fm) are shown for hadrons with $0.3 < p_T < 2.5$ GeV/c and $0.5 < p_T < 2.5$ GeV/c in Figs. 1(a) and 1(c), respectively. The same p_T selections have been made for the correlation functions shown in Figs. 1(b) and 1(d) but for more peripheral collisions (centrality = 40%–45%, $b \sim 9.6$ fm) as indicated. Figures 1(a)–1(d) show a clear anisotropic pattern which is essentially symmetric about $\Delta\phi = 90^o$. There is also a visible increase of this anisotropy with increasing impact parameter and p_T. These trends are all consistent with those expected for in-plane elliptic flow [10,11,13,20].

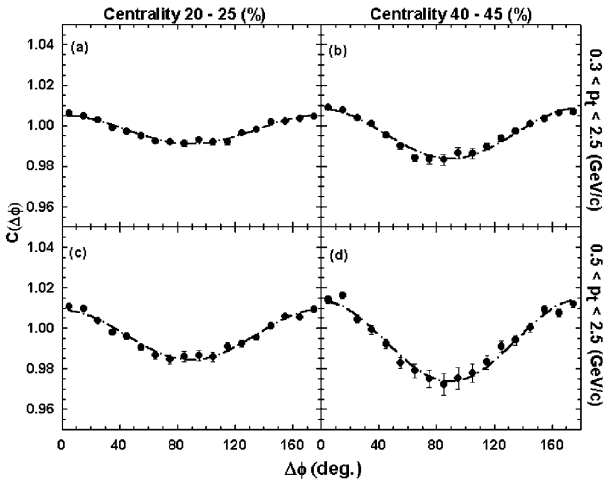

FIG. 1. Azimuthal correlation functions for charged hadrons as a function of centrality and p_T selection. The solid curves represent Fourier fits following Eq. (2). Error bars are statistical only.

The magnitude of elliptic flow and the mechanism for its development can be shown to be related to (a) the geometry of the collision zone, (b) the initial baryon and energy density developed in this zone, and (c) the detailed nature of the equation of state for the created nuclear matter [9–13,26]. Since differential flow measurements can serve to provide important insights for disentangling these separate aspects [10–13,26], we show the results of such measurements in Figs. 2 and 3. Figure 2 shows v_2 as a function of centrality for several p_T selections: $0.40 < p_T < 0.60$ GeV/c (diamonds), $0.60 < p_T < 1.00$ GeV/c (squares), and $1.0 < p_T < 2.5$ GeV/c (circles), respectively. Figure 3 compares the differential flow $v_2(p_T)$ for several centralities as indicated.

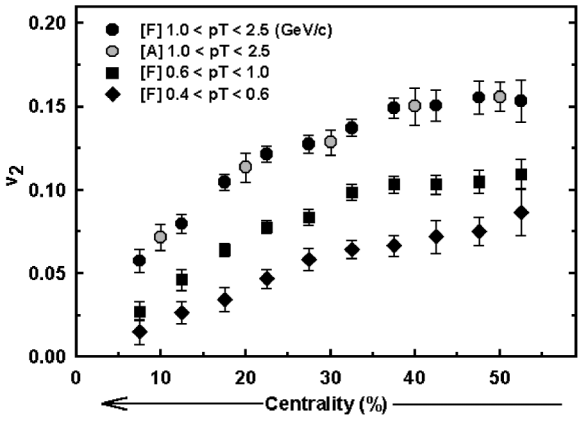

FIG. 2. v_2 vs centrality for several p_T selections. [F] and [A] indicate results obtained with the fixed-p_T and assorted-p_T methods, respectively. Systematic errors are estimated to be $\sim 5\%$; they are dominated by the normalization of the correction function for real tracks. For the centrality range 0%–5% the data points are statistically uncertain and the points are omitted.

Figures 2 and 3 both show relatively large differential flow values which increase with increasing impact parameter and the p_T of emitted hadrons. The separate effects of spatial asymmetry and the response of the collision zone, possibly due to the generated pressure are also evident in Fig. 2. That is, v_2 not only increases with increasing impact parameter for a fixed p_T, but also increases with increasing p_T for a fixed centrality selection. Trivially, the magnitude of flow should go to zero for very small and very large impact parameters. Similarly, its magnitude can be expected to be zero for $p_T = 0$. It is interesting that Fig. 3 indicates an essentially linear rise of v_2 with p_T for each of the centrality selections presented. Such a trend cannot be accounted for via simple geometric considerations alone [30]. However, it is compatible with model calculations which assume a strong transverse velocity field [30]. This suggests the presence of strong dynamically driven transverse flow at RHIC. The magnitude and trends for v_2 shown in Figs. 2 and 3 are consistent with other elliptic flow measurements at RHIC [5,6].

Figure 4 aims to disentangle the geometric and dynamical (p_T) contributions to the elliptic flow over a broad range of centralities or energy densities. To do this, we plot A_2 as a function of centrality to obtain the dynamical contributions [26,27]. This evaluation is performed for two p_T selections ($0.40 < p_T < 0.60$ and $1.0 < p_T < 2.5$ GeV/c) which give rise to relatively low and high p_T values, respectively. The underlying idea is that this ratio should remove the geometric dependence of v_2, while the p_T selections may provide greater sensitivity to different time scales and energy densities associated with the expanding system.

Figure 4 shows an increase in the magnitude of A_2 with increasing p_T. This increase can be attributed to the dynamical response of the created system, resulting from the generated pressure gradients. For hadrons of $0.4 < p_T < 0.6$ the observed centrality dependence of A_2 is compatible with ε scaling. However, a breakdown of this scaling is observed for hadrons with $1.0 < p_T < 2.5$. Such a trend may point to a change in the particle production mechanism or the possibility that pressures larger than those predicted by current hydrodynamic calculations [10,11] are being produced in the most central collisions at RHIC. It is also interesting to note that the species' composition of the charged particle spectra changes dramatically between the two p_T ranges used in Fig. 4 [31].

To summarize, we have measured two-particle azimuthal correlation functions for charged hadrons produced in Au + Au collisions at RHIC ($\sqrt{s_{NN}} = 130$ GeV). The integral, differential, and scaled elliptic flow values extracted from these measurements indicate strong sensitivity to the collision centrality and the transverse momenta of emitted hadrons. The centrality dependence of v_2 suggests that the high-energy-density nuclear matter created at RHIC efficiently translates the initial spatial asymmetry into a similar asymmetry in momentum space. The p_T dependence is consistent with the development of strong transverse velocity fields in the collision zone. The centrality dependence of A_2 for hadrons in the range $0.4 < p_T < 0.6$ is compatible with ε scaling. However, a breakdown of this scaling is observed for hadrons with $1.0 < p_T < 2.5$. Such a trend could result from a number of effects, the most intriguing of which is a possible change in the equation of state [26,27]. Additional experimental signatures and model calculations will undoubtedly be necessary to test the detailed implications of these results. Nevertheless, the results presented here clearly show that two-particle azimuthal

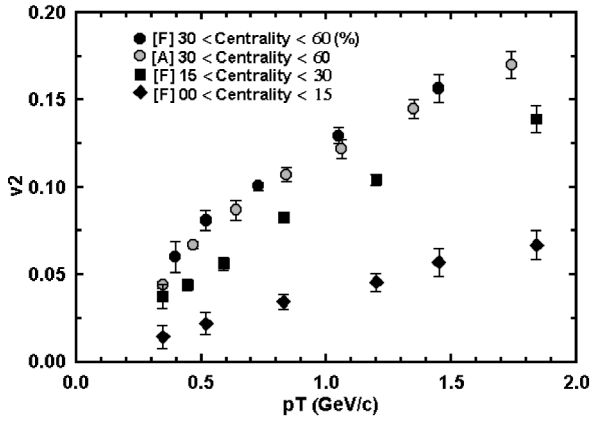

FIG. 3. v_2 vs p_T for several centrality selections. [F] and [A] follow the notation in Fig. 2. Systematic errors are estimated to be ~5%.

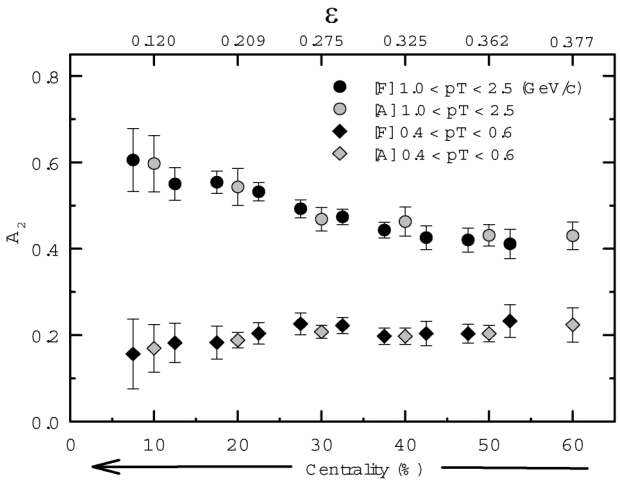

FIG. 4. The centrality dependence of A_2 for two different p_T selections. [F] and [A] follow the notation in Fig. 2. Estimates of the eccentricity ε for several centralities are indicated on the upper abscissa. Systematic errors are estimated to be ~10%, dominated by the normalization of the correction function and the model determination of ε.

correlation measurements provide an important probe for the high-energy-density nuclear matter created at RHIC.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 22 March 2002; published 2 August 2002)

Distributions of event-by-event fluctuations of the mean transverse momentum and mean transverse energy near mid-rapidity have been measured in Au+Au collisions at $\sqrt{s_{NN}}=130$ GeV at the Relativistic Heavy-Ion Collider. By comparing the distributions to what is expected for statistically independent particle emission, the magnitude of nonstatistical fluctuations in mean transverse momentum is determined to be consistent with zero. Also, no significant nonrandom fluctuations in mean transverse energy are observed. By constructing a fluctuation model with two event classes that preserve the mean and variance of the semi-inclusive p_T or e_T spectra, we exclude a region of fluctuations in $\sqrt{s_{NN}}=130$ GeV Au+Au collisions.

DOI: 10.1103/PhysRevC.66.0149XX PACS number(s): 25.75.Dw

I. INTRODUCTION

Phase instabilities near the QCD phase transition can result in nonstatistical fluctuations that are detectable in final state observables [1]. These instabilities, which may occur due to random color fluctuations [2], critical behavior at the QCD tricritical point [3], or fluctuations from the decay of a Polyakov loop condensate [4], can result in a broadening of the transverse momentum or transverse energy distributions of particles produced for different classes of events. This phenomenon is expected to be detected experimentally by searching for deviations of the distributions of the event-by-event mean transverse momentum M_{p_T} or mean transverse energy M_{e_T} of produced particles from the random distributions expected for statistically independent particle emission.

An event-by-event analysis of M_{p_T} was previously performed for 158 A GeV/c Pb+Pb collisions at the CERN SPS by Experiment NA49 [5]. In that analysis, the M_{p_T} distributions measured over the rapidity range $4<y_\pi<5.5$ and p_T range $0.005<p_T<1.5$ GeV/c were found to be consistent with random fluctuations. NA49 also performed an event-by-event analysis of the K/π ratio [6], showing only very small deviations from random fluctuations. With an increase of $\sqrt{s_{NN}}$ to 130 GeV in Relativistic Heavy-Ion Collider (RHIC) collisions, unprecedented energy densities have been observed [10]; hence conditions may be more favorable for a phase transition from hadronic matter to a quark-gluon

plasma which may be indicated in nonrandom fluctuations. Presented here is an event-by-event analysis of M_{p_T} fluctuations and the first measurement of M_{e_T} fluctuations at midrapidity at the RHIC.

II. ANALYSIS

The PHENIX Experiment [7] consists of four spectrometers designed to measure simultaneously hadrons, leptons, and photons produced in nucleus-nucleus, proton-nucleus, and proton-proton collisions at RHIC. The two central arm spectrometers, which are located within a focusing magnetic field, each covering ± 0.35 in pseudorapidity and $\Delta\phi = 90°$ in azimuthal angle, are utilized in this analysis. The primary interaction trigger was defined using the Beam-Beam Counters (BBCs) [8] and Zero Degree Calorimeters (ZDCs) [9]. Events are selected with a requirement that the collision vertex along the beam axis has $|z| < 20$ cm as measured by both the BBCs and ZDCs. Event centrality is defined using correlations in the BBC and ZDC analog response as described in [10]. For the present analysis, the events are classified according to the 0–5 %, 0–10 %, 10–20 %, and 20–30 % most central events.

The drift chamber [11] is used in conjunction with the innermost pad chamber, called PC1, to measure the transverse momentum of charged particles traversing the PHENIX acceptance. A fiducial section of the drift chamber is chosen to minimize the effect of time-dependent variations in the performance of the detector during the data-taking period. The fiducial volume of the M_{p_T} analysis spans an azimuthal range of $\Delta\phi = 58.5°$ and covers the pseudorapidity range $|\eta| < 0.35$. Reconstructed tracks [12] are required to contain a match to a hit in PC1 to ensure that the tracks are well reconstructed in three dimensions for reliable momentum determination.

The M_{e_T} distribution is determined from clusters reconstructed in the two instrumented sectors of the lead-scintillator electromagnetic calorimeter [7,13,14]. The quantity e_T is defined as the transverse energy per reconstructed calorimeter cluster as described in [14], which can include clusters that have been merged. The effects of cluster merging on the M_{e_T} distribution are discussed later. The fiducial volume of the M_{e_T} analysis spans an azimuthal range of $\Delta\phi = 45°$ and covers $|\eta| < 0.35$.

There are no acceptance or efficiency corrections applied to the semi-inclusive p_T or e_T distributions prior to the calculation of M_{p_T} or M_{e_T}. Here, the term semi-inclusive refers to spectra in p_T or e_T summed over all events in a given centrality class. These corrections do not vary from event to

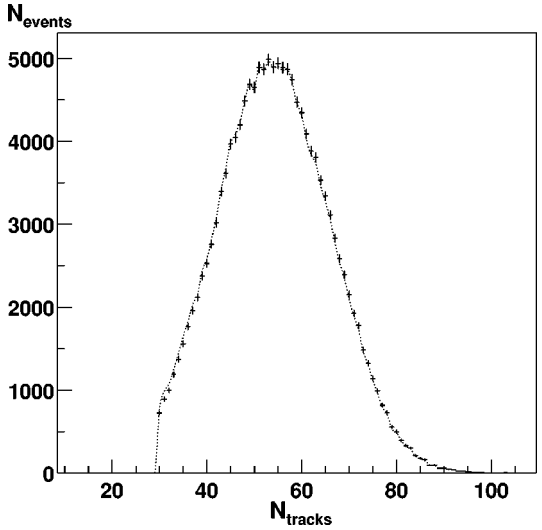

FIG. 1. The N_{tracks} distribution for the 0–10 % centrality class (data points) compared to the N_{mix} distribution from the mixed event sample (curve). Very good agreement in the data and mixed event N_{tracks} distribution is required for a precise comparison of the corresponding M_{p_T} distributions shown in Fig. 3 below.

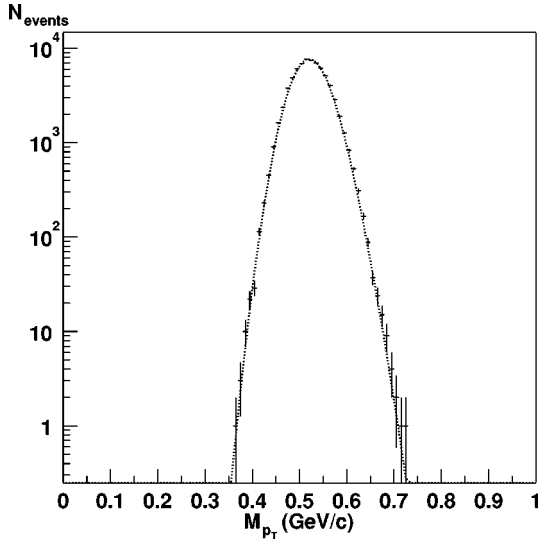

FIG. 2. The M_{p_T} distribution for the 0–5 % centrality class. The curve is the result of a Γ distribution calculation with parameters taken from the semi-inclusive p_T spectra.

event and are identical for data and mixed events (defined below); therefore they do not modify the values of the fluctuation quantities defined later. The M_{p_T} distributions are calculated using the formula

$$M_{p_T}=(1/N_{tracks})\sum_{i=1}^{N_{tracks}} p_{Ti}, \tag{2.1}$$

where N_{tracks} is the number of tracks in the event that pass the cuts outlined above and lie within the p_T range $0.2<p_T<1.5$ GeV/c. Similarly, the M_{e_T} distributions are calculated using the formula

$$M_{e_T}=(1/N_{clus})\sum_{i=1}^{N_{clus}} e_{Ti}, \tag{2.2}$$

where N_{clus} is the number of calorimeter clusters in the event that lie within the e_T range $0.225<e_T<2.0$ GeV. An event is excluded from the analysis if N_{tracks} or N_{clus} is below a minimum value to ensure that there are a sufficient number of tracks or clusters to determine a mean and to exclude background events. This minimum value for the 0–5 %, 0–10 %, 10–20 %, and 20–30 % centrality classes, respectively, is 40, 30, 20, and 10 for the M_{p_T} analysis and 30, 20, 10, and 10 for the M_{e_T} analysis. Table I lists statistics pertaining to the data samples used to determine M_{p_T} and Table II lists the statistics pertaining to the data samples used to determine M_{e_T}. The events used for the M_{p_T} and M_{e_T} analyses are considered independently of each other.

In order to compare the M_{p_T} and M_{e_T} distributions to what is expected for statistically independent particle emission, the baseline for the random distribution is defined by mixed events, which are events of multiplicity m assembled using individual tracks or clusters taken from a collection of m data events with one track or cluster taken from each data event. To obtain a precision comparison, it is important to match the number of tracks or clusters along with the mean of the semi-inclusive distribution of the mixed events to those of the data. Therefore, in both analyses, mixed events are constructed by predetermining the number of charged particle tracks or calorimeter clusters in the mixed event N_{mix} by directly sampling the corresponding data N_{tracks} or N_{clus} distributions. Figure 1 shows a comparison of the N_{tracks} distributions from the data and the normalized mixed event N_{mix} distribution for the 0–10 % centrality class. Once N_{mix} is determined, a mixed event is filled with p_T or e_T values from the data with the following criteria: (a) no two p_T or e_T values from the same data event are allowed to reside in the same mixed event, (b) only p_T or e_T values passing all cuts in the determination of M_{p_T} or M_{e_T} from the data events are placed in a mixed event, and (c) only data events from the same centrality class are used to construct a mixed event corresponding to that class. Once a mixed event is filled with N_{mix} tracks or clusters, its M_{p_T} or M_{e_T} is calculated in the same manner as for the data events.

For both analyses, the data contain a fraction of tracks or clusters within close physical proximity that have merged into a single track or cluster. This fraction is estimated by embedding simulated single-particle events that are processed through a detailed simulation of the detector response into real data events, which are then reconstructed in the same manner as the data. For the 0–5 % centrality class, we estimate that 6% of the tracks and 5% of the clusters are affected.

For the M_{p_T} analysis, tracks that are merged into a single reconstructed track typically have similar values of p_T. The result is a slightly lower value of N_{tracks} which causes a slight broadening in the width of the M_{p_T} distribution due to the reduced statistics per event. However, since the N_{tracks}

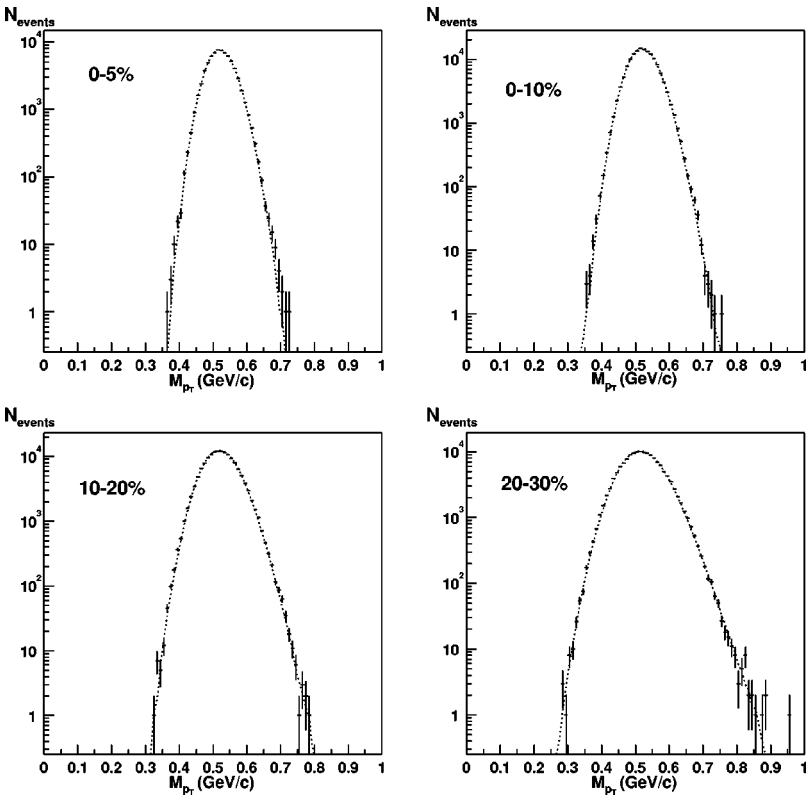

FIG. 3. The M_{p_T} distributions for all centrality classes. The curves are the random baseline mixed event distributions.

data distribution is directly sampled during the construction of mixed events, the effect of merged tracks cancels for comparisons between the data and mixed events.

For the M_{e_T} analysis, the effect of merged clusters is complicated by the fact that a single cluster is reconstructed with an e_T corresponding to the sum of the two (or more) particles contributing to the cluster. To understand this effect on the mixed events, we note that the fraction of merged clusters within a data event increases with event multiplicity. Also, many of the data events with the lowest M_{e_T} coincide with the lowest multiplicity events since they contain few, if any, merged clusters that would yield a higher M_{e_T}. When the merged clusters in the data events are randomly redistributed among the mixed events, low multiplicity mixed events can contain more merged clusters than the data events with the same multiplicity, resulting in a gross upward shift in M_{e_T} for those mixed events. This results in apparent excess nonrandom fluctuations at low M_{e_T}. Conversely, high multiplicity mixed events can contain fewer merged clusters than the data events with the same multiplicity, resulting in a gross downward shift in M_{e_T} for those mixed events. However, since the mean is taken over more clusters in this case, the effective shift in M_{e_T} is reduced at high M_{e_T}, and the apparent nonrandom fluctuations are much less pronounced. An estimate of the magnitude of this effect is presented later.

III. RESULTS

To compare directly the semi-inclusive p_T distribution to the M_{p_T} distribution assuming a statistically independent particle emission, the closed form prescription outlined in [15] is used. This prescription describes the semi-inclusive p_T distribution using a Gamma distribution,

$$f(p_T)=f_\Gamma(p_T,p,b)=\frac{b}{\Gamma(p)}(bp_T)^{p-1}e^{-bp_T}, \quad (3.1)$$

where p and b are free parameters that are related to the mean and standard deviation of the semi-inclusive distribution as

$$p=\frac{\langle p_T\rangle^2}{\sigma^2_{p_T}}, \quad b=\frac{\langle p_T\rangle}{\sigma^2_{p_T}}, \quad (3.2)$$

where

$$\sigma_{p_T}=(\langle p_T^2\rangle-\langle p_T\rangle^2)^{1/2}. \quad (3.3)$$

The reciprocal of b is the inverse slope parameter of the p_T distribution. With the track multiplicity distribution assumed to be a negative binomial distribution, $f_{NBD}(N_{tracks},1/k,\langle N_{tracks}\rangle)$, the M_{p_T} distribution can be calculated using

$$g(p_T)=\sum_{N=N_{min}}^{N_{max}} f_{NBD}(N,1/k,\langle N\rangle)f_\Gamma(p_T,Np,Nb), \quad (3.4)$$

where the sum is over N_{tracks} from N_{min} to N_{max}, which are the limits of the multiplicity. The value of the negative binomial distribution parameter k is given by

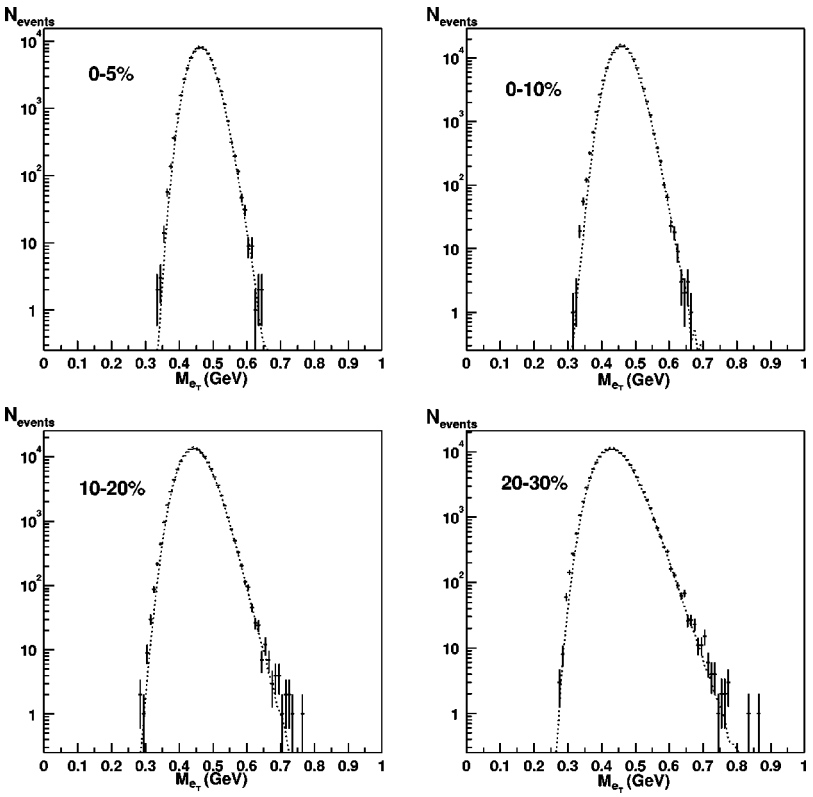

FIG. 4. The M_{e_T} distributions for all centrality classes. The curves are the random baseline mixed event distributions. The source of differences in the data and mixed event distributions are addressed in the text.

$$\frac{1}{k} = \frac{\sigma_{p_T}^2}{\langle N_{tracks} \rangle^2} - \frac{1}{\langle N_{tracks} \rangle}. \tag{3.5}$$

Therefore, given $\langle p_T \rangle$, σ_{p_T}, and $\langle N_{tracks} \rangle$ extracted from the semi-inclusive p_T distribution, the expected random M_{p_T} distribution can be calculated. Figure 2 shows the M_{p_T} distribution for the 0–5 % centrality class. Overlaid on the data as a dotted curve is the result of the calculation. The agreement between the data distribution and the calculation illustrates the absence of large nonstatistical fluctuations in the data. The remainder of this paper will quantify the amount of non-

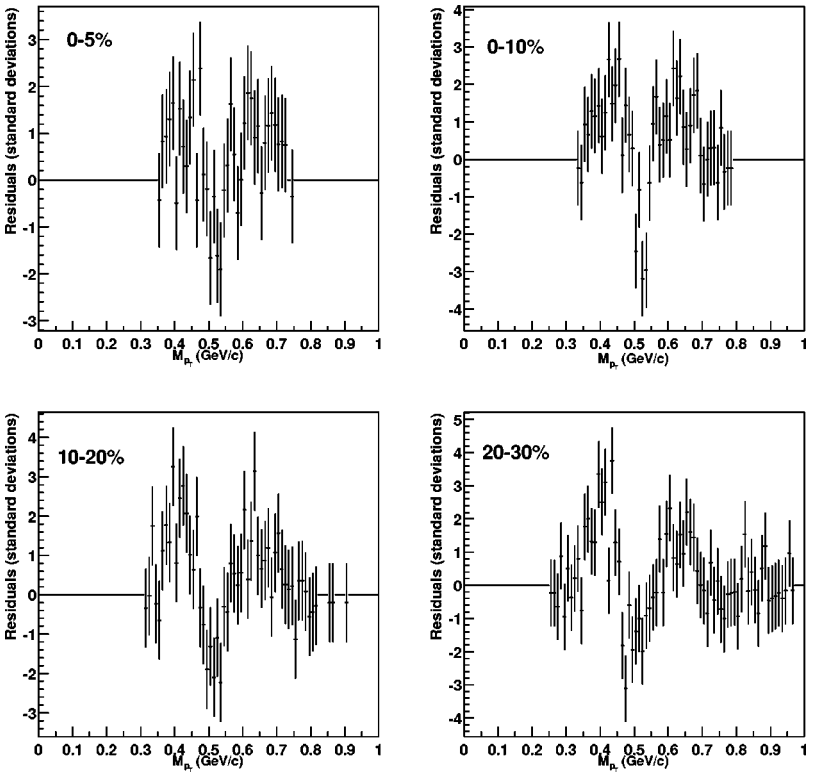

FIG. 5. The residual distribution between the data and mixed event M_{p_T} spectra as a function of M_{p_T} in units of standard deviations for all centrality classes. The total χ^2 and the number of degrees of freedom for the 0–5 %, 0–10 %, 10–20 %, and 20–30 % centrality classes are 89.0/37, 155.7/40, 163.3/47, and 218.4/61, respectively.

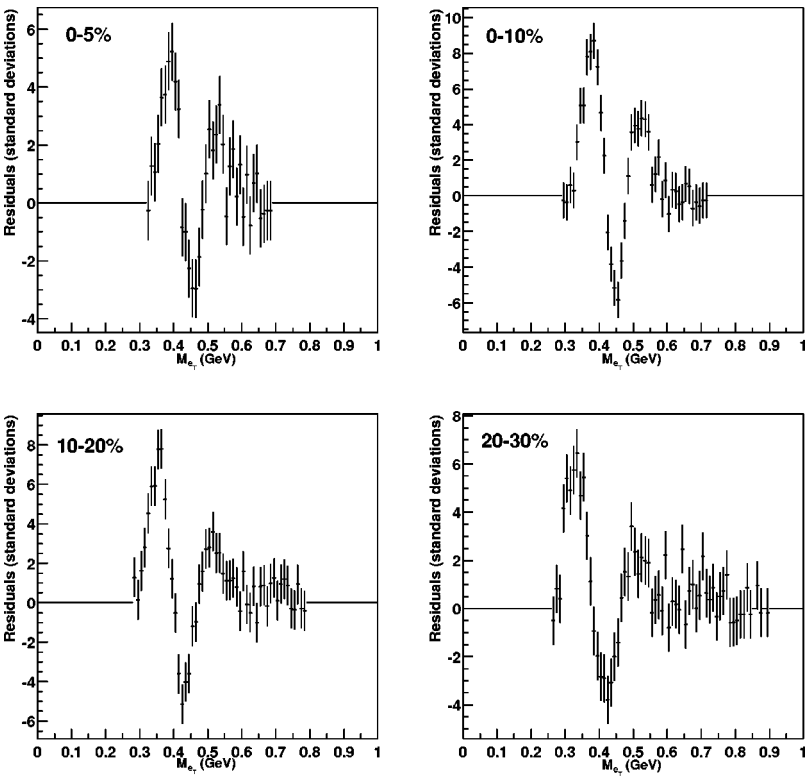

FIG. 6. The residual distribution between the data and mixed event M_{e_T} spectra as a function of M_{e_T} in units of standard deviations for all centrality classes. The total χ^2 and the number of degrees of freedom for the 0–5 %, 0–10 %, 10–20 %, and 20–30 % centrality classes are 310.0/32, 896.4/36, 678.7/47, and 553.9/53, respectively. A large fraction of the residual contributions are due to the effects of cluster merging.

statistical fluctuations observed and place limits on the level of fluctuations that can be present in central Au+Au collisions at $\sqrt{s_{NN}}=130$ GeV.

To quantify the magnitude of the deviation of fluctuations from the expectation of statistically independent particle emission, the magnitude of the fluctuation ω_T in the transverse quantity M_T, representing M_{p_T} or M_{e_T}, is defined as

$$\omega_T=\frac{(\langle M_T^2\rangle-\langle M_T\rangle^2)^{1/2}}{\langle M_T\rangle}=\frac{\sigma_{M_T}}{\langle M_T\rangle}. \tag{3.6}$$

The value of ω_T is calculated independently for the data distribution and for the baseline, or mixed event, distribution. The difference in the fluctuation from a random baseline distribution is defined as

$$d=\omega_{(T,data)}-\omega_{(T,baseline)}. \tag{3.7}$$

The sign of d is positive if the data distribution contains a correlation, such as Bose-Einstein correlations [16], when compared to the baseline distribution. The fraction of fluctuations that deviate from the expectation of statistically independent particle emission is given by

$$F_T=\frac{(\omega_{(T,data)}-\omega_{(T,baseline)})}{\omega_{(T,baseline)}}=\frac{(\sigma_{(T,data)}-\sigma_{(T,baseline)})}{\sigma_{(T,baseline)}}, \tag{3.8}$$

where $\sigma_{(T,\ data)}$ refers to the standard deviation of the event-by-event M_T data distribution and $\sigma_{(T,\ baseline)}$ is the corresponding quantity for the baseline, or mixed event, distribution. In the absence of a common language for the analysis of M_{p_T} and M_{e_T} fluctuations, the commonly used fluctuation quantity ϕ_T [17] is also presented in order to compare this measurement to previous results [5]. The quantity d is related directly to ϕ_T via

$$\phi_T=(\sigma_{(T,data)}-\sigma_{(T,baseline)})\sqrt{\langle N_T\rangle}=d\langle M_T\rangle\sqrt{\langle N_T\rangle}, \tag{3.9}$$

where N_T represents N_{tracks} or N_{clus}. The quantity ϕ_T is related to F_T by

$$\phi_T=F_T\sigma_{(T,baseline)}\sqrt{\langle N_T\rangle}. \tag{3.10}$$

TABLE III. Fluctuation quantities for the M_{p_T} analysis.

ϕ_{e_T} (MeV)	11.5±3.59	13.6±4.23	11.1±5.75	9.28±7.34

The standard deviation of the semi-inclusive spectra can be approximated by $\sigma_{(T,incl.)} \approx \sigma_{(T,baseline)} \sqrt{\langle N_T \rangle}$ [15], where $\sigma_{(T,incl.)}$ is the standard deviation of the semi-inclusive distribution as defined in Eq. (3.3). Therefore, ϕ_T is simply the fraction of nonrandom fluctuations in the event-by-event mean p_T or e_T, F_T, scaled by $\sigma_{(T,incl.)}$. An advantage of F_T over ϕ_T is that measurements expressed in F_T can be directly compared without further scaling.

The magnitudes of any nonrandom fluctuations are established by comparing the data distributions to the mixed event distributions, which serve as the random baseline distributions. For this purpose, the mixed event distributions are normalized to minimize the χ^2 value with respect to the data distributions. Figures 3 and 4 show the M_{p_T} and M_{e_T} distributions for all four centrality classes (data points) with the corresponding mixed event M_{p_T} and M_{e_T} distributions overlayed on the data as dotted curves. The broadening of the distributions for less central collisions are due to the reduction in $\langle N_{tracks} \rangle$ or $\langle N_{clus} \rangle$. Shown in Fig. 5 and Fig. 6 are the residuals between the data and mixed events, defined for each bin i as residual$_i = (M_{(T,data)_i} - M_{(T,mixed)_i})/\sigma_i$, in units of standard deviations, for each centrality class. The shapes of the residual distributions are primarily driven by the normalization procedure applied to the mixed events.

For the M_{p_T} distributions, the data and mixed event distributions are indistinguishable. However, the upper M_{e_T} edges of the data and mixed event M_{e_T} distributions show good agreement while the lower M_{e_T} edge of the data distributions are slightly wider than the mixed event distribution. If this low e_T effect were physical, it would imply fluctuations with slightly more low e_T photons since the effect is not seen in the M_{p_T} distribution for charged particle tracks. However, some of the excess fluctuations at low e_T can be attributed to the effects of cluster merging previously discussed. The magnitude of this effect has been investigated using a Monte Carlo simulation which calculates M_{e_T} after reproducing the calorimeter cluster separation distribution, the N_{clus} distribution, and the semi-inclusive e_T distributions from the data. The fluctuations in the M_{e_T} distribution with this effect included in each event are compared to a simulated mixed event M_{e_T} distribution constructed from the same generated data set using the same procedure that is applied to the data. In this manner, it is estimated that the cluster merging effect contributes an additional $F_T = 1.5\%$, 2.1%, 0.9%, and less than 0.01% to the nonrandom fluctuations for the 0–5 %, 0–10 %, 10–20 %, and 20–30 % centrality classes, respectively. The simulation confirms that the cluster merging effect significantly contributes only to the lower M_{e_T} edge of the distribution. The remainder of the excess low e_T fluctuations is likely due to correlated low energy background. GEANT [19] simulations indicate that the primary background contribution is produced by low energy electrons and muons that scatter off the pole tips of the central arm spectrometer magnet but still pass the cluster selection cuts. Because of the difficulty in quantifying the contribution of background to the excess fluctuations, the present M_{e_T} data are taken to indicate an upper limit on nonstatistical fluctuations rather than an indication of true nonstatistical fluctuations.

The values of ω_T, d, F_T, and ϕ_T for each centrality class using the mixed events as the random baseline distribution are tabulated in Table III for M_{p_T} and Table IV for M_{e_T}. The errors quoted for these quantities include statistical errors and systematic errors due to time-dependent variations over the data-taking period. The systematic errors are estimated by dividing each data set into nine subsets with each subset containing roughly equal numbers of events. For the M_{p_T} analysis, the systematic errors contribute to 81%, 88%, 76%, and 75% of the total error in ω_T and 85%, 88%, 80%, and 85% of the total error in the variables d, F_T, and ϕ_t for the 0–5 %, 0–10 %, 10–20 %, and 20–30 % centrality classes, respectively. The corresponding values for the M_{e_T} analysis are a 67%, 63%, 81%, and 82% contribution to the total errors in ω_T, and a 64%, 63%, 81%, and 82% contribution to the total errors in d, F_T, and ϕ_t for each centrality class. The cluster merging contribution estimates noted above are not applied to the values quoted in Table IV.

IV. DISCUSSION

Based upon the fluctuation measurements presented here, certain fluctuation scenarios in RHIC Au+Au collisions at $\sqrt{s_{NN}} = 130$ GeV are excluded. For this purpose, we consider two variations of a model that contains two classes of events with a difference of effective temperature, defined as $\Delta T = T_2 - T_1$, where T_2 is the inverse slope parameter of the event class with the higher effective temperature, and T_1 is the inverse slope parameter of the event class with the lower effective temperature. The first variation, model A, will consider a case where the means of the semi-inclusive p_T spectra for the two event classes are identical, but the standard deviations are different. The second variation, model B, will consider a case where the means of the semi-inclusive p_T spectra are different, but the standard deviations are identical. Since the semi-inclusive p_T distribution is an observed

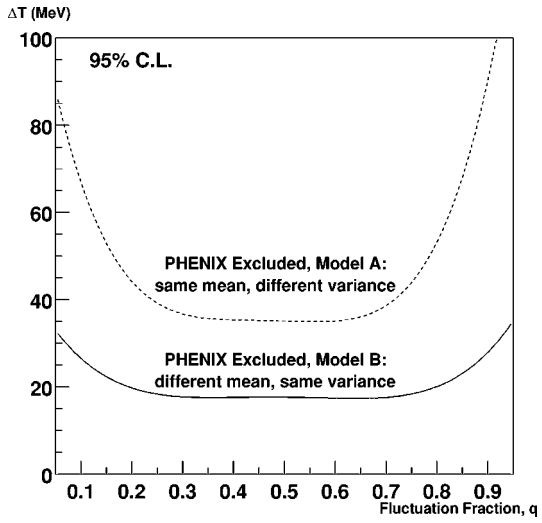

FIG. 7. The PHENIX sensitivity to nonrandom fluctuations in the two variations of the dual event class model that are excluded at the 95% confidence level by the M_{p_T} analysis in the 0–5 % centrality class. The fraction of events q in the class of events with the lower inverse slope parameter (event class 1) is plotted on the horizontal axis while the difference in inverse slope parameter between event class 1 and event class 2, ΔT, is plotted on the vertical axis. The curves represent the lower boundaries of the excluded regions.

quantity, the two event classes must be constrained in such a way that the mean and standard deviation of the final semi-inclusive p_T distribution remain constant while the effect of the fluctuation manifests itself in the M_{p_T} distribution.

The dual event class model is applied to the determination of the sensitivity to fluctuations in M_{p_T} for the 0–5 % centrality class as follows. Returning to the prescription outlined in [15], the semi-inclusive transverse p_T spectrum can be parametrized by the $f_\Gamma(p_T,p,b)$ distribution defined in Eq. (3.1). For both model variations, the fraction of events in the event class with the higher effective temperature is defined as

$$q=\frac{(N_{events})_{class\ 1}}{(N_{events})_{class\ 1}+(N_{events})_{class\ 2}}. \tag{4.1}$$

The p_T distribution of the combined sample can then be expressed as

$$f(p_T)=q\Gamma(p_T,p_1,b_1)+(1-q)\Gamma(p_T,p_2,b_2), \tag{4.2}$$

where $T_1=1/b_1$ and $T_2=1/b_2$.

For model A, the semi-inclusive p_T distributions of each event class are constrained to have the same mean, so we require

$$\mu=p/b=p_1/b_1=p_2/b_2. \tag{4.3}$$

The variance of the final semi-inclusive p_T distribution for model A is constrained by

$$\frac{\sigma^2}{\mu^2}=\frac{1}{p}=\frac{q}{p_1}+\frac{(1-q)}{p_2}. \tag{4.4}$$

With these constraints, the choice of a value for q and the effective temperature of one event class is sufficient to extract the remaining parameters from which sensitivity estimates for fluctuations in M_{p_T} are obtained.

For model B, the semi-inclusive p_T distributions of each event class are allowed to have different means, μ_1 and μ_2, so the mean of the total semi-inclusive distribution can be expressed as $\mu=q\mu_1+(1-q)\mu_2$. Defining a mean shift $\Delta\mu$ as $\Delta\mu=\mu_2-\mu_1$, we obtain

$$\mu_2=\mu+q\Delta\mu. \tag{4.5}$$

Allowing $p_1=p_2$ and applying the constraint that the variances of the two event classes are identical, yields

$$\frac{1}{p_1}=\frac{1/p-q(1-q)(\Delta\mu/\mu)^2}{1+q(1-q)(\Delta\mu/\mu)^2}. \tag{4.6}$$

With a choice of values for q and $\Delta\mu$, the remaining parameters can be calculated, including ΔT.

Both variations of the dual event class model are implemented in a Monte Carlo simulation in the following manner. The number of particles in an event is determined by sampling the N_{tracks} data distribution, approximated by a Gaussian distribution fit to the data. The p_T of each particle in an event is determined individually by sampling the appropriate $\Gamma(p_T,p,b)$ distribution fit to the semi-inclusive p_T data distribution, which yields $p=0.8$ and $b=2.46$ for 0–5 % centrality. The p_T of each particle is restricted to the p_T range of the measurement. With N_{tracks} and the p_T distribution determined, the M_{p_T} for a given number of events is calculated. The generated M_{p_T} distribution with $q=0$ for either model variation is found to be statistically consistent with the mixed event M_{p_T} distribution.

The data contain a fraction of background particles that did not originate from the collision vertex that effectively dilute the sensitivity to nonrandom fluctuations. To address this, a fraction of the particles in an event are randomly tagged as background particles, whose p_T distribution is then generated with a separate parametrization prior to calculating M_{p_T} for an event. The level of background contamination is estimated by processing HIJING [18] Au+Au events through a software chain that includes a detailed GEANT simulation [19] with the complete PHENIX detector geometry included, followed by a detailed simulation of the detector electronics response [12], whose output is then processed by track, cluster, and momentum reconstruction using the identical software and input parameters as is used for the data analysis. It is estimated that 11% of the tracks and 26% of the clusters are due to background particles, independent of centrality class over the centrality range of these measurements. The estimated p_T and e_T distributions for the background particles are well parametrized by exponential distributions. Again, the majority of the e_T background occurs at low e_T, so any correlated background would most likely contribute to the lower side of the M_{e_T} distribution.

To determine the sensitivity to fluctuations within the dual event class model, the fluctuation fraction q and the value of p_1 for model A and $\Delta\mu$ for model B are varied and the M_{p_T} distribution is generated at each step. A χ^2 test is then performed on the generated M_{p_T} distribution with respect to the mixed event data M_{p_T} distribution. For a given value of q, the χ^2 result increases as ΔT increases, which allows a fluctuation exclusion region to be defined for the single degree of freedom. The curves in Fig. 7 show the lower exclusion boundaries for the 0–5 % centrality M_{p_T} measurement at the 95% confidence level as a function of q and ΔT for both variations of the model. If the sensitivity is determined based upon the nonmixed data distribution, the lower exclusion boundary increases by less than 2 MeV for all values of q for either model. Also, for all values of q in either model, the estimated background contribution degrades the sensitivity estimates by $\Delta T = 3$ MeV for both models.

A recent model of event-by-event fluctuations where the temperature parameter $T = 1/b$ fluctuates with a standard deviation σ_T on an event-by-event basis [20] can be simply related to F_T:

$$\frac{\sigma_T^2}{\langle T\rangle^2} = \frac{2F_T}{p(\langle n\rangle - 1)}, \tag{4.7}$$

where $p = 0.8$ is the semi-inclusive parameter extracted from the present data. For the 0–5 % centrality class, the present measurement establishes a 95% confidence limit of 2.6×10^{-3} for $\sigma_T^2/\langle T\rangle^2$, or 5% for $\sigma_T/\langle T\rangle$.

V. CONCLUSIONS

The fluctuations in the M_{p_T} distributions for all centrality classes are consistent with the presence of no fluctuations in excess of the random expectation. The magnitude of F_T in all cases is positive, which may be due to the presence of Hanbury-Brown-Twiss correlations. The fluctuations in the M_{e_T} distributions do have a small nonstatistical component, much of which is attributable to the effects of merged clusters, the remainder of which are taken to indicate an upper limit on nonstatistical fluctuations in transverse energy. By defining a dual event class model, limits are set on the amount of M_{p_T} fluctuations that can be present in the angular aperture $|\eta| < 0.35$ and $\Delta\phi = 58.5°$ in $\sqrt{s_{NN}} = 130$ GeV Au+Au collisions. During the RHIC run of 2001, PHENIX has taken data for $\sqrt{s_{NN}} = 200$ GeV Au+Au collisions with about a factor of 4 increase in azimuthal angular acceptance for both the M_{p_T} and M_{e_T} analyses, which will allow the measurements to be extended toward more peripheral collisions.

(Received 21 March 2002; published 5 August 2002)

Data from Au + Au interactions at $\sqrt{s_{NN}} = 130$ GeV, obtained with the PHENIX detector at the Relativistic Heavy-Ion Collider, are used to investigate local net charge fluctuations among particles produced near midrapidity. According to recent suggestions, such fluctuations may carry information from the quark-gluon plasma. This analysis shows that the fluctuations are dominated by a stochastic distribution of particles, but are also sensitive to other effects, like global charge conservation and resonance decays.

DOI: 10.1103/PhysRevLett.89.082301 PACS numbers: 25.75.Dw

The PHENIX detector [1] at the Relativistic Heavy-Ion Collider (RHIC) is a versatile detector designed to study the properties of nuclear matter at extreme temperatures and energy densities, obtained in central heavy-ion collisions at ultrarelativistic energies. A central goal of these studies is to collect evidence for the existence of the quark-gluon plasma (QGP) characterized by deconfined quarks and gluons.

There are several proposed ways to experimentally verify the existence of a QGP [2]. A general problem is that many of these signals also can be produced in a hadronic scenario, albeit special conditions of highly compressed matter have to prevail. Furthermore, it is not straightforward to determine how the various plasma signals are distorted when the deconfined matter transforms back to hadronic matter. Recent theoretical investigations [3–5] predict a drastic decrease of the event-by-event fluctuations of the net charge in local phase-space regions as a signature of the plasma state. These fluctuations are not related to the transition itself, but rather with the charge distribution in the primordial plasma state. The basic idea is that each of the charge carriers in the plasma carries less charge than

the charge carriers in ordinary hadronic matter. The charge will thus be more evenly distributed in a plasma. The main concern of the theoretical discussions is how and why the original distribution survives the transition back to ordinary matter [6,7]. Predictions, for a rapidity coverage $\Delta y \geq 1$, range up to an 80% reduction in the magnitude of the fluctuations, as measured by the variance of the net charge.

Decays of hadronic resonances influence the net charge fluctuations, whether or not deconfinement is reached. In the absence of a QGP, deviations from statistical behavior can be used to determine the abundance of, e.g., ρ and ω mesons [8]. In a hadron gas resonances are expected to decrease the fluctuations by about 25%. Globally, fluctuations will be further reduced, since charge is a conserved quantity. Although multiplicity fluctuations have been studied extensively in both hadronic and nuclear processes [9], net charge fluctuations have only recently been addressed experimentally [10,11].

In this Letter we report results from an analysis of net charge fluctuations for particles produced in Au + Au interactions at $\sqrt{s_{NN}} = 130$ GeV. The fluctuations are studied in the variables $R = n_+/n_-$, the ratio between positive and negative particles, and $Q = n_+ - n_-$, the net charge [3]. The advantages and disadvantages of these variables will also be discussed.

Information from one of the PHENIX central tracking arms (west) is used in this analysis, where events are required to have a well-defined vertex close to the center of the apparatus ($|Z| < 17$ cm), as defined by the two beam-beam counters (BBC). These cover the pseudorapidity region $3.0 < |\eta| < 3.9$. Together with the information from the two zero-degree calorimeters (ZDC), placed farther away (18 m), the BBC information is used for off-line centrality selection [12]. A total of about 5×10^5 minimum bias events has been analyzed. The PHENIX west arm spectrometer has an acceptance of 0.7 units of pseudorapidity ($-0.35 < \eta < 0.35$) and $\pi/2$ radians in azimuth φ. Charged-particle trajectories are recorded in a multiwire focusing drift chamber (DC) [13]. The combination of reconstructed DC tracks [14] with matching hits in the innermost pad-chamber plane defines the sign of the charge of the particle and also provides a high resolution measurement of the transverse momentum p_T of tracks originating from the collision vertex. Tracks with a reconstructed p_T less than 0.2 GeV/c have been excluded from the analysis due to a low reconstruction efficiency and large contributions from background sources, as revealed by simulations. No upper p_T cut has been applied.

The tracking efficiency and the charge assignment have been studied using GEANT [15] simulations. Of particular importance in this context is a realistic description of the drift chamber response, which is extracted from measured data, parametrized, and applied empirically in the simulation.

RQMD [16] simulations are used to study the detection efficiency, and the fraction of reconstructed particles that preserve their charge, as well as to evaluate the results of the analysis. The charge fluctuations in RQMD are consistent with calculations based on other hadronic models like URQMD and HIJING [3]. The overall efficiency for detecting a charged particle within the acceptance is found to be around 80% for both positive and negative particles. Correlated inefficiencies due to the limited two-track resolution and detector inhomogeneities are small enough ($<1\%$) to be safely neglected for this analysis.

Depending on p_T, between 70% and 85% of the reconstructed tracks are in one-to-one correspondence with a primarily produced particle. The remaining tracks come from secondary interactions in the detector material and from decays, where the original charge information is lost. The composition of these tracks has been studied in detail through RQMD and GEANT. The different sources are weak decays (e.g., K^0_S, Λ, $\overline{\Lambda}$ decays) (28%), γ conversion (16%), $\eta \to \pi^+\pi^-$ (6%). The remaining 50% are mainly from interactions in the detector material. Instead of trying to correct the data for effects from individual sources, we have directly compared the data with the outcome of the simulations. The predictions of RQMD have been studied both with and without experimental distortions, in order to quantify the net effect. It turns out that the experimental bias pushes the value of $\nu(Q)$ closer to the stochastic limit, as will be further discussed below.

In each event the numbers of positively charged particles n_+, negatively charged particles n_-, and their sum n_{ch} are recorded. In a stochastic scenario, with a fixed number of charged particles within the acceptance, where each particle is assigned a random charge ($+1$ or -1 with equal probability), the variance of the net charge, Q, is

$$V(Q) \equiv \langle Q^2 \rangle - \langle Q \rangle^2 = n_{ch}\,. \tag{1}$$

The normalized variance in Q is

$$\nu(Q) \equiv \frac{V(Q)}{n_{ch}} = 1\,. \tag{2}$$

For the charge ratio, in the stochastic scenario, $V(R) \equiv \langle R^2 \rangle - \langle R \rangle^2$ will approach the value $4/n_{ch}$ as n_{ch} increases and $\nu(R) \equiv n_{ch} \cdot V(R)$ asymptotically approaches 4. When an asymmetry between positive and negative particles is introduced, $\nu(R)$ is drastically affected, whereas the effect on $\nu(Q)$ is marginal. If we write the probability p_+ that a given particle has positive charge in the form $p_+ = \frac{1}{2}(1 + \varepsilon)$, and subsequently $p_- = \frac{1}{2}(1 - \varepsilon)$, we find $\nu(Q) = 1 - \varepsilon^2$, while the asymptotic value of $\nu(R)$ is $4 + 16\varepsilon + O(\varepsilon^2)$. Detector or reconstruction inefficiencies, which randomly remove particles independent of charge, do not influence those results in the stochastic scenario. The variance, $V(R)$, can be calculated from

$$\langle R\rangle = \frac{1}{A}\sum_{i=1}^{n_{ch}-1}\frac{n_{ch}-i}{i}\binom{n_{ch}}{i}p_{+}^{n_{ch}-i}p_{-}^{i};$$
$$\langle R^2\rangle = \frac{1}{A}\sum_{i=1}^{n_{ch}-1}\left(\frac{n_{ch}-i}{i}\right)^2\binom{n_{ch}}{i}p_{+}^{n_{ch}-i}p_{-}^{i}, \quad (3)$$

where $A = 1 - p_{+}^{n_{ch}} - p_{-}^{n_{ch}}$ is the new normalization due to discarding events with n_+ or n_- equal to zero. The variance of R, even for a purely stochastic charge distribution, depends on multiplicity and on the fractions of positive and negative particles.

There are other proposed measures of net charge fluctuations. Most of these are modifications of R or Q, and deal with corrections for large charge asymmetries (i.e., $\varepsilon \neq 0$) and large acceptances. Since in our case ε is close to zero, and the fraction of observed to all produced particles in an event is small, we can safely neglect those complications [17].

The data show a small excess of positive particles, growing proportionally with n_{ch}, in qualitative agreement with calculations using RQMD and GEANT. A part of this excess comes from the intrinsic isospin asymmetry and a part from secondary interactions in the detector and surrounding material.

In Fig. 1(a), $v(R)$ and $v(Q)$ are displayed as functions of n_{ch} and $v(Q)$ is multiplied by a factor of 4 to compensate for the asymptotical difference between $v(R)$ and $v(Q)$. Both $v(Q)$ and $v(R)$ are well described by the results obtained from the stochastic scenario.

Since $v(Q)$ is independent of n_{ch} one expects $v(Q)$ to be close to unity also in representations where other centrality measures are used. On the other hand, since $v(R)$ depends on multiplicity, it will have a complicated behavior as a function of centrality, making it difficult to draw any further conclusions. We will thus focus on $v(Q)$ for the rest of this analysis.

In Fig. 1(b), $v(Q)$ is displayed as a function of centrality based on the ZDC/BBC information. The full event sample, corresponding to 92% of the inelastic cross section [12], is divided into 20 centrality classes, where each class corresponds to 5% of the events. Class 20 represents the most central events. With the increased resolution on the y axis in Fig. 1(b), it is evident that $v(Q)$ is consistently below unity and deviates from stochastic behavior. The value is, however, far above the most optimistic QGP predictions $v(Q) \sim 0.2$ [3], although one should keep in mind that our coverage in rapidity is at the limit for these predictions and that we have only partial coverage in azimuth.

There may be other explanations for deviations from stochastic behavior than the one offered by the quark-gluon plasma. These include global charge conservation and neutral resonances decaying into correlated pairs of one positive and one negative particle. Both of these effects will decrease the fluctuations, and the decrease will grow in proportion to the experimental acceptance. In a stochastic scenario, taking global charge conservation into account, the normalized variance $v(Q)$ becomes $(1 - p)$, where p is the fraction of observed charged particles among all charged particles in the event. Eventually, if all charged particles are detected, $v(Q)$ will become 0.

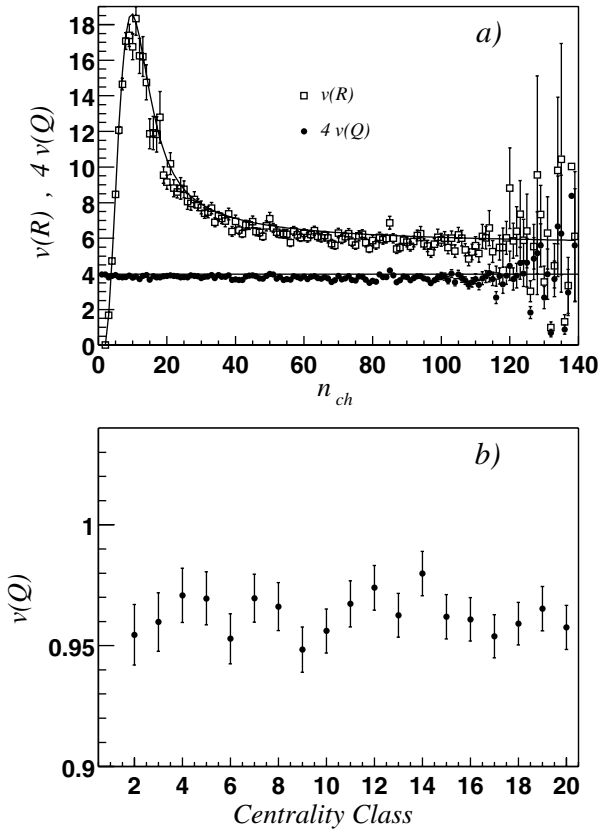

FIG. 1. (a) The normalized variances $v(Q)$ and $v(R)$ as functions of n_{ch}, together with curves for stochastic behavior. (b) The normalized variance $v(Q)$ for different centrality classes, as described in the text.

Experimentally we can change the fraction p of particles within the acceptance by using different regions of the PHENIX west arm. In Fig. 2(a), $v(Q)$, for the 10% most central events, is displayed as a function of $\Delta\varphi_d$, i.e., the chosen azimuthal interval of the spectrometer. For comparison, the results from RQMD processed through GEANT are shown. The data and the simulation show a similar trend. Note that the data points are correlated since the data in one bin is a subset of the data in the next. The error band indicates the total statistical error in each data point. The error bars represent the uncorrelated part of this statistical error. For RQMD, only the total statistical error is given. The solid line corresponds to the $(1 - p)$ dependence discussed above. The linear relationship between p and $\Delta\varphi_d$ is estimated from the phase-space distribution of particles in RQMD, including effects from reconstruction efficiency and background tracks. For larger angles, both data and the RQMD results lie consistently below the line,

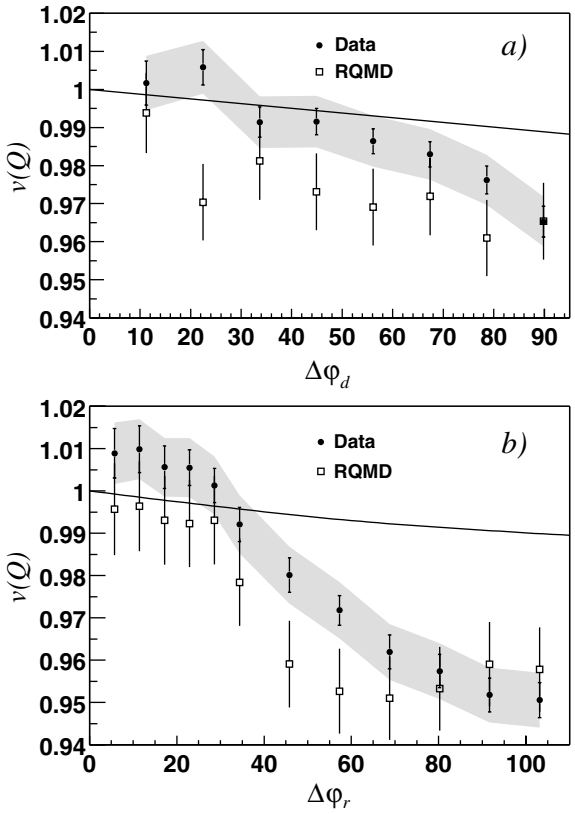

FIG. 2. $\nu(Q)$ for the 10% most central events in data and RQMD, as a function of the azimuthal coverage. For data, the error band shows the total statistical error, whereas the error bars indicate the uncorrelated part. The solid line (curve) shows the expected reduction in $\nu(Q)$ in the stochastic scenario when global charge conservation is taken into account. Azimuthal angle (in degrees) defined (a) as detector coverage, and (b) as reconstructed at the interaction vertex.

which indicates that effects from resonance decays are important.

Because of the influence of the magnetic field the positive and negative particles will have different azimuthal acceptance. On the average a charged particle (surviving the experimental cuts) will be deflected 19° in the magnetic field. The $\Delta\varphi_d$ study in Fig. 2(a) thus selects partly nonoverlapping regions of phase space for positive and negative particles. A remedy for this is to use the reconstructed φ angle for each particle φ_r, i.e., the azimuthal direction of the particle at the primary vertex, before it is deflected by the magnetic field. By choosing the azimuthal interval $\Delta\varphi_r$ symmetrically around the center of the acceptance, a better phase-space overlap is achieved for small azimuthal intervals. In Fig. 2(b), $\nu(Q)$, for the 10% most central events, is displayed as a function of $\Delta\varphi_r$. The $(1 - p)$ dependence, which is no longer linear, is given by the solid curve. Again data and the RQMD results show a similar trend, but the deviations from the curve are larger in this representation, indicating that an overlap in phase space is of importance. The errors are treated as in Fig. 2(a).

The effects of the detector inefficiency and background tracks not assigned the correct charge have been investigated in a Monte Carlo simulation. The reconstruction efficiency and the amount of background have been determined from the RQMD and GEANT simulations discussed earlier. Both the inefficiency and the background contribution have the net effect of diluting the signal and pushing the value of $\nu(Q)$ closer to 1. The dilution due to these effects can be treated as an experimental systematic error, estimated from the simulations, setting a lower limit on $\nu(Q)$. For the net charge fluctuations in the region $-0.35 < \eta < 0.35$, $p_T > 0.2$ GeV/c, and $\Delta\varphi = \pi/2$,

$$\nu(Q) = 0.965 \pm 0.007(\text{stat}) - 0.019(\text{syst}) \qquad (4)$$

is obtained for the 10% most central events. Assuming a linear behavior, an extrapolation of this value to full azimuthal coverage gives a value of $\nu(Q)$ in the range 0.78–0.86, in qualitative agreement with calculations from a hadronic gas.

Our findings are in agreement with the preliminary conclusions of NA49 [10] and STAR [11] that no indication of decreased fluctuations due to quark-gluon plasma formation is observed. STAR also attributes the deviations from a stochastic scenario to be consistent with resonance correlations.

To summarize, we have shown that the data behave in an almost stochastic manner. There are also clear indications that effects from hadronic decays are seen; the data are in good agreement with RQMD calculations, which includes the effects of global charge conservations as well as neutral hadronic resonance decays. Furthermore, the data show no centrality dependence, which is in contradiction with the expectations from a quark-gluon plasma scenario. We have clearly demonstrated that the fluctuations of the charge ratio $\nu(R)$ and of the net charge $\nu(Q)$ are well understood in a stochastic model. The R variable [3] unnecessarily complicates the evaluation of the fluctuations, and the intrinsic decrease of $\nu(R)$, as a function of centrality, can be mistaken for a "plasma fingerprint."

The measured value of $\nu(Q) = 0.965$ is far from the value predicted for a plasma. Even extrapolating the linear trend seen in the data in Fig. 2(a) to full azimuthal coverage renders values of the fluctuations, which are far above the proposed values. With the caveat of our limited acceptance in rapidity, these results clearly indicate either the absence of a plasma or a proposed signal that does not survive the transition back to hadronic matter.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. (Received 5 February 2002; published 30 April 2002)

Transverse momentum spectra of electrons from Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV have been measured at midrapidity by the PHENIX experiment at the Relativistic Heavy Ion Collider. The spectra show an excess above the background from photon conversions and light hadron decays. The electron signal is consistent with that expected from semileptonic decays of charm. The yield of the electron signal dN_e/dy for $p_T > 0.8$ GeV/c is 0.025 ± 0.004(stat) ± 0.010(syst) in central collisions, and the corresponding charm cross section is 380 ± 60(stat) ± 200(syst) μb per binary nucleon-nucleon collision.

DOI: 10.1103/PhysRevLett.88.192303 PACS numbers: 25.75.Dw

In this Letter, we report the first measurement of single electron spectra, $(e^+ + e^-)/2$, in Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV at the Relativistic Heavy Ion Collider (RHIC). The measurement of single leptons at high transverse momentum ($p_T \gtrsim 1$ GeV/c) is a useful way to study heavy-quark production, an important probe of hot and dense matter created in high energy heavy ion collisions. Charm production is sensitive to the initial state gluon density [1,2]. Nuclear and medium effects, such as shadowing and charm quark energy loss [3,4], can be studied by comparison of charm production in AA, pA, and pp collisions. Measurement of charm is important for understanding J/ψ suppression (a proposed signal of the deconfinement phase transition [5,6]) and the dilepton mass distribution in $1 < M_{l^+l^-} < 3$ GeV, where lepton pairs from charm make significant contributions [7]. In pp collisions at the CERN Intersecting Storage Rings (ISR) ($\sqrt{s} = 30$–63 GeV), production of single electrons was observed ($e/\pi \sim 10^{-4}$) for $p_T > 1$ GeV/c [8–11], and interpreted as evidence of open charm production [12]. In pp collisions at RHIC energies, the signal level is expected to be higher, since charm production increases with $\sqrt{s_{NN}}$ faster than pion production. We recently observed suppression of high p_T pion production in Au + Au collisions at

RHIC relative to binary nucleon-nucleon (NN) collision scaling [13]. If charm production scales with NN collisions, as expected in the absence of nuclear effects, the e/π ratio will be even higher in Au + Au collisions at RHIC.

Data used for this analysis were recorded by the PHENIX west-arm spectrometer [14] ($\Delta\phi = 90°$ in azimuth, $|\eta| < 0.35$ in pseudorapidity), which consisted of a drift chamber (DC), a layer of pad chambers (PC1), a ring imaging Čerenkov detector (RICH), and a lead-scintillator electromagnetic calorimeter (EMCAL). The trigger was provided by beam-beam counters (BBC) and zero-degree calorimeters (ZDC). ZDC and BBC signals were combined to select centrality: central (0%–10%), peripheral (60%–80%), and minimum bias (0%–92%) [15].

The analysis uses $1.23M$ minimum bias events with vertex position $|z| < 30$ cm. Charged particle tracks are reconstructed by the DC and the PC1 with a momentum resolution $\delta p/p \simeq 0.6\% \oplus 3.6\%\ p\ (\mathrm{GeV}/c)$. Tracks are confirmed by a matching hit in the EMCAL, which measures the energy E deposited with a resolution of $8.2\%/\sqrt{E(\mathrm{GeV})} \oplus 1.9\%$ for test beam electrons. Electron identification is performed using the RICH and the EMCAL [14]. The RICH is filled with 1 atm CO_2 and detects on average 10.8 photoelectrons per electron track, while a pion with $p < 4.7\ \mathrm{GeV}/c$ produces no signal. It is required that at least three RICH hits are associated with the track and that their hit pattern is consistent with that of an electron track. After these cuts, a clear electron signal is observed as a narrow peak centered at $E/p = 1.0$. We select tracks in the peak as electron candidates. The E/p cut reduces hadron background and removes conversion electrons created far from the vertex. A hadron deposits only a fraction of its energy in the EMCAL, and the momentum of an off-vertex conversion electron is reconstructed incorrectly. The remaining background, about 10% of the electron candidates, is caused by accidental association of RICH hits with hadron tracks. The background level is measured statistically by an event mixing method, and is subtracted from the yield.

The electron acceptance ($\sim$7.4% of dN/dy) and efficiency ($\sim$60%) are determined using a detailed GEANT [16] simulation, which satisfactorily reproduces the detector response. Additionally, a multiplicity dependent efficiency loss due to detector occupancy is evaluated by embedding simulated electrons into real events. This efficiency loss is $27 \pm 4\%$ ($4 \pm 2\%$) for central (peripheral) collisions and has no significant p_T dependence.

Figure 1 shows the p_T distributions of electrons in PHENIX for central, minimum bias, and peripheral collisions. Errors in the figure are statistical. The overall systematic uncertainty, which is the quadratic sum of several few percent effects, is about 11%. Expected sources of electrons are (1) Dalitz decays of π^0, η, η', ω, and ϕ, (2) dielectron decays of ρ, ω, and ϕ, (3) photon conversions, (4) kaon decays ($K^{0,\pm} \to \pi e \nu$),

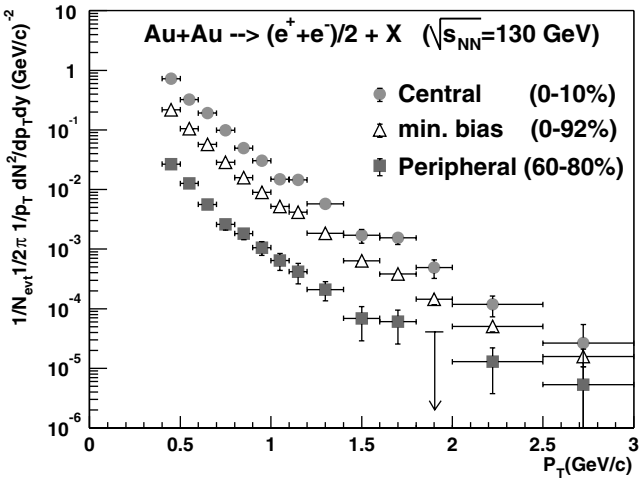

FIG. 1. Transverse momentum spectra of electrons in PHENIX from Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV.

(5) semileptonic decay of charm, and (6) other contributions such as bottom decays and thermal dileptons. In this analysis, sources (1)–(4) are considered to be background.

We have calculated the contributions from Dalitz and dielectron decays with a hadron decay generator. PHENIX has measured the p_T distributions of $\pi^{\pm}$ in $0.2 < p_T < 2.2\ \mathrm{GeV}/c$ [17] and of π^0 in $1 < p_T < 4\ \mathrm{GeV}/c$ [13]. Since the $\pi^{\pm}$ and π^0 data are consistent in the overlapping region, we fit a power law function to the combined data sets to determine the input π^0 spectrum for the decay generator. The p_T distribution of any other hadron h is obtained from the π^0 spectrum by replacing p_T with $\sqrt{p_T^2 + m_h^2 - m_{\pi^0}^2}$. The shapes of the resulting p_T spectra of $K^{\pm}$, p, and $\bar{p}$ agree with the PHENIX measurements [17] within 20%. In this parametrization h/π^0 ratios approach constants at high p_T. We assume the following asymptotic ratios to fix the relative normalizations: $\eta/\pi^0 = 0.55$, $\eta'/\pi^0 = 0.25$, $\rho/\pi^0 = \omega/\pi^0 = 1.0$, $\phi/\pi^0 = 0.40$. Except for the ϕ, these ratios are taken from proton beam data of CERN Super Proton Synchrotron (SPS), FNAL, and ISR experiments [18,19]. The η/π^0 ratio is consistent with a measurement in Pb + Pb collisions at SPS [20]. The ϕ/π^0 ratio is based on the integrated ratio $\phi/h^- \sim 0.02$ in Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV [21]. We assign to each ratio a conservative systematic uncertainty of 50%.

Photon conversions are evaluated using a combination of the GEANT simulation and the hadron decay generator. Since p_T spectra of externally converted electrons are similar to those from Dalitz decay, the conversion spectra can be approximated by scaling the Dalitz decay spectra by an experiment specific factor, $R_{\mathrm{conv}} = \mathrm{conversion/Dalitz}$. R_{conv} is evaluated using the GEANT simulation and is cross-checked by comparing the relative yield of reconstructed Dalitz and conversion pairs in the simulation and in the data. The simulation shows that R_{conv} has only a weak p_T dependence, primarily due to the energy dependence

of the pair creation cross section. $R_{\rm conv}$ is parametrized as $(1.9 \pm 0.2) \times (1 - 0.0718 \times p_T^{-0.76})$.

Background from kaon decays is also evaluated using the GEANT simulation and is found to be negligible.

The upper panel of Fig. 2 shows the ratio of the measured electrons to the calculated background versus p_T for minimum bias events. The shaded region is the quadratic sum of systematic errors in the electron measurement and in the background. The latter includes uncertainties in the normalization and the shape of the π^0 spectrum, in the h/π^0 ratios, and in $R_{\rm conv}$. A significant electron excess above the background is observed for $p_T > 0.6$ GeV/c. Central collisions show a similar excess. The peripheral collision data sample lacks sufficient statistics to reveal a signal in this analysis.

Fractional contributions to the background are shown in the lower panel of Fig. 2. More than 80% of the background is from π^0 decay, directly from the Dalitz decay or indirectly from photon conversion. The π^0 spectrum is well constrained by the PHENIX measurement. The next most important background source is η decay. Given the assigned systematic error, the upper limit of the high p_T asymptotic η/π^0 ratio is 0.83. Since this ratio, corrected for feed-down, would imply that the primary $\eta/\pi^0 \sim 1$, this provides a conservative limit on contributions from η's. Contributions from all other hadrons combined are only a few percent of the total.

Background-subtracted electron spectra are shown in Fig. 3. The error bars on the data points represent the statistical errors, while the systematic error due to the background subtraction is indicated by brackets. The integrated yield of the electron signal dN_e/dy for $p_T > 0.8$ GeV/c is 0.025 ± 0.004(stat) $\pm$ 0.010(syst) for central collisions and is 0.0079 ± 0.0006(stat) $\pm$ 0.0034(syst) for minimum bias collisions.

Semileptonic decay of charmed hadrons is an expected source of the electron signal. We use the event generator PYTHIA [22] to estimate electron spectra from charm decay. We tuned the parameters [23] of PYTHIA such that charm production data at SPS and FNAL [24] and single electron data at the ISR [9–11] are well reproduced. The charm production cross section in pp collisions from this PYTHIA calculation is $\sigma_{c\bar{c}} = 330$ μb at $\sqrt{s} = 130$ GeV. The electron spectrum in Au + Au collisions is then calculated as $EdN_e/dp^3 = T_{AA} \times Ed\sigma_e/dp^3$, where $Ed\sigma_e/dp^3$ is the electron spectrum from charm decay calculated with PYTHIA, and T_{AA} (listed in Table I) is the nuclear overlap integral calculated from a Glauber model [13]. The calculated electron spectra shown in Fig. 3 are in reasonable agreement with the data.

Before attributing the entire electron signal to open charm decays, it is necessary to quantify contributions from other possible sources. An analogous PYTHIA estimate of the bottom decay contribution is shown in Fig. 3. It becomes significant only above the measured p_T range. Expected contributions from J/Ψ and Drell-Yan are negligible. In Pb + Pb collisions at SPS, direct photons [20] and an enhanced yield of low mass dileptons [25] have been reported. If these are due to thermal radiation from hot matter, an even larger production is expected at RHIC energies and can contribute to the electron signal. Since $\rho \rightarrow e^+e^-$ contributes less than 1% to the calculated background as shown in Fig. 2, and since the dominant

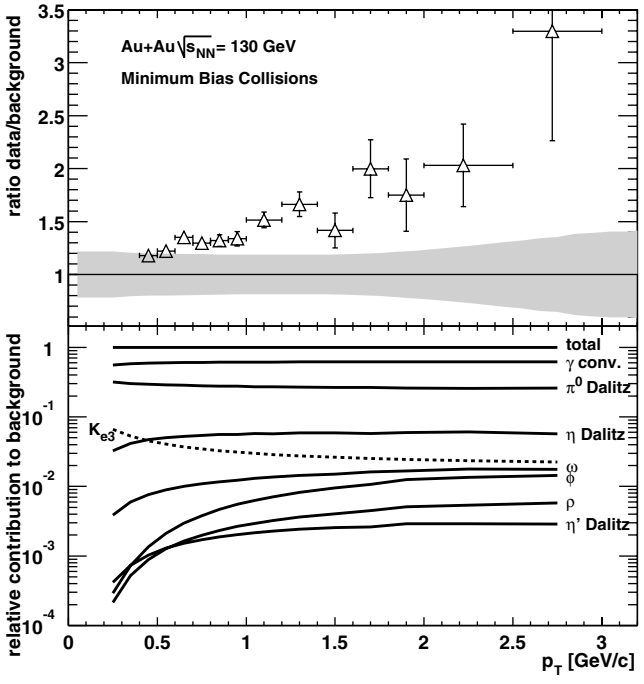

FIG. 2. Ratio of the electron data to the calculated background as a function of p_T in minimum bias collisions (upper panel) and relative contributions to the background from various sources (lower panel). The curves for ω and ϕ show the sum of the Dalitz and the dielectron decay modes.

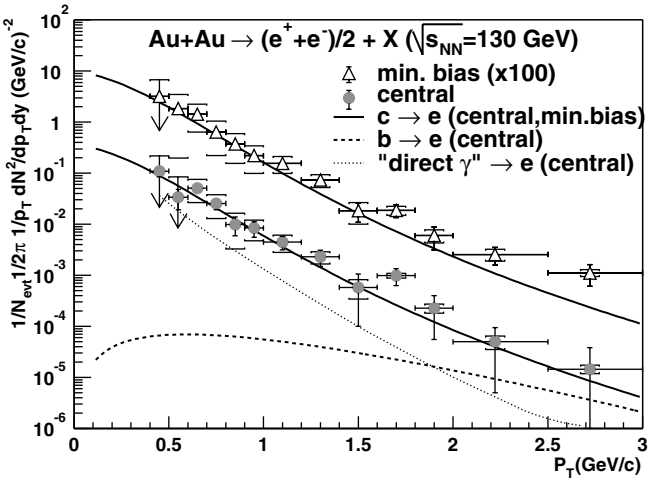

FIG. 3. The background-subtracted electron spectra for minimum bias (0%–92%) (scaled up by a factor of 100) and central (0%–10%) collisions compared with the expected contributions from open charm decays. Also shown, for central collisions only, are the expected contribution from bottom decays (dashed line) and the conversion electron spectrum from a direct photon prediction (dotted line).

TABLE I. Charm cross section per *NN* collision derived from the single electron data for central (0%–10%) and minimum bias (0%–92%) collisions. The first and second errors are statistical and systematic, respectively.

Centrality	T_{AA} (mb^{-1})	$d\sigma_{c\bar{c}}/dy\|_{y=0}$ (μb)	$\sigma_{c\bar{c}}$ (μb)
0%–10%	22.6 ± 1.6(syst)	97 ± 13 ± 49	380 ± 60 ± 200
0%–92%	6.2 ± 0.4(syst)	107 ± 8 ± 63	420 ± 33 ± 250

source of thermal dileptons is $\pi + \pi \rightarrow \rho \rightarrow e^+e^-$ [26], a significant contribution from thermal dileptons is unlikely. There are several predictions for direct photons at RHIC energies [27,28]. The conversion electron spectrum calculated from a prediction in Ref. [27] is shown in Fig. 3 for central collisions. It could explain 10%–20% of the signal, with large theoretical uncertainties.

Neglecting these other possible sources and assuming that all the electron signal is from charm, we derive the charm cross section corresponding to the electron data. We fit the charm electron spectrum from PYTHIA to the data for $p_T > 0.8$ GeV/c and obtain the rapidity density $dN_{c\bar{c}}/dy|_{y=0}$ and the total yield $N_{c\bar{c}}$ of open charm. They are then converted to cross sections per *NN* collision: $d\sigma_{c\bar{c}}/dy = (dN_{c\bar{c}}/dy)/T_{AA}$ and $\sigma_{c\bar{c}} = N_{c\bar{c}}/T_{AA}$. Results are shown in Table I. The systematic error is a quadratic sum of many sources. For central collisions, they are background subtraction (±44%), uncertainties in the PYTHIA calculation (±11% from $\langle k_T \rangle = 1.5 \pm 0.5$, ±13% from $D^+/D^0 = 0.65 \pm 0.35$, ±8% from PDFs), fit range (±18%), and T_{AA} (±7%). Note that any finite contribution from neglected sources would reduce the derived charm cross section. Without nuclear or medium effects in charm production, $\sigma_{c\bar{c}}$ per *NN* collision should be independent of centrality. Within uncertainties, our data are consistent with this expectation, in possible contrast to the attribution of increased charm production as the source of enhanced dimuon production reported in Pb + Pb collisions at SPS [29].

The single electron signal yield (divided by T_{AA} to give the cross section per *NN* collision) and the derived charm cross section are compared with single electron data of ISR experiments and charm data of fixed target experiments [24] in Fig. 4. Cross section curves calculated with PYTHIA, which has been tuned to the charm data and the ISR electron data, and a charm cross section curve from a next-to-leading order (NLO) pQCD calculation [31] are also shown in the figure. Our data are consistent with both of the calculations within large uncertainties.

In conclusion, we have observed single electrons above the expected background from decays of light hadrons and photon conversion in Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV. The observed signal is consistent with semileptonic decay of charm. The forthcoming high statistics Au + Au data and pp comparison data at full RHIC energy ($\sqrt{s_{NN}} = 200$ GeV) will be useful to clarify the nature of the single electron signal and to better determine heavy-quark production in Au + Au collisions at RHIC.

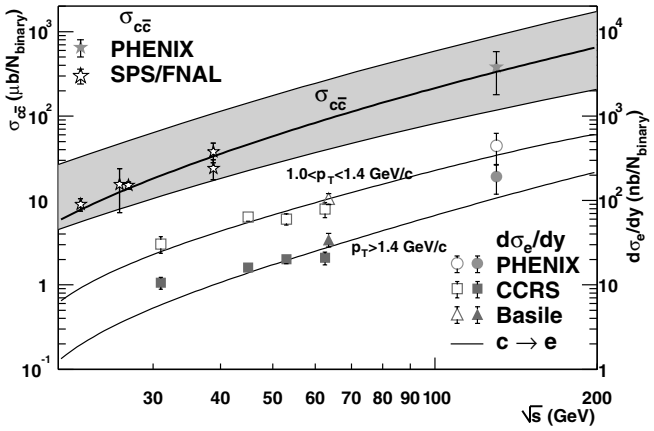

FIG. 4. Single electron cross sections $d\sigma_e/dy|_{y=0}$ of this measurement and ISR experiments [9,11,30] are displayed (bottom, right-hand scale) with charm decay contributions calculated with PYTHIA. Open and filled symbols are for $1.0 < p_T < 1.4$ GeV/c and $p_T > 1.4$ GeV/c, respectively. The derived charm cross section of this measurement is compared with charm cross sections from SPS/FNAL experiments (top, left-hand scale). The thick curve and the shaded band represent the charm cross section in the PYTHIA model and in a NLO pQCD calculation [31], respectively.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We acknowledge support from the Department of Energy and NSF (U.S.A.), MEXT and JSPS (Japan), RAS, RMAE, and RMS (Russia), BMBF, DAAD, and AvH (Germany), VR and KAW (Sweden), MIST and NSERC (Canada), CNPq and FAPESP (Brazil), IN2P3/CNRS (France), DAE and DST (India), KRF and CHEP (Korea), the U.S. CRDF for the FSU, and the U.S.–Israel BSF.

(Received 16 January 2002; published 30 April 2002)

Two-pion correlations in $\sqrt{s_{NN}} = 130$ GeV Au + Au collisions at RHIC have been measured over a broad range of pair transverse momentum k_T by the PHENIX experiment at RHIC. The k_T dependent transverse radii are similar to results from heavy-ion collisions at $\sqrt{s_{NN}} = 4.1$, 4.9, and 17.3 GeV, whereas the longitudinal radius increases monotonically with beam energy. The ratio of the outwards to sidewards transverse radii ($R_{\rm out}/R_{\rm side}$) is consistent with unity and independent of k_T.

DOI: 10.1103/PhysRevLett.88.192302 PACS numbers: 25.75.Dw

The influence of Bose-Einstein statistics on the correlation of identical charged pions at low relative momentum was first used to probe the space-time structure of pion emission in $p\bar{p}$ annihilations [1] and has subsequently been applied to relativistic heavy-ion collisions from the Bevalac to RHIC [2–7] (see [8] for recent reviews) and to a wide range of systems including e^+e^- annihilations [9]. The correlation function is defined as the ratio of the two-particle probability distribution to the product of the single-particle distributions. For a static source with no final state interactions, it is related to the Fourier transform with respect to $\mathbf{q} = \mathbf{p}_1 - \mathbf{p}_2$ of the source distribution $\rho(\mathbf{r})$, $P(\mathbf{p}_1, \mathbf{p}_2)/P(\mathbf{p}_1)P(\mathbf{p}_2) = 1 + |\tilde{\rho}(\mathbf{q})|^2$ [1]. If the source is parametrized as a multidimensional Gaussian, the enhancement in the correlation function is a Gaussian, and the Gaussian widths are each inversely proportional to the source dimensions in the canonically conjugate spatial variables. The extracted source dimensions are commonly referred to as HBT radii, after a similar technique developed by Hanbury-Brown and Twiss to measure stellar radii [10]. For dynamic sources, such as rapidly expanding sources in heavy-ion collisions, the correlation function measures "lengths of homogeneity," or the relative separations of the pions with low relative momentum. This leads to source radii which depend strongly on k_T, the mean transverse momentum of the pion pair [11–16]. If the dynamics are correctly modeled, then both the source geometry and rate of expansion can be deduced by

measuring the k_T dependence of the radii. The existence of a connection between HBT radii and heavy-ion source geometry is established by the dependence of the radii on system size [17], centrality [4,5], and reaction plane [3]. Interest in Bose-Einstein correlations in heavy-ion collisions is driven by the expectation that HBT radii are sensitive to the large and/or long-lived sources which may accompany a QCD phase transition [12,18]. Recent calculations predict that the greatest sensitivity to a long-lived source will come from measurements of the correlation function at high k_T ($\geq$0.3 GeV/c) [19,20].

We present new measurements from the PHENIX experiment on two-pion correlations in Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV in the region $|\eta| < 0.35$, $0.2 < k_T < 1.0$ GeV/c, significantly extending previous measurements by STAR [7] up to a mean-k_T 0.63 GeV/c. The data are compared to theoretical predictions for RHIC and to HBT radii from lower energy collisions at the CERN Super Proton Synchrotron and Alternating Gradient Synchrotron (at BNL). The k_T dependence of the transverse radii is used to extract a geometric transverse radius.

The PHENIX experiment has been described in detail elsewhere [21,22]. For this analysis we utilize a subset of the detectors in PHENIX. We use the hadronic particle identification capabilities present in the west arm of the PHENIX spectrometer perpendicular to the beam direction [22] with polar and azimuthal ranges of $|\eta| < 0.35$ and $\pi/4$, respectively, during its first year of running. In this analysis, the vertex is determined with a zero degree calorimeter and a pair of Čerenkov beam-beam counters (BBC). Pattern recognition and momentum reconstruction rely on a drift chamber and a pad chamber which occupy the region between 2.0 and 2.5 m from the beam axis. The momentum resolution from these detectors is $\delta p/p = 0.6\% \oplus 3.6\% p$. Particle velocity is determined from the differential time measurements of the BBC and the electromagnetic calorimeter (EMC) [23], with a combined rms resolution of 700 ps, coupled with the path length determined from pattern recognition. The momentum determination and particle identification method are similar to [24], except that the time of flight is measured by the EMC. A pion is defined as being within 1.5 standard deviations of the pion mass-squared peak but at least 2.5 standard deviations away from the kaon peak. After applying interdetector association cuts the background from misassociated EMC hits is $\sim$10% as determined by a hit randomization technique. This background does not significantly distort the extracted radius in the correlation measurements, although it reduces the measured correlation strength (λ). We did not correct for this background in our correlation analysis.

A total of 493 K events in the most central 30% of the cross section survive all off-line cuts. This sample contains 3.1 million π^+ pairs and 3.3 million π^- pairs in the analysis, and has a mean centrality of 10%.

The pion correlation function is determined from pairs of identical pions. The normalized probability of detecting two particles with relative momentum $\mathbf{q} = \mathbf{p}_1 - \mathbf{p}_2$ and average momentum $\mathbf{k} = (\mathbf{p}_1 + \mathbf{p}_2)/2$ is determined experimentally by the ratio of pairs from the same event (A) with those from different events (B): $C_2(\mathbf{q}, \mathbf{k}) = A(\mathbf{q}, \mathbf{k})/B(\mathbf{q}, \mathbf{k})$. Pairs of particles within 2 cm of each other in the drift chamber are eliminated from the analysis in both the real and background samples. Pairs that share the same EMC cluster are also removed from both samples. Finally, all pairs in the mixed background sample are required to be from events with a reconstructed BBC collision vertex within 1 cm of each other.

We correct for the Coulomb interaction of the pairs in the correlation function by parametrizing the source as a Gaussian distribution in the pair center-of-mass frame and performing an iterative procedure [25] which accounts for the finite resolution of the detector. This procedure applied to the distribution of π^+-π^- pairs is in agreement with the data, although the statistics in the Run-1 opposite-signed analysis are not sufficient to independently determine the required Coulomb correction. Systematic studies of the Coulomb correction which vary both radius and magnitude within reasonable constraints produce variations in the final radii which never exceed 0.25 fm.

The relative momenta are projected into the variables q_{long}, along the beam direction, q_{out}, parallel to the transverse momentum of the pair $\mathbf{k}_T = \frac{1}{2}(\mathbf{p}_{T_1} + \mathbf{p}_{T_2})$, and q_{side}, perpendicular to q_{long} and q_{out} [11,18]. These variables are calculated in the longitudinal comoving system (LCMS), obtained by a longitudinal boost from the lab frame to the frame in which the longitudinal pair velocity vanishes. This frame is commonly used for sources expected to be invariant under longitudinal boosts [26].

The fully corrected correlation function for π^- pairs is shown in the top panels of Fig. 1; the large q region of the correlation function has been normalized to 1 in the plots. The data are fit to a Gaussian parametrization of the source using a MINUIT based log-likelihood method [4].

$$C_2 = 1 + \lambda \exp(-R_{\text{long}}^2 q_{\text{long}}^2 - R_{\text{side}}^2 q_{\text{side}}^2 - R_{\text{out}}^2 q_{\text{out}}^2), \quad (1)$$

where R_{long}, R_{side}, and R_{out} are the conjugate variables to q_{long}, q_{side}, and q_{out}, respectively. Errors quoted in the tables and figures are statistical only. Systematic errors come mainly from the Coulomb correction and dependence of the results on the two-track distance cuts. The combined systematic error for these effects, estimated by varying the cuts and corrections within reasonable bounds, is 8% for R_{long}, and R_{side}, and 4% for R_{out}. The systematic error from residual correlations in the event-mixed background [2] is 2%, yielding a total systematic error of $\sim$8% for R_{long} and R_{side} and $\sim$4.5% for R_{out}.

The data set is subdivided into three k_T bins of equivalent statistics in order to study the momentum dependence of the correlation function. In Fig. 2, the radii for π^-

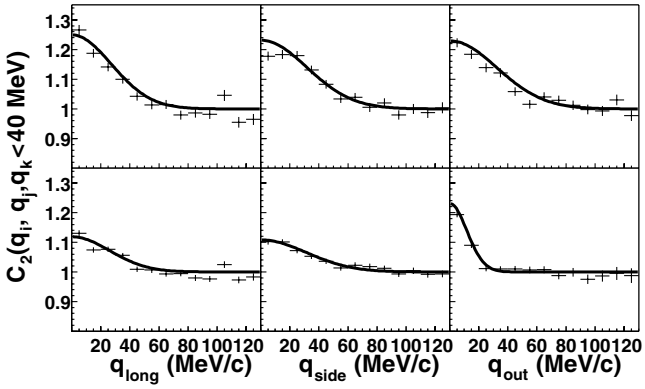

FIG. 1. The three dimensional correlation function for π^- pairs versus $q_{\rm long}$, $q_{\rm side}$, and $q_{\rm out}$ in both the LCMS frame (top) and the pair center-of-mass frame (bottom). The data are plotted versus one momentum difference variable while requiring the other two to be less than 40 MeV/c. The lines correspond to the fit to the entire distribution.

pairs are shown to agree within statistical and systematic errors with previous measurements for overlapping k_T bins at this energy for the 12% most central events. For STAR, the mean pair centrality can be approximated by the geometric mean of 8%, which is slightly more central than the mean pair centrality of 10% for the PHENIX data. This figure also shows k_T dependent radii for midrapidity pions from central collisions for $\sqrt{s_{NN}} = 17.3$ GeV Pb + Pb [6,27] and for $\sqrt{s_{NN}} = 4.9$ and 4.1 GeV Au + Au [3,4]. For the transverse radii, $R_{\rm out}$ and $R_{\rm side}$, the variation with collision energy is generally smaller than the statistical and systematic errors of the individual data points. There is no evidence for a change in the low-k_T extrapolation of $R_{\rm side}$ with increasing $\sqrt{s_{NN}}$ which would indicate a larger geometric source at higher energy. Nor is any change evident in $R_{\rm out}$ relative to $R_{\rm side}$ at high k_T, indicating a longer-lived source. This result is surprising given the factor of $\sim$3 change in the total charged particle multiplicity per unit rapidity at midrapidity [28]. Only $R_{\rm long}$ exhibits a significant variation with collision energy. To quantify this difference, we fit the $R_{\rm long}$ dependence to $A/\sqrt{m_T}$ [13,16,29] for the three sets of beam energies. The results are overlayed with the data in the bottom panel of Fig. 2 and yield $A = 3.32 \pm 0.03$, 3.05 ± 0.06, and 2.19 ± 0.05 fm GeV$^{1/2}$ for $\sqrt{s_{NN}} = 130$, 17.3, and 4.9/4.1 GeV, respectively.

Although a finite emission duration contributes to $R_{\rm out}$ but not to $R_{\rm side}$, dynamical correlations affect the two radii differently. A quantitative determination of the source lifetime can be performed only in the context of a dynamical model. The lower panel of Fig. 3 shows the k_T dependence

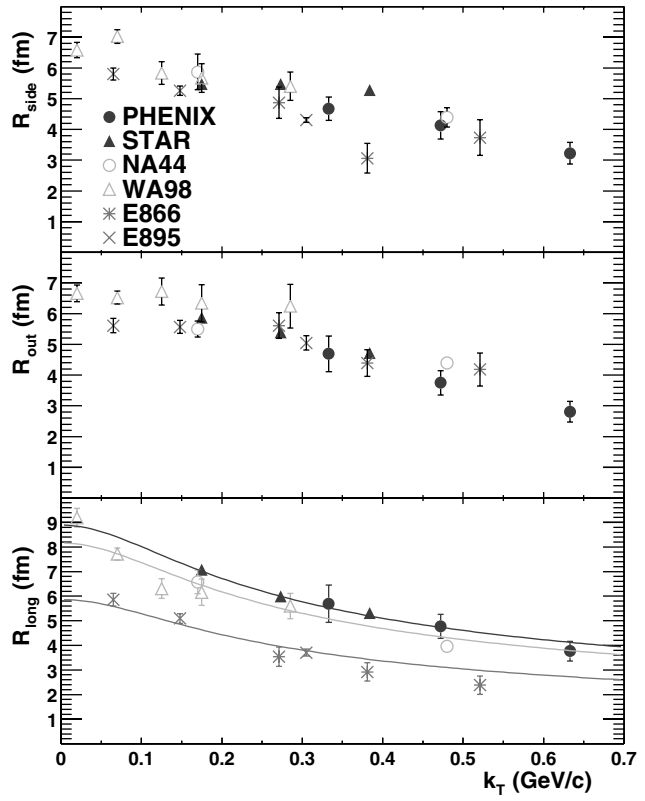

FIG. 2. HBT radii for pion pairs as a function of k_T measured at midrapidity for various energies from E895 ($\sqrt{s_{NN}} = 4.1$ GeV), E866 ($\sqrt{s_{NN}} = 4.9$ GeV), NA44, WA98 ($\sqrt{s_{NN}} = 17.3$ GeV), STAR, and PHENIX Collaborations ($\sqrt{s_{NN}} = 130$ GeV). The bottom plot includes fits to $A/\sqrt{m_T}$ for each energy region. The data are for π^- results except for the NA44 results, which are for π^+.

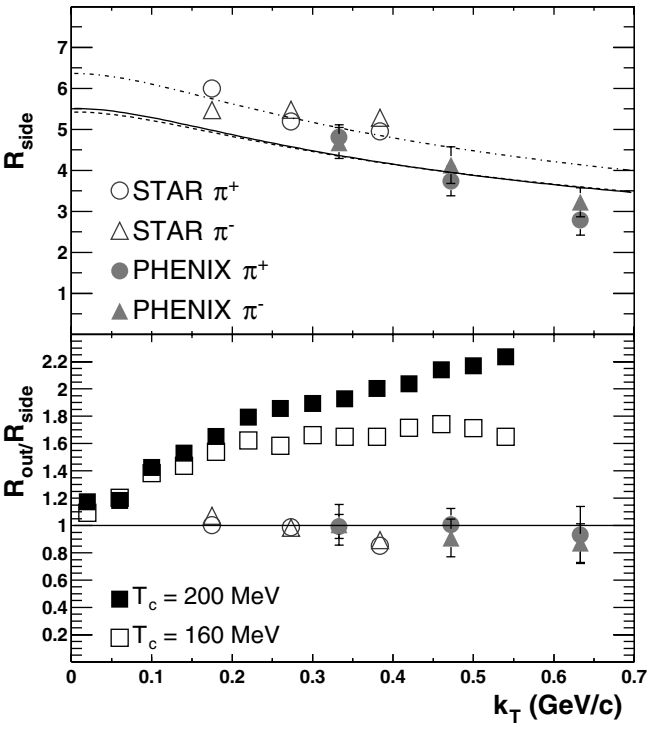

FIG. 3. The top panel shows the measured $R_{\rm side}$ from identical pions for STAR and PHENIX. The solid line is a fit of Eq. (3) to the PHENIX data, and the dashed line is the same fit for Eq. (2). The dot-dashed line is a fit of Eq. (3) to the STAR data. The bottom panel shows the ratio $R_{\rm out}/R_{\rm side}$ as a function of k_T overlayed with theoretical predictions for a phase transition for two critical temperatures.

TABLE I. The k_T dependencies of the π^+ and π^- radii in the LCMS and PCMS frames. All momenta are in MeV and all radii are in fm. The errors are statistical only.

	k_T (MeV)	200–400	400–550	550–1000
	$\langle k_T \rangle$	333	472	633
π^+	$R_{\rm inv}$	6.74 ± 0.31	6.42 ± 0.46	3.46 ± 0.46
	$\lambda_{\rm LCMS}$	0.423 ± 0.037	0.389 ± 0.039	0.287 ± 0.048
	$R_{\rm long}$	6.01 ± 0.45	4.76 ± 0.35	2.97 ± 0.38
	$R_{\rm side}$	4.81 ± 0.30	3.74 ± 0.36	2.79 ± 0.37
	$R_{\rm out}$	4.78 ± 0.30	3.76 ± 0.26	2.59 ± 0.46
	$R_{\rm out}^{\rm PCMS}$	11.35 ± 0.69	12.20 ± 1.02	8.60 ± 1.13
π^-	$R_{\rm inv}$	6.00 ± 0.30	5.96 ± 0.41	4.58 ± 0.48
	$\lambda_{\rm LCMS}$	0.431 ± 0.079	0.405 ± 0.067	0.353 ± 0.062
	$R_{\rm long}$	5.69 ± 0.76	4.77 ± 0.49	3.76 ± 0.41
	$R_{\rm side}$	4.67 ± 0.38	4.13 ± 0.45	3.22 ± 0.35
	$R_{\rm out}$	4.69 ± 0.58	3.75 ± 0.40	2.81 ± 0.34
	$R_{\rm out}^{\rm PCMS}$	11.27 ± 0.72	12.42 ± 1.18	11.89 ± 1.73

of the ratio $R_{\rm out}/R_{\rm side}$ for PHENIX and STAR along with recent calculations for a thermalized source which undergoes a first order phase transition at critical temperatures (T_c) of 160 and 200 MeV [20]. The rise in $R_{\rm out}/R_{\rm side}$ which comes predominantly from a hadronic rescattering phase is not present in the data, and the values of 1.6 ($T_c = 160$ MeV) and 2.2 ($T_c = 200$ MeV) at high k_T are excluded.

An additional consequence of strong dynamics occurs for sources in which the transverse expansion is relativistic. In this case, $R_{\rm out}$ measured in the LCMS frame is Lorentz contracted by the γ of the pion source velocity along the direction of $q_{\rm out}$ [30,31]. Current Lorentz invariant formulations of the correlation function [14,32] are insufficient to determine the source velocity due to transverse expansion; however, the pair center-of-mass system (PCMS) can be used to provide an upper limit on $R_{\rm out}$ [33]. The correlation function for π^- pairs in the PCMS frame is shown in the bottom panels of Fig. 1, and fit results for $R_{\rm out}^{\rm PCMS}$ are listed in Table I. As expected, $R_{\rm side}$ and $R_{\rm long}$ are equal to the corresponding LCMS parameters within errors.

Two analytic expressions have been used to describe $R_{\rm side}$ as a function of $m_T = \sqrt{k_T^2 + m_\pi^2}$ for a transversely expanding source,

$$R_{\rm side}^2(m_T) = \frac{R_{\rm geom}^2}{1 + \beta_f^2(\frac{m_T}{T})}, \qquad (2)$$

$$R_{\rm side}^2(m_T) = \frac{R_{\rm geom}^2}{1 + \eta_f^2(\frac{1}{2} + \frac{m_T}{T})}. \qquad (3)$$

Equation (2) is a first order approximation in $\frac{T}{m_T}$ for a longitudinally boost invariant source with finite temperature, T, and expansion velocity, $\beta_T = \beta_f \rho / R_{\rm geom}$, where $R_{\rm geom}$ is the Gaussian transverse radius [14]. Equation (3) includes an additional term in the approximation and the linear transverse expansion velocity is replaced by a transverse rapidity, $\eta_T = \eta_f \rho / R_{\rm geom}$ [16]. For a transverse surface rapidity of $\eta_f = 0.85$ ($\beta_f = 0.69$) and $T = 125$ MeV [34], a fit of Eq. (3) to the PHENIX $R_{\rm side}$ m_T dependence yields $R_{\rm geom} = 8.1 \pm 0.3$ fm with a $\chi^2/{\rm d.o.f.} = 9.6/6$. To assess systematic errors the PHENIX data are also fit to Eq. (2), yielding $R_{\rm geom} = 6.7 \pm 0.2$ fm and $\chi^2/{\rm d.o.f.} = 9.1/6$, and the STAR data are fit to Eq. (3), yielding $R_{\rm geom} = 9.4 \pm 0.1$ fm with $\chi^2/{\rm d.o.f.} = 21/6$. These fits are shown in the top panel of Fig. 3. All values of $R_{\rm geom}$ are significantly larger than the comparable 1D rms radius for a Au nucleus [35] of $\sqrt{1/3} \times \sqrt{3/5} \times 6.87 = 3.07$ fm.

In conclusion, we have extended the measurement of two particle correlations for Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV to $\langle k_T \rangle = 0.63$ GeV/c using the PHENIX detector at RHIC. Values of $R_{\rm out}^{\rm PCMS}$ are used to constrain the Lorentz effects for a relativistic transverse expansion. Fitting $R_{\rm side}(k_T)$ to two analytic expressions for an expanding source yields a transverse geometric radius that is much larger than the comparable radius for Au. We find that $R_{\rm long}(k_T)$ increases monotonically with collision energy, yet no energy dependence is discernible in the k_T dependence of $R_{\rm out}$ and $R_{\rm side}$, and the ratio, $R_{\rm out}/R_{\rm side}$, is consistent with unity and independent of k_T. The results for the transverse radii are contrary to common expectations for a first order phase transition in Au + Au collisions at these energies, as demonstrated by the comparison to a typical hydrodynamic model with hadronic rescattering. Therefore, we conclude that current concepts regarding the space-time evolution of the pion source inferred from two-pion correlations in Au + Au collisions at RHIC will need to be revised.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. [33] Here the radii are Lorentz *extended* by γ_s measured in the PCMS frame. For a toy model of an azimuthally symmetric source in motion but not expanding, $R_{\rm out}^{\rm PCMS} = \gamma_s\sqrt{R_{\rm side}^2 + \beta_s^2\tau^2}$.
[34] These values are taken from fits to the single particle spectra for the 5%–15% centrality bin for a linear velocity profile in a hard sphere. For a linear transverse rapidity in a Gaussian source these values vary by less than 2%.

(Received 17 December 2001; published 28 May 2002)

Identified $\pi^{+/-}$, $K^{+/-}$, p, and $\overline{p}$ transverse momentum spectra at midrapidity in $\sqrt{s_{NN}} = 130$ GeV Au + Au collisions were measured by the PHENIX experiment at RHIC as a function of collision centrality. Average transverse momenta increase with the number of participating nucleons in a similar way for all particle species. Within errors, all midrapidity particle yields per participant are found to be increasing with the number of participating nucleons. There is an indication that $K^{+/-}$, p, and $\overline{p}$ yields per participant increase faster than the $\pi^{+/-}$ yields. In central collisions at high transverse momenta ($p_T \gtrsim 2$ GeV/c), $\overline{p}$ and p yields are comparable to the $\pi^{+/-}$ yields.

DOI: 10.1103/PhysRevLett.88.242301 PACS numbers: 25.75.Dw

We report first results on identified $\pi^{+/-}$, $K^{+/-}$, p, and $\overline{p}$ production as a function of collision centrality in $\sqrt{s_{NN}} = 130$ GeV Au + Au collisions, measured by the PHENIX experiment at the Relativistic Heavy Ion Collider (RHIC). The PHENIX objective is to search for signatures of deconfinement and chiral symmetry restoration and to study the transition from normal to deconfined nuclear matter by utilizing a wide variety of probes.

Early RHIC results show that the transverse energy density and particle multiplicities are considerably higher than previously observed in relativistic heavy-ion collisions [1,2]. Measured energy densities extend into the region predicted to be favorable for the formation of a quark-gluon plasma [3]. Identified hadron spectroscopy provides a tool for studying reaction dynamics beyond that of global event characterization. The yields of hadrons reflect the particle production mechanism, while spectral shapes are sensitive to the dynamical evolution of the system. The mass and centrality dependence of the spectra can help differentiate between competing theoretical descriptions such as collective hydrodynamical expansion [4,5] or transverse momentum (p_T) broadening in the partonic

stage of the reaction [6]. Additionally the relative yields of baryons and mesons at high $p_T (\simeq 2\ \mathrm{GeV}/c)$ may give insight into baryon number transport [7] and the interplay between soft and hard processes.

The PHENIX detector has diverse particle identification (PID) capabilities [8], including excellent hadron identification over a broad momentum range. This measurement was performed using a portion of the east central-arm spectrometer, covering pseudorapidity $|\eta| < 0.35$ and $\Delta\phi = \pi/4$ in azimuthal angle.

The collision z-vertex and the timing system's start signal are generated by the Beam-Beam Counters (BBC), two arrays of quartz Cherenkov radiators which surround the beam axis covering $\eta = \pm(3.0 - 3.9)$. The tracking system includes a multilayer focusing drift chamber (DC) located outside an axially symmetric magnetic field at a radial distance between 2.0 and 2.4 m followed by a multiwire proportional chamber with pixel-pad readout (PC1) [9]. Pattern recognition in the DC is based on a combinatorial Hough transform in the track bend plane [10]. The polar angle of the track is determined by PC1 and the collision z vertex. A track model based on a field-integral lookup table determines the charged particle momentum and the path length to the time-of-flight (TOF) wall. The momentum resolution is $\delta p/p \simeq 0.6\% \oplus 3.6\% p$ (GeV/c).

The timing system's stop signal for each particle is measured by the TOF scintillator wall, located at a radial distance of 5.06 m, resulting in a flight-time measurement with a resolution of $\sigma \simeq 115$ ps. Reconstructed tracks are projected to the TOF and matched with hits in the scintillator slats using a momentum-dependent search window determined by multiple scattering and the momentum resolution. A velocity dependent energy loss cut based on a Bethe-Bloch parametrization is applied to the measured TOF pulse height. Combining the momentum and flight time, we reconstruct the particle mass and select particles by applying 2σ momentum dependent cuts in mass squared.

Corrections for geometrical acceptance, decay-in-flight, momentum resolution and reconstruction efficiency are determined using a single-particle full GEANT Monte Carlo (MC) simulation. The acceptance correction assumes that the spectra are flat in azimuth and in rapidity for $|y| < 0.5$ [11]. Fiducial area cuts, energy loss, and hit-track matching cuts are applied consistently in simulation and data. In peripheral events the track reconstruction efficiency is $\approx$98%. As the centrality increases, the efficiency is reduced due to the increased detector occupancy. Multiplicity dependent corrections are obtained by embedding simulated tracks into real events. Track-by-track corrections are applied taking into account the event centrality and the particle species. The efficiency for $\pi^{+/-}$ in the most central events is $\approx(68 \pm 6)\%$, independent of momentum. In the case of overlapping hits in the TOF wall, the earliest pulse reaching each photomultiplier is recorded. This favors the faster particles; hence, in central events heavier particles suffer an additional reconstruction inefficiency of $\approx$4%. Corrections for feed-down from weak decays are not applied. A MC simulation is used to estimate the probability for reconstructing protons from Λ decays as prompt protons. Within the PHENIX acceptance this probability is $\approx$50% at $p_T = 0.5$ GeV/c, $\approx$32% at $p_T = 1$ GeV/c, and $\approx$12% at $p_T \geq 2$ GeV/c. Taking $\frac{\Lambda}{p} = 1$ as an upper limit, we estimate 33% as the upper limit of weak decay contribution to the reported p and $\overline{p}$ yields and maximal 16% change of measured $\langle p_T \rangle$.

About 140 000 minimum bias events, representing $92\% \pm 4\%$ of the total inelastic cross section of 6.8 b [1] were analyzed. This sample was subdivided into five centrality classes: 0%–5%, 5%–15%, 15%–30%, 30%–60%, and 60%–92%, using the BBC and zero-degree calorimeters for event characterization [1]. For each class, the average number of nucleons participating in the collision (N_{part}) is obtained from a Glauber model calculation [12].

Figure 1 shows the invariant yield as a function of p_T for π^+, K^+, p (left panel) and π^-, K^-, $\overline{p}$ for three centrality selections. Error bars in the figure are the combined statistical errors in the data and the corrections. Systematic uncertainties from acceptance, multiplicity-dependent efficiency corrections, and PID cuts result in an overall systematic error in the absolute normalization of $\approx$11% for all species. As a consistency check, we have added all identified charged hadron spectra in the

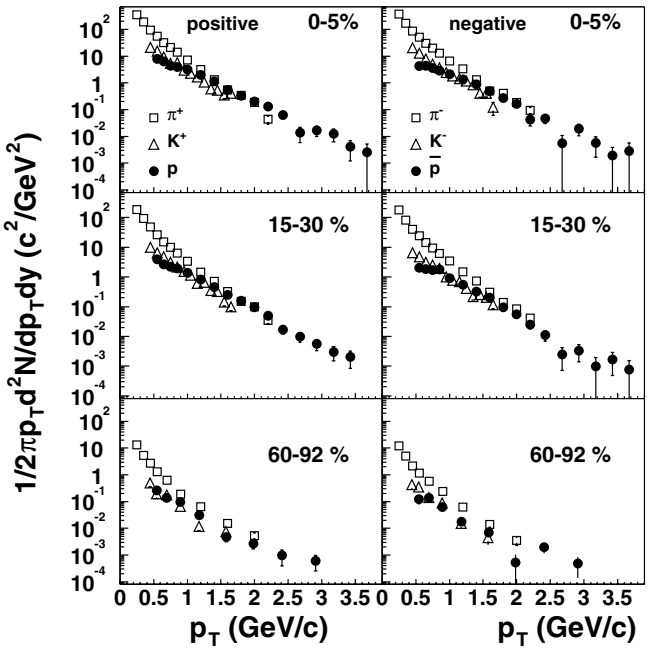

FIG. 1. Transverse momentum spectra measured at midrapidity for π^+, K^+, p (left) and π^-, K^-, $\overline{p}$ at the three different centrality selections indicated in each panel. The symbols indicated in the top panels apply for all centrality selections.

p_T region where PID is available for all species and compared to the PHENIX charged hadron measurement [12]. The results agree to better than 10% for all centralities. Additionally, the PHENIX π^0 spectra [12] and the $\pi^{+/-}$ spectra in the region of overlapping p_T are within ≈10% for the central and ≈25% for the peripheral selections, which is within the systematic errors of the two measurements. $\overline{p}$ results presented here are also in agreement (within errors) with a recent STAR publication [13].

In peripheral events the $\pi^{+/-}$ spectra exhibit a concave shape, well described by a power-law parametrization as observed in hadron-hadron collisions [14]. With increasing centrality the curvature in the spectra decreases, leading to an almost exponential dependence on p_T for the most central events. Over the measured p_T range, the $K^{+/-}$ spectra can be described by an exponential distribution either in p_T or in $m_T = \sqrt{p_T^2 + m^2}$, while the p and $\overline{p}$ spectra can be described either as a Boltzmann or an exponential distribution in m_T. The slopes of the m_T spectra flatten and the mean transverse momentum ($\langle p_T \rangle$) increases with particle mass and with centrality. This behavior has been previously observed in lower energy heavy ion collisions at the BNL-AGS [15] and at the CERN-SPS [16,17] and was attributed to collective radial motion (flow).

At lower energies, it is not uncommon for the proton yields to equal or exceed the π^+ yields, since many of the protons come from the initial state. A new feature observed for the first time at RHIC is that in central collisions at $p_T \approx 2$ GeV/c the $\overline{p}$ yields are comparable to the π^- yields. Positive and negative hadrons behave in a similar way. In central events the proton yields approach the π^+ spectra around $p_T \simeq 1.6$ GeV/c. As the centrality decreases, this happens at larger p_T. In peripheral events, p and $\overline{p}$ spectra are below the $\pi^{+/-}$ spectra over the whole measured p_T range. Since antiprotons are not as numerous as the protons, $\overline{p}$ and π^- yields become comparable only at the high end of the measured pion p_T range in the most central collisions. We note that in pp [18] and $p\overline{p}$ [19] collisions at $\sqrt{s} = 23$–63 GeV and $\sqrt{s} = 300$–1800 GeV, respectively, the $\overline{p}/\pi^-$ ratio steadily increases with p_T up to $\simeq 0.33$ at $p_T \simeq 1.5$ GeV/c nearly independent of $\sqrt{s}$. Data on baryon/meson ratios at higher p_T are available only from pp collisions at ISR energies ($\sqrt{s} = 23$–63 GeV) and show that above $p_T \simeq 1.5$ GeV/c the $\overline{p}/\pi^-$ ratio rises to $\simeq 0.4$ at $p_T \simeq 2$ GeV/c and then drops, as expected if valence quark jet fragmentation is the dominant production mechanism for high p_T hadrons. In central collisions at RHIC the high p_T (anti)proton/pion ratios are ∼1—much larger than in pp collisions.

Hydrodynamic calculations with fixed freeze-out temperature [5] or with freeze-out modeled using a hadronic cascade [4] suggest that hydrodynamic expansion is responsible for the baryon dominance at high p_T. However, protons/antiprotons produced via a baryon junction mechanism combined with jet quenching in the pion channel are shown to exhibit the same effect [7]. Intrinsic p_T broadening in the partonic phase caused by gluon saturation [6] gives yet another alternative explanation. The above models have similar predictions in the p_T range measured here, but show different behavior at higher p_T. New data with broader p_T range is needed in order to distinguish between currently available theories.

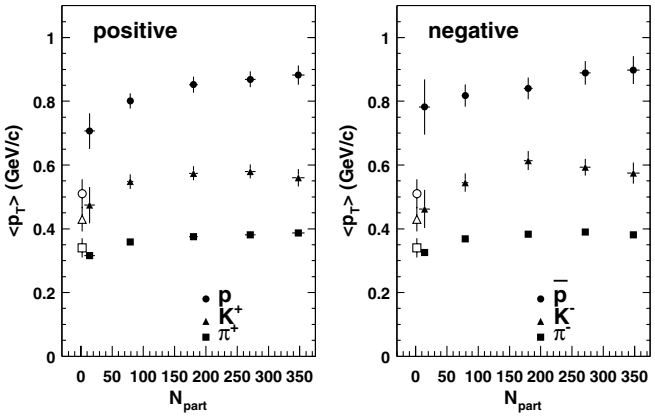

FIG. 2. Average transverse momentum for π^+, K^+, p (left) and π^-, K^-, $\overline{p}$ as a function of the number of nucleons participating in the collision $N_{\rm part}$. The error bars represent the statistical errors. The systematic errors are discussed in the text. The open points are interpolations from pp and $p\overline{p}$ data; see text for details.

To quantify the centrality and mass dependencies of hadron production, we determine the mean ($\langle p_T \rangle$ shown in Fig. 2) and the integral (dN/dy shown in Fig. 3) of the p_T distributions. Both quantities require extrapolation of the spectra below and above the measured range. For each particle species, we use at least two functional forms consistent with the data, as outlined above, and the results presented are averaged between two fits. The frac-

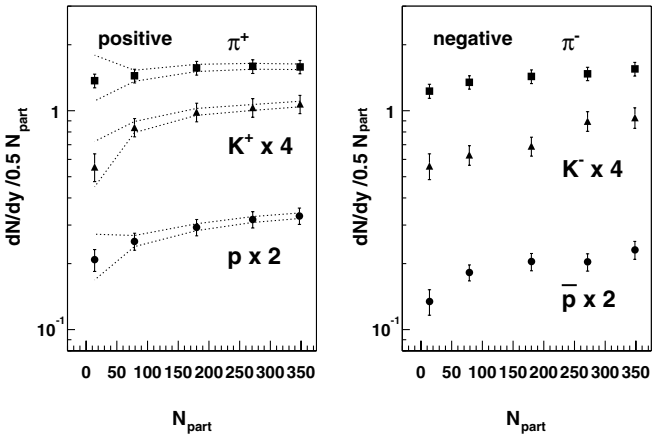

FIG. 3. $dN/dy_{|y=0}$ per participant for π^+, K^+, p (left) and π^-, K^-, $\overline{p}$ as a function of $N_{\rm part}$. The error bars include statistical and systematic errors in dN/dy. The dashed lines around the positive hadrons show the effect of the systematic error on $N_{\rm part}$ which affects all curves in the same way.

TABLE I. Integrated hadron ($\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$) yields at midrapidity for five centrality classes (see text) identified by the indicated number of participants $N_{\rm part}$. The errors on $N_{\rm part}$ are the systematic errors. The errors listed for $\langle dN/dy_{|y=0}\rangle$ are statistical. The systematic errors are 13%, 15%, and 14% for $\pi^{\pm}$, $K^{\pm}$, p, and $\overline{p}$, respectively.

$N_{\rm part}$	348 ± 10.0	271 ± 8.4	180 ± 6.6	79 ± 4.6	14 ± 3.3
π^+	276 ± 3	216 ± 2	141 ± 1.5	57 ± 0.6	9.6 ± 0.2
π^-	270 ± 3	200 ± 2	129 ± 1.4	53.3 ± 0.6	8.6 ± 0.2
K^+	46.7 ± 1.5	35.0 ± 1.3	22.2 ± 0.8	8.3 ± 0.3	0.97 ± 0.11
K^-	40.5 ± 2.3	30.4 ± 1.4	15.5 ± 0.7	6.2 ± 0.3	0.98 ± 0.1
p	28.7 ± 0.9	21.6 ± 0.6	13.2 ± 0.4	5.0 ± 0.2	0.73 ± 0.06
$\overline{p}$	20.1 ± 1.0	13.8 ± 0.6	9.2 ± 0.4	3.6 ± 0.1	0.47 ± 0.05

tion of the yield in the extrapolated regions is estimated to be 30% ± 6% for $\pi^{+/-}$, 40% ± 8% for $K^{+/-}$, and 25% ± 7.5% for $p/\overline{p}$. Combining systematic uncertainties in the extrapolation fractions and the estimated background under mass-squared peaks (2%, 5%, and 3%) yield systematic uncertainties in the measured $\langle p_T\rangle$ of 7%, 10%, and 8% for $\pi^{+/-}$, $K^{+/-}$, and $p/\overline{p}$, respectively. Further combining the above uncertainties, which affect only the shape of the spectra, with the 11% uncertainty in the absolute normalization gives systematic uncertainties of 13%, 15%, and 14% in the measured dN/dy for $\pi^{+/-}$, $K^{+/-}$, and $p/\overline{p}$, respectively. We note that after converting to $dN/d\eta$, the sum of the identified charged hadron yields agrees with the previously published PHENIX results on total charged multiplicity $dN_{ch}/d\eta$ [1] within 5%.

Figure 2 shows the $\langle p_T\rangle$ as a function of $N_{\rm part}$ for π^+, K^+, p (left panel) and π^-, K^-, $\overline{p}$. Filled points are this measurement; open points at $N_{\rm part} = 2$ are interpolations to $\sqrt{s} = 130$ GeV obtained from pp and $p\overline{p}$ data at lower [18] and higher energies [19], respectively. In peripheral Au-Au collisions at RHIC $\pi^{+/-}$ and $K^{+/-}$ exhibit similar $\langle p_T\rangle$ to those in pp collisions, but protons and antiprotons have significantly higher $\langle p_T\rangle$, indicating that nuclear effects are important even at small $N_{\rm part}$. For all measured particle species, $\langle p_T\rangle$ increases by ≈12%–14% from the first to the second centrality bin (i.e., $N_{\rm part} = 14$ to 79). Above $N_{\rm part} = 100$ the pion and kaon average momentum appears to saturate, whereas for p and $\overline{p}$ it rises slowly. However, we note that going from peripheral to the most central event class the overall increase in $\langle p_T\rangle$ is ≈20% ± 5% independent of particle species.

Figure 3 shows the yields per participant versus $N_{\rm part}$. Error bars include statistical and multiplicity dependent systematic errors. Systematic uncertainties in $N_{\rm part}$ that can move all curves independent of mass are shown with bands around the positive hadron points. Total systematic uncertainties in $N_{\rm part}$ and the yields at each $N_{\rm part}$ are listed in Table I.

For all particle species, the yield per participant increases with $N_{\rm part}$. As for $\langle p_T\rangle$, most of the increase occurs between the two most peripheral centrality selections (i.e., $N_{\rm part} = 14$ to 79). However, in contrast with the centrality dependence of $\langle p_T\rangle$, we see an indication that the total increase in the yields per participant differs among particle species as we go from peripheral to central events. The pion yield per participant rises by 21% ± 6%(stat) ± 8%(syst). The kaon yields per participant rise faster: 94% ± 11%(stat) ± 26%(syst) and 66% ± 12%(stat) ± 20%(syst), for K^+ and K^-, respectively. Similar trends in the centrality dependence of strangeness production have been observed in lower energy heavy-ion collisions at the BNL-AGS [20] and at the CERN-SPS [17]. It is interesting to note that at RHIC p and $\overline{p}$ yields per participant behave similarly to the $K^{+/-}$ yields and also rise faster than the pions with increasing $N_{\rm part}$. The increase is 58% ± 5%(stat) ± 16%(syst) and 72% ± 9%(stat) ± 20%(syst), respectively. The similar centrality dependence in p and $\overline{p}$ yields per participant indicates that baryon/antibaryon pair production is the dominant source of protons and antiprotons alike.

In heavy-ion collisions at AGS energies [21] the $\overline{p}$ production is close to threshold, the yields per participant are lower than in pp collisions, and they decrease from peripheral to central collisions, probably due to annihilation. At the SPS, the $\overline{p}$ yield per participant is larger than the pp value and has almost no centrality dependence [22]. At RHIC, the total yield of antiprotons at midrapidity in central Au-Au collisions is a factor of ≃1000 larger than at the AGS [23] and nearly an order of magnitude above that in Pb + Pb collisions at CERN [24]. Most of the increase is due to the $\sqrt{s}$ dependence of baryon/antibaryon pair production; however, the yield per participant rises noticeably from peripheral to central collisions.

In conclusion, an intriguing new behavior in identified hadron production at RHIC is reported. In central Au-Au collisions the antiprotons yield is comparable to the π^- at high p_T—a behavior never observed before in elementary or in heavy-ion collisions. $\langle p_T\rangle$ rises with centrality similarly for all particle species, while $K^{+/-}$, p, and $\overline{p}$ yields per participant increase somewhat faster than the $\pi^{+/-}$ yields.

Suppression of Hadrons with Large Transverse Momentum in Central Au + Au Collisions at $\sqrt{s_{NN}} = 130$ GeV

(Received 5 September 2001; published 21 December 2001)

Transverse momentum spectra for charged hadrons and for neutral pions in the range 1 GeV/c < p_T < 5 GeV/c have been measured by the PHENIX experiment at RHIC in Au + Au collisions at $\sqrt{s_{NN}}$ = 130 GeV. At high p_T the spectra from peripheral nuclear collisions are consistent with scaling the spectra from $p + p$ collisions by the average number of binary nucleon-nucleon collisions. The spectra from central collisions are significantly suppressed when compared to the binary-scaled $p + p$ expectation, and also when compared to similarly binary-scaled peripheral collisions, indicating a novel nuclear-medium effect in central nuclear collisions at RHIC energies.

DOI: 10.1103/PhysRevLett.88.022301 PACS numbers: 25.75.Dw

Ultrarelativistic heavy ion collisions provide the opportunity to study strongly interacting matter at high temperature and density. At Brookhaven National Laboratory's Relativistic Heavy Ion Collider (RHIC), nuclei as heavy as gold (Au) are accelerated to energies of $\sqrt{s_{NN}}$ = 200 GeV per nucleon-nucleon pair. In the early stages of a central collision, energy densities are expected to be sufficient to dissolve normal nuclear matter into a phase of deconfined quarks and gluons, the "quark gluon plasma" (QGP). The PHENIX experiment is designed to investigate nuclear collisions with a wide variety of probes, focusing primarily on those produced in the early stages of the collision.

Of particular interest are the products of parton scatterings with large momentum transfer ("hard scatterings"). In $p + p$ collisions hard-scattered partons fragment into jets of hadrons; these fragments are the primary source of hadrons at high transverse momentum (p_T), typically above ~2 GeV/c [1]. In a high-energy nuclear collision hard scattering will occur at the earliest time during the collision, well before the QGP is expected to form, and thus the scattered partons will subsequently experience the

strongly interacting medium created in the collision. These partons are expected to lose energy [2] in hot and dense nuclear matter through gluon bremsstrahlung, effectively quenching jet production. This would have many observable consequences, of which the most directly measurable would be a depletion in the yield of high p_T hadrons [3]. It has been suggested that the energy loss is larger in a medium of deconfined color charges than in hadronic matter [4], making "jet quenching" a potential signature for QGP formation.

To quantify such modifications we need a baseline expectation for spectra from nuclear ($A + A$) collisions in the absence of nuclear medium effects. Given that hard parton scatterings have small cross sections, one can regard the nuclei as an incoherent superposition of partons ("point-like scaling"). We approximate this by modeling the $A + A$ collision as a sum of independent nucleon-nucleon ($N + N$) collisions ("binary scaling"). For a given class of $A + A$ collisions, we can determine $\langle N_{\rm binary}\rangle$ the average number of inelastic $N + N$ collisions per event and then define the *nuclear modification factor* as the ratio,

$$R_{AA}(p_T) = \frac{(1/N_{\rm evt})d^2N^{A+A}/dp_T\,d\eta}{(\langle N_{\rm binary}\rangle/\sigma_{\rm inel}^{N+N})d^2\sigma^{N+N}/dp_T\,d\eta}. \quad (1)$$

In the absence of nuclear modifications to hard scattering, the ratio R_{AA} will be unity; thus departures from $R_{AA} = 1$ indicate nuclear medium effects. Previous measurements indicate that for p_T below 2 GeV/c, R_{AA} is smaller than one since the bulk of particle production scales with the number of nucleons participating in the reaction [5,6]. For p_T above 2 GeV/c particle production in $p + A$ collisions is enhanced compared to binary scaling, commonly referred to as the "Cronin effect" [7]. Parton shadowing as measured in lepton + A collisions [8] is also expected to modify the hadron spectra in $p + A$ and $A + A$ compared to binary scaling.

We examine high-p_T spectra of charged hadrons and neutral pions measured by the PHENIX experiment [9,10] in a central and a peripheral class of Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV. These data are obtained with the central spectrometer, which consists of two arms, "east" and "west," each covering $\Delta\phi = 90°$ and $|\eta| < 0.35$. The arms are positioned outside an axially symmetric magnetic field centered around the beam axis.

Charged particles are reconstructed using a drift chamber (DC) and two layers of multiwire proportional chambers with pad readout (PC1, PC3) in the east arm. The DC measures the particle trajectories between 2.0 and 2.4 m radius in the plane perpendicular to the beam axis. A matching hit in PC1 at ~2.5 m, together with location of the collision vertex, fixes the polar angle. Particle momenta are determined with a resolution of $\delta p/p \simeq 0.6\% \oplus 3.6\%\ p$ (GeV/c). The absolute momentum scale is known to better than 2%. Trajectories are confirmed by requiring a matching hit within a $\pm 2\sigma$ window (about 2.5 cm) in PC3 at a radius of 5 m, which eliminates nearly all secondary tracks from decays and interactions in material. The remaining background is due primarily to accidental associations. The level of background to signal is negligible below $p_T < 2$ GeV/c, rises to 1/10 at 3.5 GeV/c, and reaches 1/1 at 6 GeV/c. This background is measured statistically, by swapping the z coordinate of the PC3 hits, and subtracted from the yield.

Corrections for acceptance, reconstruction efficiency, decays in flight, momentum resolution, and dead areas are determined using a full GEANT simulation. Simulated single particles are embedded in real events to model the effect of detector occupancy. In peripheral Au + Au collisions the track reconstruction efficiency exceeds 98%, while it is reduced to 68 ± 6% for central collisions, independent of momentum. Corrections due to finite momentum resolution are negligible at low p_T and rise to the level of 30% at 5 GeV/c. The systematic errors (Table I) are dominated by the uncertainty in the Monte Carlo description of the detector, including the dead areas and the momentum resolution.

Neutral pions are measured via their $\pi^0 \to \gamma\gamma$ decay. Two separate analyses are performed, the first using a lead-scintillator (PbSc) sampling calorimeter in half ($\Delta\phi = 45°$) of the west arm aperture and the second with a lead-glass Cerenkov (PbGl) calorimeter in a quarter ($\Delta\phi = 22.5°$) of the east arm aperture. The two analyses have very different systematics, and Fig. 1 shows the agreement of their final π^0 spectra.

In both analyses, pairs of calorimeter showers are binned in pair p_T and invariant mass $m_{\gamma\gamma}$. The energy scale is verified using both the π^0 mass and E/p ratio for identified

TABLE I. Relative systematic errors on hadron yields and central-to-peripheral ratios. The errors are quoted for representative p_T and vary between the values shown. For the charged hadron (h) data the errors are highly correlated in p_T for both yields and ratios. For the π^0 data, approximately half of the error in the yield is perfectly correlated in p_T, and some correlation remains in the ratio.

Sys. error	Yield	p_T (GeV/c)	Cent/Per	p_T (GeV/c)
h data	27%	0.5	8%	all
	16%–18%	0.8-3.5		
	30%	4.7		
π^0 data	25%	1.2	24%	1.2
(PbSc)	35%	3.7	33%	3.2
π^0 data	33%	1.2	32%	1.2
(PbGl)	52%	3.7	40%	2.7
π^0 data	21%	1.2	20%	1.2
(Combined)	30%	3.7	24%	2.7
$N + N$ ref.	20%	1.0	N/A	
	35%	5.0		
$\langle N_{\rm binary}\rangle$			29%	all
Central	11%	all		
Peripheral	30%	all		

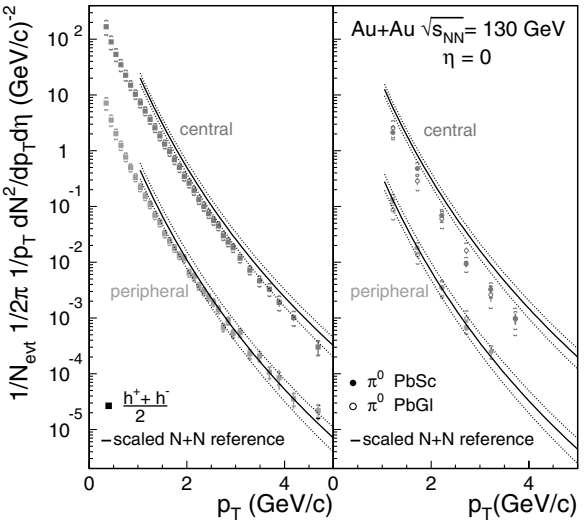

FIG. 1. The yields per event at mid-rapidity for charged hadrons (left) and neutral pions (right) are shown as a function of p_T for 60%–80% (lower) and 0%–10% (upper) event samples. The error bars indicate the statistical errors on the yield; the surrounding brackets indicate the systematic errors. Also shown are the $N + N$ references for charged hadrons and neutral pions, each scaled up by $\langle N_{\text{binary}} \rangle$ for the class. The bands indicate the uncertainty in the $N + N$ reference and in the $\langle N_{\text{binary}} \rangle$.

electrons and is known to $<1.5\%$ [11]. Hadron-induced showers are suppressed with arrival time and shower shape cuts. The combinatorial pair background is estimated by mixing showers from different events with similar centrality. The mixed $m_{\gamma\gamma}$ distribution is subtracted from the true distribution after being normalized in a region outside the π^0 mass peak. The π^0 yield in each p_T bin is determined by integrating the subtracted $m_{\gamma\gamma}$ distribution in a window determined by a Gaussian fit to the π^0 peak.

The π^0 spectra are corrected for losses due to energy resolution, cluster overlaps, analysis cuts, dead detector areas, and acceptance. Smearing of the photon energy due to resolution and cluster overlaps is used to simulate the $m_{\gamma\gamma}$ peak at each p_T, which agrees with that seen in the data. To estimate the π^0 reconstruction efficiency, the same cuts are applied to the simulated $m_{\gamma\gamma}$ distributions as applied to the real data.

Contributions to the yield from pions not originating from the vertex are estimated by GEANT simulation to be 6%–8%. The dominant sources of error are the uncertainty in the particle identification, the effect of energy smearing, and the peak extraction procedure. Their relative contributions to the total errors (see Table I) differ for the two analyses.

Event classification is provided by the combination of two beam-beam counters (BBC's) and two zero-degree calorimeters (ZDC's). We present data from two event samples, central and peripheral. The central sample covers the 0%–10% most central fraction of the geometrical Au + Au cross section, while the peripheral sample contains events in the 60%–80% selection. Using a Glauber model combined with a simulation of the BBC and ZDC responses [5], we estimate $\langle N_{\text{binary}} \rangle = 905 \pm 96$ for the central sample, $\langle N_{\text{binary}} \rangle = 20 \pm 6$ for the peripheral sample, and 45 ± 13 for the ratio between them. The errors include the uncertainties in the parameters used in the Glauber model [12], as well as in the fraction of the total geometrical cross section ($92\% \pm 4\%$) seen by the interaction trigger [13].

The p_T distributions for charged hadrons and neutral pions are shown for both centrality classes in Fig. 1. In this figure, those following, and Table I, the systematic errors shown are the quadrature sums of conservatively estimated limits on several independent errors and represent upper bounds on standard deviations. They are also substantially correlated between points.

The data are compared to the binary-scaled yield from $N + N$ collisions. Since no $N + N$ data exist at $\sqrt{s} = 130$ GeV, we parametrize the cross section $1/(2\pi p_T) d^2\sigma/d\eta\, dp_T$ for $(h^+ + h^-)/2$ as $A/(1 + p_T/p_0)^n$. We determine the parameters $A = 330$ mb/(GeV/c)^2, $p_0 = 1.72$ GeV/c, and $n = 12.4$ by interpolating between results from $p + p$ collisions at the ISR [14] and $\bar{p} + p$ collisions at the $Sp\bar{p}S$ [15] and the Tevatron [16]. The systematic error in the $N + N$ reference (Table I) is due to the error in the absolute normalization of the data used and in the interpolation technique. For neutral pions we scale the charged hadron cross section by the charged pion to charged hadron ratio π/h observed at the ISR [14]. This was found to be 0.63 ± 0.06 nearly independent of p_T above 1.5 GeV/c.

For $p_T > 2$ GeV/c the binary-scaling prediction agrees with the data from peripheral collisions for both charged and neutral particles, while for central collisions the data lie noticeably below the prediction. To examine this difference more directly, we plot the ratio R_{AA} for central collisions in Fig. 2. For the charged spectrum R_{AA} rises up to 2 GeV/c, as expected; but above 2 GeV/c, R_{AA} remains significantly below unity for both spectra.

The depletion is quite striking, since the production of high-p_T hadrons in $p + A$ collisions at fixed-target energies is known to be enhanced compared to the binary-scaling expectation for $p_T > 2$ GeV/c, i.e., the Cronin effect [7]. A similar enhancement has also been observed in heavy ion collisions at lower energies [17,18], as shown in Fig. 2. Phenomenological calculations [17] including shadowing and the Cronin effect predicted that for central Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV, $R_{AA} > 1$ for hadron spectra in the p_T range 3–9 GeV/c with a peak value of $R_{AA} \simeq 1.3$ at 4 GeV/c.

Above 2 GeV/c, R_{AA} is lower for pions than for charged hadrons, which implies that the π/h ratio is smaller in central RHIC Au + Au collisions than in ISR $p + p$ collisions. This is consistent with identified charged hadron spectra measured by PHENIX [19] for which a large yield of protons and antiprotons is observed at $p_T \sim 2$ GeV/c.

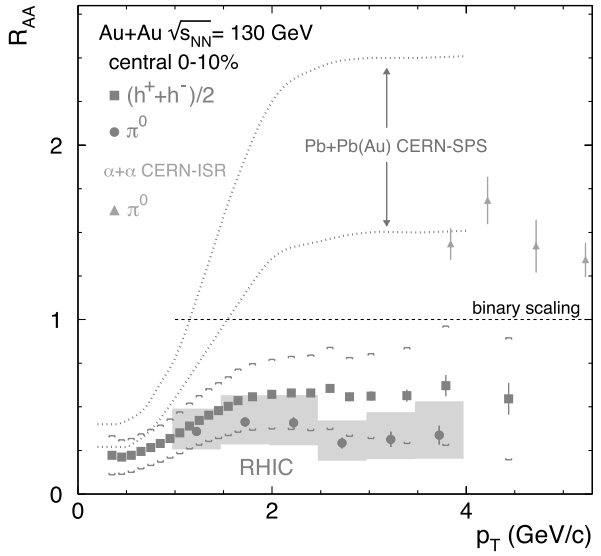

FIG. 2. The ratio R_{AA} for charged hadrons and neutral pions (weighted average of PbSc and PbGl results) in central Au + Au collisions. The error bars indicate the statistical errors on the measurement. The surrounding bands [shaded for π^0's, brackets for $(h^+ + h^-)/2$] are the quadrature sums of (i) the systematic errors on the measurement, (ii) the uncertainty in the $N + N$ reference, and (iii) the uncertainty in $\langle N_{\text{binary}} \rangle$. Also shown are the ratio of inclusive cross sections in $\alpha + \alpha$ compared to $p + p$ at $\sqrt{s_{NN}} = 31$ GeV [18], and spectra from central Pb + Pb, Pb + Au compared to $p + p$ collisions at $\sqrt{s_{NN}} = 17$ GeV [17] shown as a band indicating the range of uncertainty.

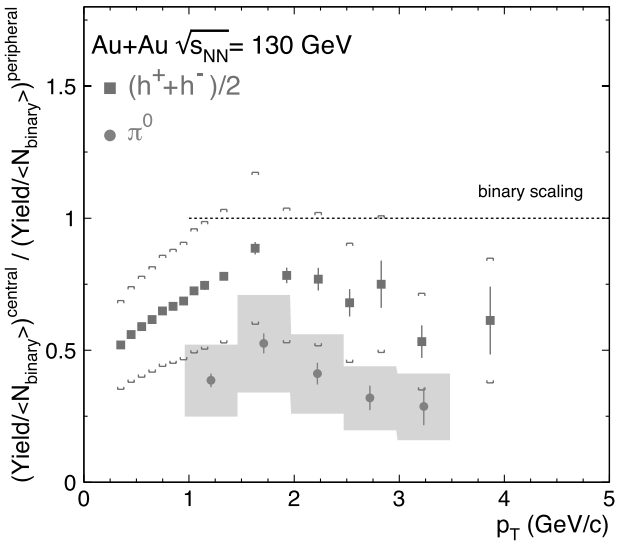

FIG. 3. Ratio of yield per event in central vs peripheral Au + Au collisions, with each divided by $\langle N_{\text{binary}} \rangle$ for that class. For π^0 the weighted average of PbSc and PbGl results is shown. The error bars indicate the statistical errors on the spectra. The surrounding bands [shaded for π^0's, brackets for $(h^+ + h^-)/2$] are the quadrature sums of (i) the parts of the systematic errors on the spectra that do not cancel in the ratio, and (ii) the uncertainty in $\langle N_{\text{binary}} \rangle$ (see Table I).

We can also examine the spectra from central collisions for modifications at high p_T by comparing them to the spectra from peripheral collisions after dividing each by the corresponding values of $\langle N_{\text{binary}} \rangle$. The central-to-peripheral ratio is a useful complement to R_{AA}, since it should be unity in the limit of point-like scaling. Many of the experimental uncertainties are reduced in this ratio (see Table I). Additionally, the uncertainty induced by the $p + p$ interpolation is eliminated, albeit at the expense of incurring that in $\langle N_{\text{binary}} \rangle$ for the peripheral class. We note that there may be effects from the centrality dependence of nuclear shadowing and/or the Cronin effect that would also be present in this comparison.

The central-to-peripheral ratios are plotted in Fig. 3. Like R_{AA} this ratio is below unity at all observed p_T for both charged hadrons and neutral pions, indicating a suppression of the yield per $N + N$ collision in central collisions relative to peripheral. The difference between the two ratios implies that the π/h ratio is smaller in central collisions than in peripheral.

We have presented spectra for charged hadrons and neutral pions measured at 90° from central and peripheral Au + Au collisions in the PHENIX experiment at RHIC. Above $p_T \sim 2$ GeV/c, the spectra from peripheral collisions appear to be consistent (albeit within a substantial systematic error) with a simple, incoherent sum of underlying $N + N$ collisions. The spectra from central collisions, in contrast, are systematically below the scaled $N + N$ expectation, when compared both to data from $p + p$ collisions and to spectra from Au + Au peripheral collisions. The suppression in central collisions is in qualitative agreement with the predictions of energy loss by scattered partons traversing a dense medium. However, other nuclear medium effects should be understood before a quantitative conclusion can be drawn. Measurements in $p + A$ at RHIC can help in this direction.

We thank the staff of the RHIC project, Collider-Accelerator, and Physics Departments at BNL and the staff of PHENIX participating institutions for their vital contributions. We acknowledge support from the Department of Energy and NSF (U.S.A.), Monbu-sho and STA (Japan), RAS, RMAE, and RMS (Russia), BMBF, DAAD, and AvH (Germany), FRN, NFR, and the Wallenberg Foundation (Sweden), MIST and NSERC (Canada), CNPq and FAPESP (Brazil), IN2P3/CNRS (France), DAE and DST (India), LG-YF, KRF, and KOSEF (Korea), and the U.S.-Israel Binational Science Foundation.

(Received 31 August 2001; published 17 May 2002)

Event-by-event fluctuations in the multiplicities of charged particles and photons, and the total transverse energy in 158*A* GeV Pb+Pb collisions are studied for a wide range of centralities. For narrow centrality bins the multiplicity and transverse energy distributions are found to be near perfect Gaussians. The effect of detector acceptance on the multiplicity fluctuations has been studied and demonstrated to follow statistical considerations. The centrality dependence of the charged particle multiplicity fluctuations in the measured data has been found to agree reasonably well with those obtained from a participant model. However, for photons the multiplicity fluctuations have been found to be lower compared to those obtained from a participant model. The multiplicity and transverse energy fluctuations have also been compared to those obtained from the VENUS event generator.

I. INTRODUCTION

Fluctuations in physical observables in heavy-ion collisions have been a topic of interest for some years as they may provide important signals regarding the formation of quark-gluon plasma (QGP) and help to address the question of thermalization [1]. With the large number of particles produced in heavy-ion collisions at Super Proton Synchrotron (SPS) and Relativistic Heavy-Ion Collider (RHIC) energies [2,3], it has now become feasible to study fluctuations on an event-by-event basis. Recently, several new methods have been proposed for the study of event-by-event fluctuations in various global observables to probe the nature of the QCD phase transition [4–7]. In a thermodynamical picture of a strongly interacting system formed in the collision, the fluctuations in particle multiplicities, mean transverse momenta ($\langle p_T \rangle$), and other global observables, are related to the fundamental properties of the system, such as the specific heat, chemical potential, and matter compressibility. These, in turn, lead towards understanding the critical fluctuations at the QCD phase boundary. The existence of a tricritical point at the QCD phase transition [4], which has lately been a topic of intense discussion, has been predicted to be associated with large event-by-event fluctuations in the above observables.

In a first-order phase transition scenario, it is believed that supercooling might lead to density fluctuations resulting in droplet formation and hot spots [8]. These might lead to rapidity fluctuations in the form of spikes and gaps in the rapidity distribution. The study of event-by-event fluctuations in the number of photons to charged particles has also been proposed as a means to search for production of disoriented chiral condensates (DCC) [9,10].

In nucleus-nucleus collisions the transverse energy E_T is an extensive global variable [11–13], which provides a direct measure of the violence of an interaction. E_T is produced by redirection of the longitudinal energy into transverse motion through interactions in which the interacting particles undergo multiple scatterings and approach thermalization. E_T is also an indicator of the energy density achieved in the collision. Since the energy density is directly related to the QGP phase transition, it is extremely important to study E_T and fluctuations in E_T. Moreover, it is interesting to compare the fluctuations of E_T to those observed in the particle multiplicities.

Much theoretical interest has been directed toward the subject of event-by-event fluctuations, motivated by the near perfect Gaussian distributions of $\langle p_T \rangle$ and particle ratios [14] measured at the SPS. For these Gaussian distributions, the variance or the width of the distributions contain information about the reaction mechanism as well as the nuclear geometry [4,15–17].

The relative fluctuation (ω_X) in an observable X can be expressed as:

$$\omega_X = \frac{\sigma_X^2}{\langle X \rangle}, \tag{1}$$

where σ_X^2 is the variance of the distribution and $\langle X \rangle$ denotes the mean value.

The value of ω_X that can be extracted from experimental data has contributions that originate both from trivial statistical effects as well as dynamical sources. To extract the dynamical part associated with new physics from the observed fluctuations, one has to understand the contributions from statistical and other known sources. Examples of known sources of fluctuations contributing to the observed experimental value of ω_X include finite particle multiplicity, effect of limited acceptance of the detectors, impact parameter fluctuations, fluctuations in the number of primary collisions, effects of rescattering of secondaries, resonance decays, and Bose-Einstein correlations. These sources of fluctuations, along with estimates of the ω_X contributions for each have been discussed by Stephanov *et al.* [4] and by Baym and Heiselberg [5].

In nucleus-nucleus (AA) collisions relative fluctuations in global observables have been found to be smaller compared to those in pp collisions. It is suggested that thermal equilibration in AA collisions makes the fluctuations small. However, the origin of fluctuations and hence the physical information content are quite different in pp and AA collisions. While in pp collisions one hopes to extract quantum mechanical information about the initial state from the event-by-event fluctuations in the final state, in heavy-ion collisions equilibration makes it difficult to achieve this goal, instead the basic aim here has been to relate the event-by-event fluctuations of the final state with the thermodynamic properties at freeze-out.

In this paper, we present fluctuations in the multiplicities of both charged particles and photons, and in the total transverse energy, over a large range of centralities as measured in the WA98 experiment at the CERN SPS. A major interest has been to search for fluctuations that have a new physical origin, such as those associated with QCD phase transition or from the formation of a DCC.

We compare the fluctuations observed in the experimental data for varying centrality conditions and rapidity intervals to those obtained from different models. In the following section the WA98 experimental setup is described. In Sec. III the criteria for the centrality selection appropriate for fluctuation studies are discussed. Multiplicity fluctuations of photons and charged particles and the effect of acceptance are presented in Sec. IV. In Sec. V, we estimate the multiplicity fluctuations in a participant model and compare to those obtained from data. Section VI deals with transverse energy fluctuations. A final discussion and summary is presented in Sec. VII.

II. EXPERIMENT AND DATA ANALYSIS

In the WA98 experiment at CERN [18], the main emphasis has been on high precision and simultaneous detection of both hadrons and photons. The experimental setup consisted of large acceptance hadron and photon spectrometers, detectors for charged particle and photon multiplicity measurements, and calorimeters for transverse and forward energy measurements. The experiment obtained data with 158A GeV Pb beams from the CERN SPS in 1994, 1995,

and 1996. The results presented here are from the Pb run in 1996 taken with the magnetic field (Goliath) turned off. The analysis makes use of the data taken with the photon multiplicity detector (PMD), the silicon pad multiplicity detector (SPMD), the midrapidity calorimeter (MIRAC), and the zero degree calorimeter (ZDC).

The circular SPMD, used for measuring charged particle multiplicity, was located 32.8 cm from the target. It had full azimuthal coverage in the region $2.35 \leqslant \eta \leqslant 3.75$. The detector had four overlapping quadrants, each fabricated from a single 300-μm-thick silicon wafer. The active area of each quadrant was divided into 1012 pads forming 46 azimuthal wedges and 22 radial bins with pad size increasing with radius to provide a uniform pseudorapidity coverage. The intrinsic efficiency of the detector was better than 99%. During the data recording, 95% of the pads worked properly. It was nearly transparent to high-energy photons, since only about 0.2% are expected to interact in the silicon. Details of the characteristics of the SPMD can be found in Refs. [19,20].

The photon multiplicity was measured using the preshower PMD placed at a distance of 21.5 m from the target. The detector consisted of 3 radiation length (X_0) thick lead converter plates placed in front of an array of square scintillator pads of four different sizes, varying from 15×15 mm^2 to 25×25 mm^2, placed in 28 box modules. Each box module had a matrix of 38×50 pads that were read out using one image intensifier and one charge-coupled device camera system. Details of the design and characteristics of the PMD may be found in Refs. [21,22]. The results presented here make use of the data from the central 22 box modules covering the pseudorapidity range $2.9 \leqslant \eta \leqslant 4.2$. The clusters of hit pads, having total analog-to-digital converter content above a hadron rejection threshold were identified as photonlike. Detailed simulations showed that the photon counting efficiencies for the central to peripheral cases varied from 68% to 73%. The purity of the photon sample, $N_{\gamma\text{-like}}$, in the two cases varied from 65% to 54%.

The transverse energy was measured with the MIRAC [23] placed 24.7 m downstream from the target. It consisted of 30 stacks, each divided vertically into six towers, each of size 20×20 cm^2, and segmented longitudinally into an electromagnetic (EM) section and a hadronic section. The depth of an EM section was $15.6X_0$ (equivalent to 51% of an interaction length), which ensured almost complete containment of the electromagnetic energy (97.4% and 91.0% containment calculated for 1 GeV and 30 GeV photons, respectively). The MIRAC was used to measure both the transverse electromagnetic (E_{T}^{em}) and hadronic (E_{T}^{had}) energies in the interval $3.5 \leqslant \eta \leqslant 5.5$ with a resolution of $17.9\%/\sqrt{E}$ and $46.1\%/\sqrt{E}$, (E in GeV), respectively. The E_{T} provides a measure of the centrality of the reaction. Events with large E_{T} correspond to very central reactions with small impact parameter and vice versa.

The ZDC measured the total forward energy E_{F} at $\theta \leqslant 0.3°$ with a resolution of $(80\%/\sqrt{E}) + 1.5\%$, with E expressed in GeV. E_{F} provides complementary information on the centrality with low E_{F} energy deposit corresponding to small impact parameter collisions.

For the results to be presented below, the following sources of errors have been included in the systematic error estimates.

A. Errors in $N_{\gamma\text{-like}}$

(a) The major source of error in $N_{\gamma\text{- like}}$ is due to the effect of clustering of the pad signals. This error is determined from the simulation by comparing the number of known tracks on the PMD with the total number of photonlike clusters. The result is that the number of clusters exceeds the number of tracks by 3% in the case of peripheral events and by 7% for high multiplicity central events [22].

(b) The uncertainty in the ADC value of the hadron rejection threshold in the PMD leads to an error in the estimation of $N_{\gamma\text{-like}}$ clusters. The hadron rejection threshold has been set at three times the minimum ionizing particle (MIP) peak. The value of MIP peak was changed by 10% of the peak value (3 ADC) in order to estimate the systematic error. The error in $N_{\gamma\text{-like}}$ value is 2.5% [22].

(c) The error due to the variation in scintillator pad-to-pad gains is found to be less than 1%.

The combined systematic error on $N_{\gamma\text{-like}}$ is asymmetric and centrality dependent. The errors are -3.2% and $+3.4\%$ for peripheral collisions and -7.1% and $+3.0\%$ for central collisions. The errors on N_{γ}, obtained after correcting for photon counting efficiency and purity of photonlike sample, will be discussed in Sec. V.

B. Errors in N_{ch}

The uncertainty in the N_{ch} obtained from SPMD has been discussed in detail in Ref. [19]. The total error has been estimated to be about 4%.

C. Errors in centrality selection through E_{T} and E_{F}

The centrality of the interaction is determined by the total transverse energy (E_{T}) measured in the MIRAC. The finite resolution in the measurement of E_{T} contributes to the systematic error. For the analysis of fluctuation in E_{T}, which uses MIRAC data directly, the centrality is determined by the forward energy E_{F}. The finite resolution in the measurement E_{F} contributes to the systematic error in E_{T} fluctuations. These errors are centrality dependent.

D. Fitting errors

The fitting errors associated with the determination of the fit parameters of the multiplicity and transverse energy distributions also contribute to the final systematic error in both the photons and charged particles and transverse energy, respectively. The maximum contribution of this error to the fluctuation was found to be 2%.

III. CENTRALITY SELECTION FOR FLUCTUATION STUDIES

The centrality of the interaction was determined by the total transverse energy measured in the MIRAC. For the part of the analysis where transverse energy data are used for the

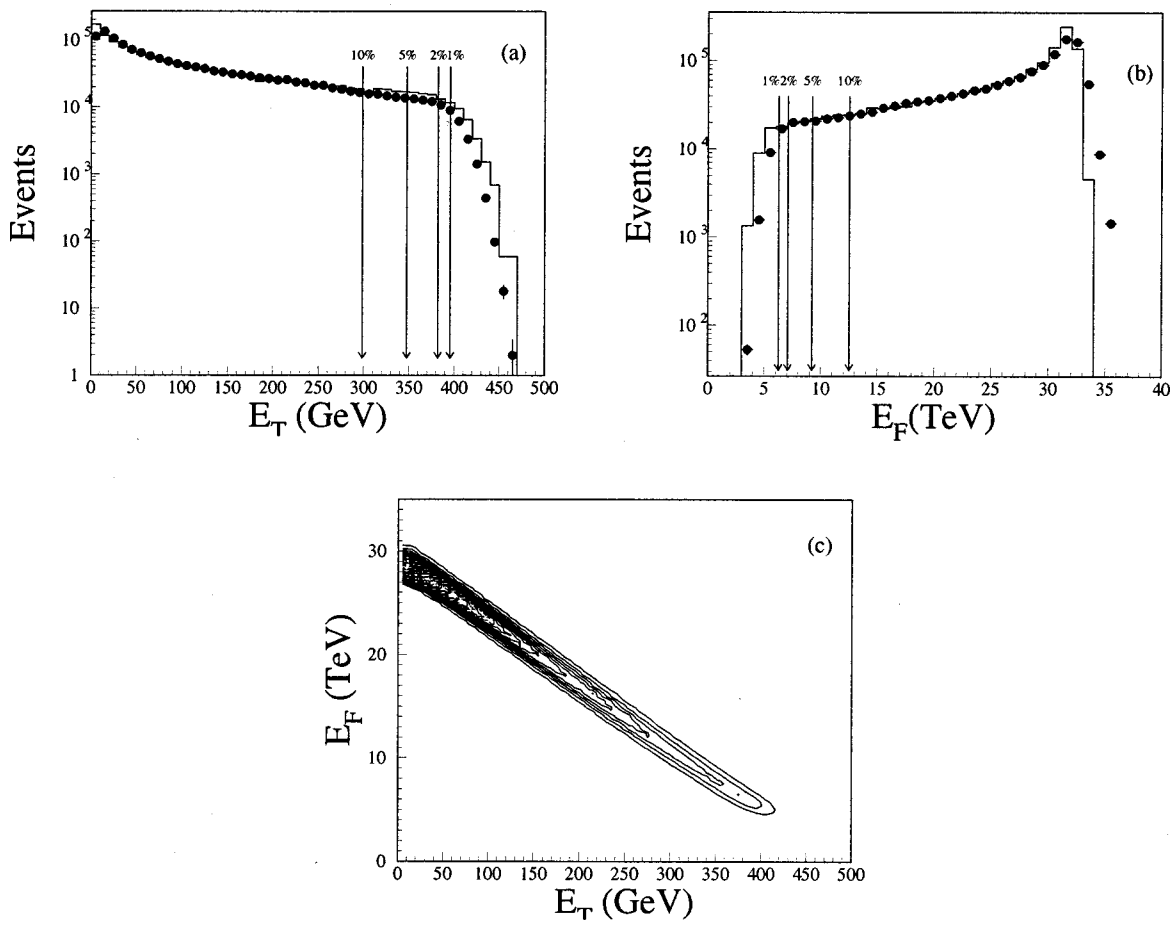

FIG. 1. Minimum bias distributions of (a) transverse energy E_T and (b) forward energy E_F produced in Pb induced reactions at 158*A* GeV on Pb. Solid histograms show the results obtained from VENUS event generator. (c) shows the anticorrelation of measured total transverse energy E_T and forward energy E_F.

fluctuation studies, the centrality was determined instead by the forward energy E_F as measured in the ZDC. The centralities are expressed as fractions of the minimum bias cross section as a function of the measured total transverse energy using MIRAC, or total forward energy using the ZDC. Figures 1(a) and 1(b) show the minimum bias distributions of E_T and E_F, respectively. The arrows in the figures indicate the values of E_T and E_F for the top (most central) 1%, 2%, 5%, and 10% of the minimum bias cross section. Predictions from VENUS 4.12 [24] are also shown as solid histograms. This will be discussed in a later section.

The anticorrelation of E_T and E_F is shown in Fig. 1(c). It illustrates that either E_T or E_F can be used nearly equivalently to define the centrality of the reaction.

Figures 2(a) and 2(b) show the minimum bias distributions for γ-like clusters and charged particles, respectively, for the full acceptances of the two detectors (PMD and SPMD). The multiplicity distributions corresponding to the centrality cuts using the total E_T for the top 1%, 2%, and 5% of the minimum bias cross section are also shown in the same figures. These distributions have been fitted to the Gaussians. The extracted fit parameters are used for the analysis of the fluctuations.

Figure 3 shows the variation of the mean (μ), standard deviation (σ), and chi square per degree of freedom (χ^2/ndf) of the photon and charged particle multiplicity distributions for different centrality bins. Here the centrality class is chosen with increasing width, as 0–1 %, 0–2 %, 0–3 %, . . . ,0–10 %. As expected, the mean value decreases and the sigma increases as we make broader centrality selection to include more of the cross section. From the χ^2/ndf values, one observes that the distributions increasingly deviate from the Gaussians with increasing width in the centrality selection. For a centrality selection width of greater than 5%, the χ^2/ndf rises above 2. The variation of μ and σ indicate that the extracted relative fluctuation (ω_χ) will grow with the increase in the width of the centrality selection interval. This indicates that the impact parameter fluctuations will dominate as the centrality selection is broadened. From this we conclude that the centrality selections should be made with as narrow bins in E_T as possible, such that the multiplicity distributions are good Gaussians and the impact parameter fluctuations are minimized. With this in mind we have used centrality selection bins of 2% widths in cross section, taken as 0–2 %, 2 − 4 %, . . . ,62–64 %.

Figure 4 shows the variation of μ, σ, and χ^2/ndf of the photon and charged particle multiplicity distributions within the full acceptance of the detectors with these narrow bins in

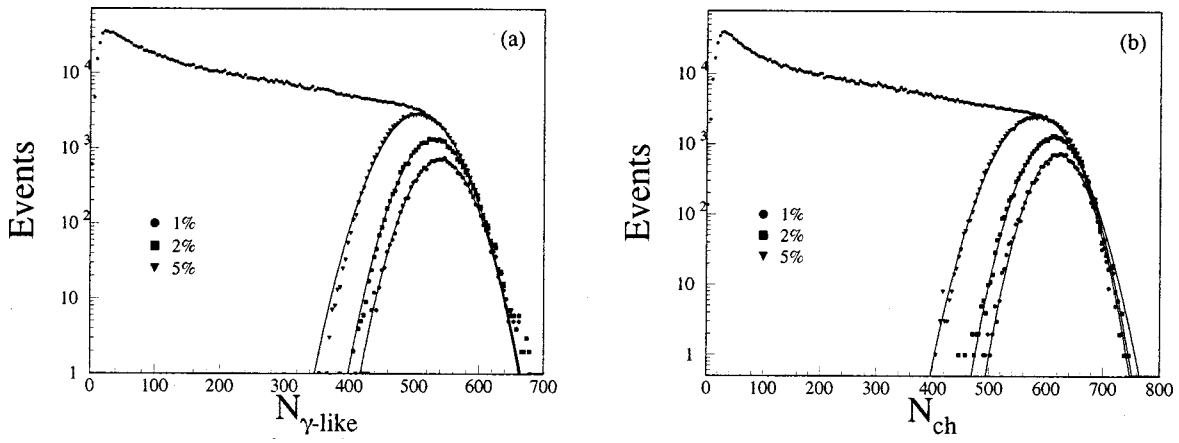

FIG. 2. Minimum bias distributions of (a) γ-like cluster multiplicity, and (b) charged particle multiplicity produced in Pb induced reactions at 158*A* GeV on Pb. The multiplicity distributions for the top 1%, 2%, and 5% most central events are also shown and fitted to the Gaussian distributions.

centrality. The data presented here cover the region from central (top 2% of the minimum bias cross sections) to peripheral collisions (up to 65% of the minimum bias cross section where the average number of participants is 26). It is seen that both the μ and σ values decrease towards peripheral collisions. The χ^2/ndf values are mostly in the region between 1.0 and 2.0 over the entire range of centralities considered. This suggests that narrow cross section slices in the E_T or E_F distributions are necessary to study the multiplicity fluctuations and minimize the influence from impact parameter fluctuations.

IV. MULTIPLICITY FLUCTUATIONS AND THE EFFECT OF ACCEPTANCE

The relative fluctuations in multiplicity for γ-like clusters and charged particles have been calculated using the μ and σ values from Fig. 4 and Eq. (1). These values are shown in Fig. 5 as functions of centrality, for full coverage of PMD ($2.9 \leqslant \eta \leqslant 4.2$) and SPMD ($2.35 \leqslant \eta \leqslant 3.75$), respectively. The errors shown in the figures are systematic errors, the sources of which have been already discussed in preceding section. For both γ-like clusters and charged particles the relative fluctuations are seen to increase in going from central to peripheral collisions. However, for charged particles the increase is much stronger.

In order to make a direct comparison of the fluctuations of photons and charged particles, the multiplicities should be studied in the region of common coverage of the detectors in terms of both pseudorapidity and azimuthal angle. In a latter section, we will compare the results obtained from data with those from model calculations for the common coverage. The region of common coverage of the two detectors in the WA98 experiment was 0.85 units in η ($2.9 \leqslant \eta \leqslant 3.75$). The general trend of the variation of the Gaussian fit parameters, with the reduced number of particles, for the common cov-

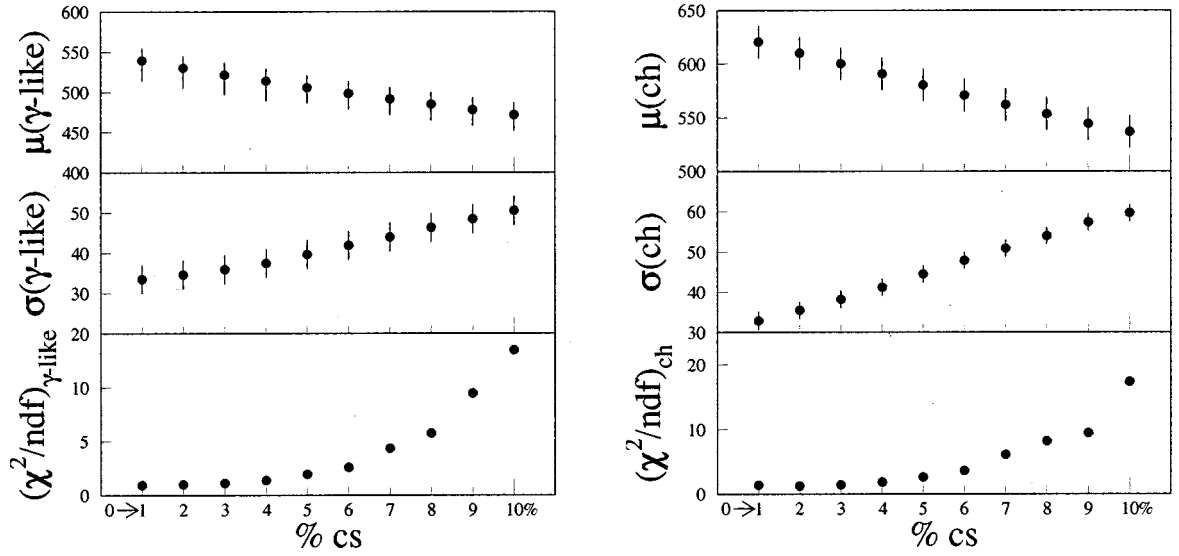

FIG. 3. The Gaussian fit parameters of the multiplicity distributions of γ-like clusters and charged particles for increasing centrality bins of increasing width. The centrality selection has been made by increasing the widths of E_T bins corresponding to $0-1\,\%, 0-2\,\%, 0-3\,\%, \ldots, 0-10\,\%$ of the minimum bias cross section.

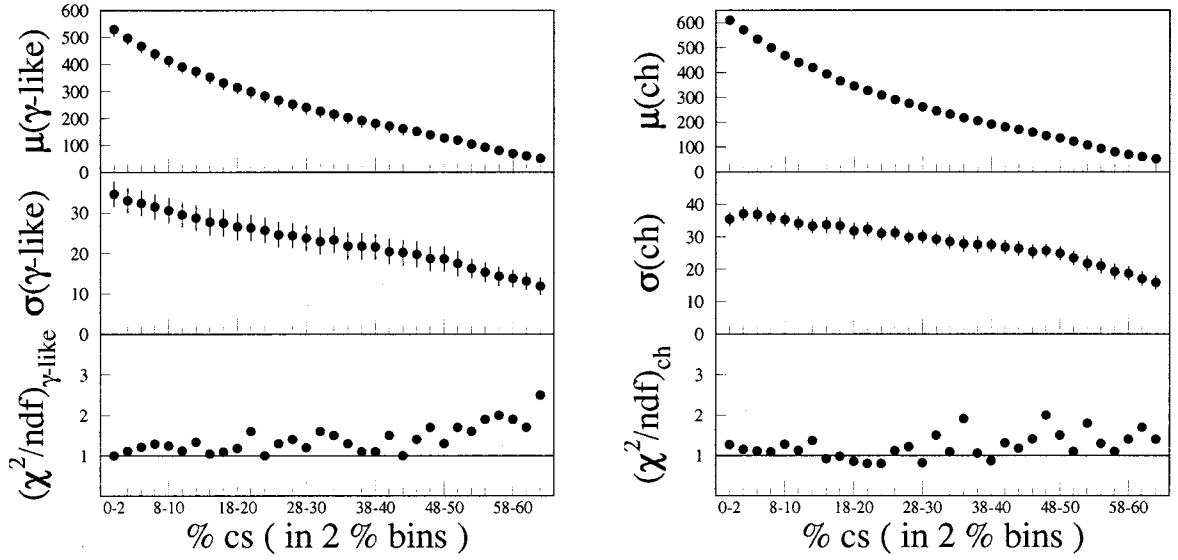

FIG. 4. The Gaussian fit parameters of the multiplicity distributions of γ-like clusters and charged particles as a function of centrality. The centrality selection has been made by selecting 2% bins in minimum bias cross section, viz., 0–2 %, 2–4 %, 4–6 %, . . . ,62–64 %. The multiplicity distributions for these centrality bins are near perfect Gaussians as can be seen from the χ^2/ndf values.

erage is found to be similar to that obtained with full coverage for each detector. Fit parameters μ, σ, and χ^2/ndf, as obtained for centrality bins of 2% in width, for the common coverage of the two detectors are shown in Fig. 6. As was the case for the larger acceptance, the μ and σ values are seen to decrease towards more peripheral event selection. The χ^2/ndf values are reasonable. Using the above values of the Gaussian parameters together with Eq. (1), the relative multiplicity fluctuations were calculated and are shown in Fig. 7. The error shown include the fit errors as well as the other systematic errors discussed earlier. The relative fluctuations for γ-like clusters is seen to be rather constant over the full centrality range with an average value of 2.2 ± 0.21. In comparison, the relative fluctuations for charged particles is 1.56 ± 0.13 at the most central bin (0–2 %) increasing to 2.8 ± 0.16 for the least central bin (62–64 %).

Following this discussion of the fluctuations in the multiplicity of photons and charged particles for the full acceptance regions and for the regions of common coverage of the photon and charged particle detectors, we now analyze the effect of detector acceptance on the observed fluctuations in more detail. For this we have taken two different η coverage regions for each detector. For the PMD the η ranges chosen are $3.0 \leqslant \eta \leqslant 4.0$ and $3.25 \leqslant \eta \leqslant 3.75$ (with full ϕ coverage). The resulting ω values for the two cases are shown in Fig. 8(a). Qualitatively, the variation of the fluctuations with centrality is similar for both coverages, but the magnitude of the relative fluctuations is lower for smaller η coverage.

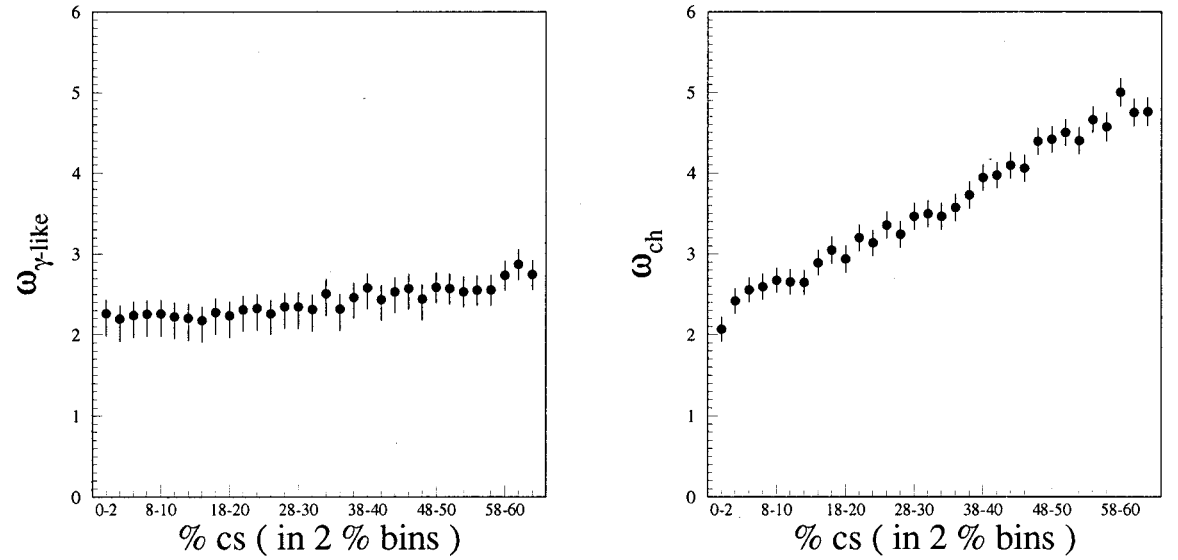

FIG. 5. Fluctuations of the multiplicity of γ-like clusters and charged particles within the full coverage of PMD and SPMD for various 2% bins of the minimum bias cross section.

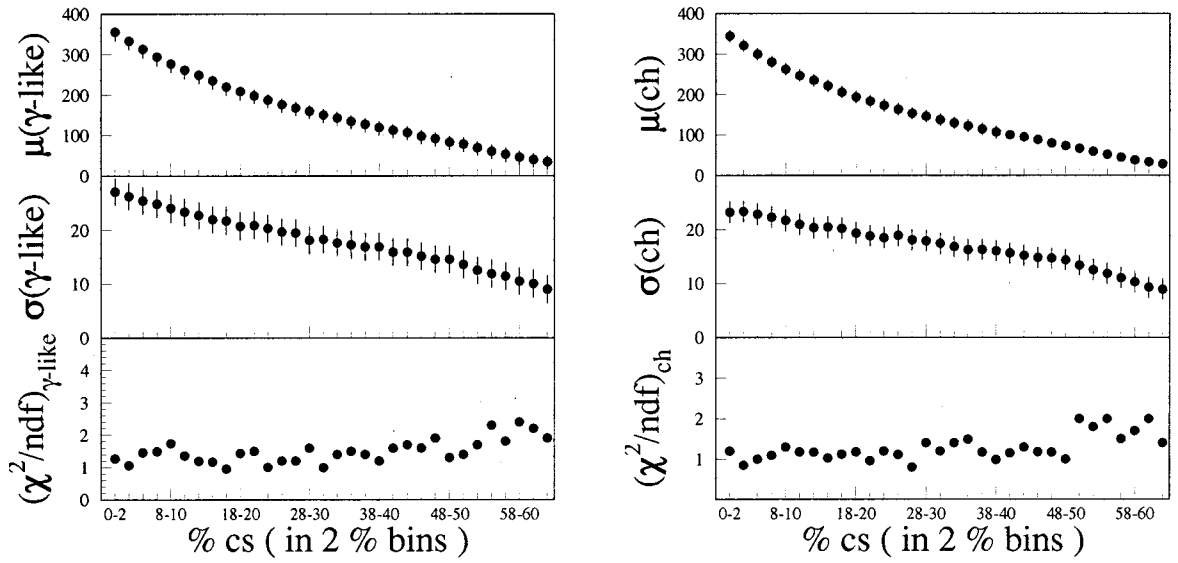

FIG. 6. Centrality dependence of the Gaussian fit parameters of the multiplicity distribution of γ-like clusters and charged particles within the common coverage of PMD and SPMD.

For the SPMD, the fluctuations were calculated for the rapidity intervals $2.35 \leqslant \eta \leqslant 3.35$ and $2.65 \leqslant \eta \leqslant 3.15$. These bins have width of one and one half units in η around midrapidity. The results are shown in Fig. 8(b). Qualitatively, the results are again similar to each other with the magnitude of the relative fluctuations decreasing as the coverage in η is decreased.

The decrease in the relative fluctuations as the acceptance is decreased can be understood in terms of a simple statistical picture [25]. Assume that there are m particles produced in the collision out of which n particles are accepted randomly into the detector acceptance. In this case, the distribution of n will follow a binomial distribution with mean mf and variance $mf(1-f)$, where f is the fraction of particles accepted. Therefore, the fluctuations in the number of particles accepted for a fixed (m) number of particles produced is $1-f$. In principle, m can have an arbitrary distribution as given by $P(m)$ with known first and second moments. The fluctuations in the n accepted particles out of the m particles produced is then given as

$$\omega_n = 1 - f + f\omega_m . \tag{2}$$

Thus considering the fluctuations in one unit of η as ω_m we can calculate the expected fluctuations for one half unit of η using the above equation. Here f corresponds to the ratio of the total number of particles accepted in one half unit of η coverage to that accepted over one unit in η. For the acceptance regions used, the average value of f for photons is about 0.52 and that of charged particles is about 0.54. Using

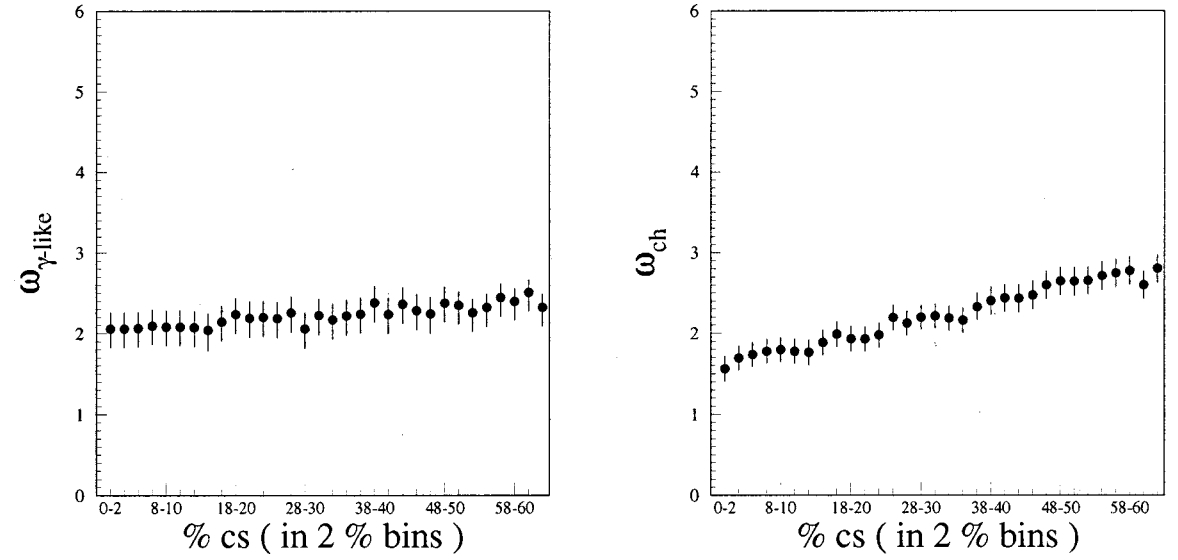

FIG. 7. Centrality dependence of the fluctuations of the multiplicity of photons and charged particles within the common coverage of the PMD and SPMD.

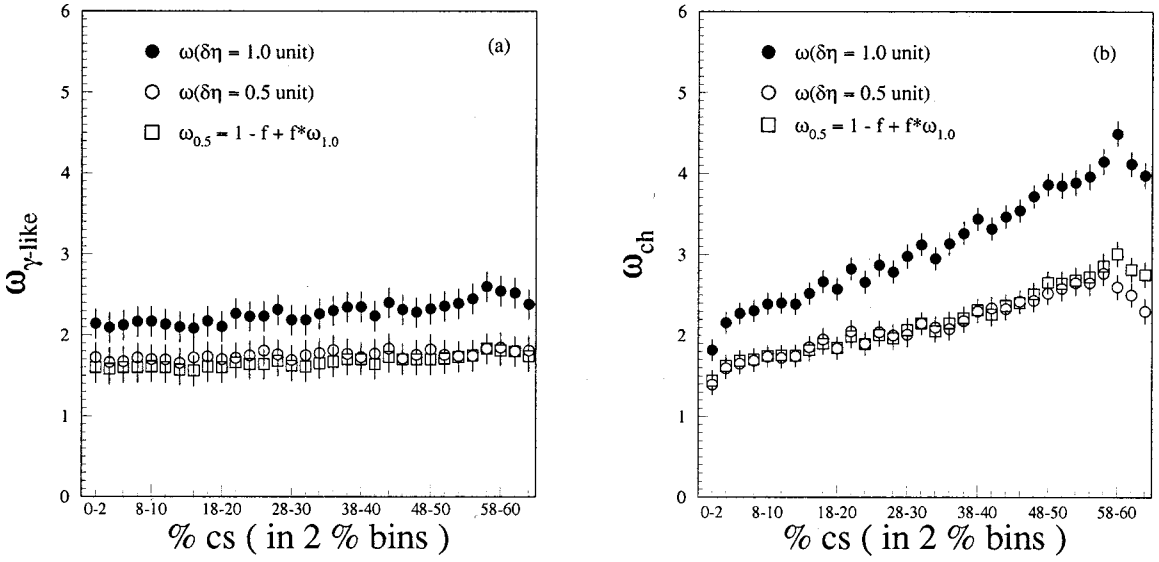

FIG. 8. Multiplicity fluctuations of photons and charged particles for two η acceptance selections. The open squares represent estimated values of fluctuations in 0.5 unit of $\delta\eta$ from the observed fluctuations in 1.0 unit of $\delta\eta$.

these values in Eq. (2) we can calculate the expected fluctuations for half unit of η coverage from the results of one unit of η coverage, under the assumption of a binomial sampling. As shown in Fig. 8 the empirical calculations almost exactly reproduce the observed result in the narrower acceptance window for charged particles and agrees reasonably well within the quoted errors for photons.

V. ESTIMATION OF FLUCTUATIONS IN A PARTICIPANT MODEL

In a picture where the nucleus-nucleus collision is thought of as the sum of contributions from many sources created in the early stage of the interaction, the variance of the distribution of any observable has contributions from (a) the fluctuations in the number of sources, largely due to different impact parameters. Even if the impact parameter window is narrowed, density fluctuations within the nucleus will make this contribution nonzero, (b) the fluctuations in the number of particles produced by each source. Quantum fluctuations in the nucleon-nucleon (*NN*) cross section can lead to such effects, (c) the fluctuations due to any dynamical process or critical behavior in the evolution of the system.

The contribution from the first two effects leads to fluctuations in the number of participant nucleons, which may be related to the initial size of the interacting system before it thermalizes. Resonance decays have also been shown to increase the multiplicity fluctuations by a large factor [4,5].

Following a simple participant model [5,15,16,26,27], the particle multiplicity (of photons or charged particles) N may be expressed as

$$N=\sum_{i=1}^{N_{\rm part}} n_i, \tag{3}$$

where $N_{\rm part}$ is the number of participants and n_i is the number of particles produced in the detector acceptance by the ith participant. On an average, the mean value of n_i is the ratio of the average multiplicity in the detector coverage to the average number of participants, i.e., $\langle n\rangle=\langle N\rangle/\langle N_{\rm part}\rangle$.

Thus the fluctuations in N will have contributions due to fluctuations in $N_{\rm part}$ ($\omega_{N_{\rm part}}$) and also due to the fluctuations in the number particles produced per participant (ω_n). Again, the fluctuations of n given as ω_n, will have a strong dependence on the acceptance of the detector. In the absence of correlations between the n_i's, the multiplicity fluctuations ω_N can be expressed as

$$\omega_N=\omega_n+\langle n\rangle\omega_{N_{\rm part}}. \tag{4}$$

Comparison of data with the results of such model calculations might reveal the extent to which the principle of superposition of nucleon-nucleon (*NN*) interactions is valid in the case of heavy-ion collisions. The participant model is expected to hold reasonably well for peripheral collisions where there are only few *NN* collisions, while for central collisions the particle production gets affected by *NN* scattering, rescatterings between produced particles, energy degradation, and other effects. Next we discuss the calculation of each of the terms in Eq. (4).

A. Calculation of $\omega_{N_{\rm part}}$

The impact parameter fluctuations are reflected in the fluctuations in the number of participants. We have estimated this contribution using the VENUS 4.12 event generator with default setting. A set of 100-K minimum bias Pb+Pb events at 158*A* GeV was generated for calculation of the number of participants. To match the centrality selection of the reaction in simulation to that in data, we have carried out a fast simulation in which $E_{\rm T}$ from VENUS was calculated within MIRAC coverage taking the resolution factors for the hadronic and electromagnetic energies of MIRAC into account.

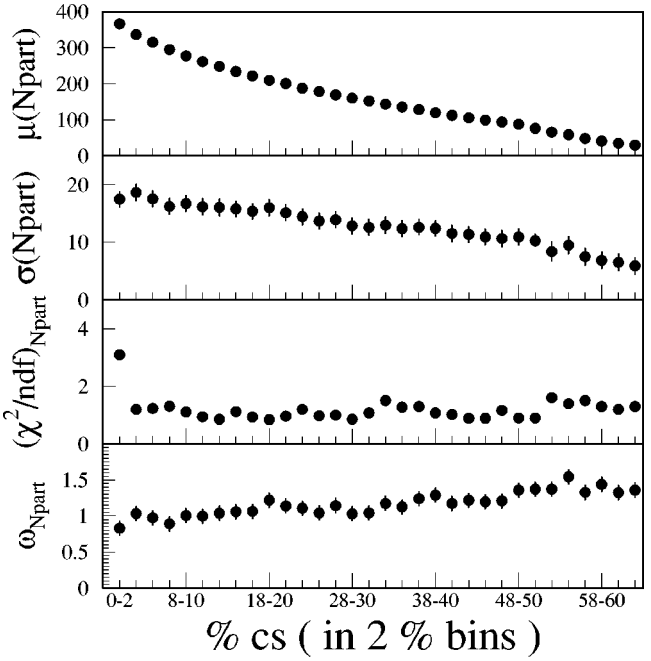

FIG. 9. Variation of μ, σ, and χ^2/ndf of the distribution of the number of participants as a function of centrality.

The corresponding E_T distributions for VENUS are shown as the solid curve in Fig. 1(a). It is seen that the agreement with data is quite reasonable.

The distributions of $N_{\rm part}$ for the same narrow (2%) bins of centrality, as discussed above for the data, are well described by the Gaussian distributions. Figure 9 shows the variation of μ, σ, χ^2/ndf, and relative fluctuation $\omega_{N_{\rm part}}$ calculated from the fit parameters with the 2% bins in centrality. One can see that the relative fluctuation in the number of participants, $\omega_{N_{\rm part}}$, is around 1. The statistical errors are small and are within the size of the symbols.

The systematic errors shown in the figures have contribution from the following sources, which have been added in quadrature.

(1) Nucleon density distribution: In order to estimate the error due to this we have calculated the number of participants from VENUS (as shown in the figure) and those from FRITIOF. The difference for each centrality bin was considered as representative of the error [28].

(2) Finite resolution of E_T: Systematic errors due to this were calculated by varying the centrality as per the MIRAC resolution [22].

(3) Fitting errors: Errors associated with the determination of the fit parameters of the Gaussian distributions also contribute to the final systematic error in the number of participants.

The quantity $\langle n\rangle$ is equal to the ratio of the mean charged particle (or photon) multiplicity for a given acceptance to the mean number of participants for the same centrality bin. Thus the contribution from the term $\langle n\rangle\omega_{N_{\rm part}}$ to the total fluctuations [Eq. (4)] can be easily obtained.

B. Calculation of ω_n

This term gives the fluctuations in the number of particles produced per participant. It has a strong dependence on acceptance as given earlier in Eq. (2) and shown in Fig. 8. To calculate ω_n as per Eq. (2) we next obtain the terms f and ω_m. The quantity f is the ratio of the number of particles per participant accepted within the acceptance of the detector ($\langle n\rangle$) to the total number of particles produced per participant ($\langle m\rangle$). The value of $\langle n\rangle$ for each centrality bin and for a given acceptance can be calculated as discussed in the preceding section. To obtain the value of $\langle m\rangle$ we make use of the data existing in the literature for *NN* collisions. As discussed in Refs. [29,30] the mean number of charged particles and photons produced in nucleon-nucleon collisions can be parametrized as a function of c.m. system energies ($\sqrt{s}$ from 2 GeV to 500 GeV) in the following manner:

$$\langle N_{\rm ch}\rangle^{NN} = -4.7(\pm 1.0) + 5.2(\pm 0.8)s^{0.145(\pm 0.01)}, \quad (5)$$

$$\langle N_{\gamma}\rangle^{NN} = -9.9(\pm 2.1) + 8.5(\pm 1.9)s^{0.113(\pm 0.015)}. \quad (6)$$

For the 158*A* GeV SPS energy discussed here this parametrization gives the average charged particle multiplicity to be 7.2 with the corresponding number for photons being 6.3. Thus the average charged particle and photon multiplicities per participant are 3.6 and 3.15, respectively.

In addition, σ for the charged particle multiplicity in nucleon-nucleon collisions shows a linear dependence with the average charged particle multiplicity as $0.576(\langle N_{\rm ch}^{NN}\rangle - 1)$, as given in Ref. [30].

This can be used to calculate ω_m, which is given as

$$\omega_m = 0.33\frac{(\langle N_{\rm ch}\rangle - 1)^2}{\langle N_{\rm ch}\rangle}. \quad (7)$$

For charged particles at SPS energies this gives a value of $\omega_m = 1.8$. However, for photons this number is not known since there is no similar parametrization. In the absence of such a parametrization of σ for photons we will also assume that $\omega_m = 1.8$ for the photon multiplicity. Fluctuations of photons, in principle, are expected to be similar to those for charged particles. This is because the majority of photons come from decay of π^0, while the majority of charged particles are charged pions ($\pi^{\pm}$).

From the values of $\langle n\rangle$, $\langle m\rangle$, and ω_m for a given acceptance and centrality, the term ω_n can then be calculated.

C. Comparison of data to model calculations

We first compare the experimental results of multiplicity fluctuations to those of the calculations using the participant model in the common coverage of PMD and SPMD. Figure 10 shows a comparison of the fluctuation in charged particles from data to that obtained from the calculations using the model described above. The results are plotted as a function of the number of participants. The horizontal errors on the number of participants are shown only on the data points. The error on ω calculated in the model is mainly due to the error on the mean number of charged particles in nucleon-

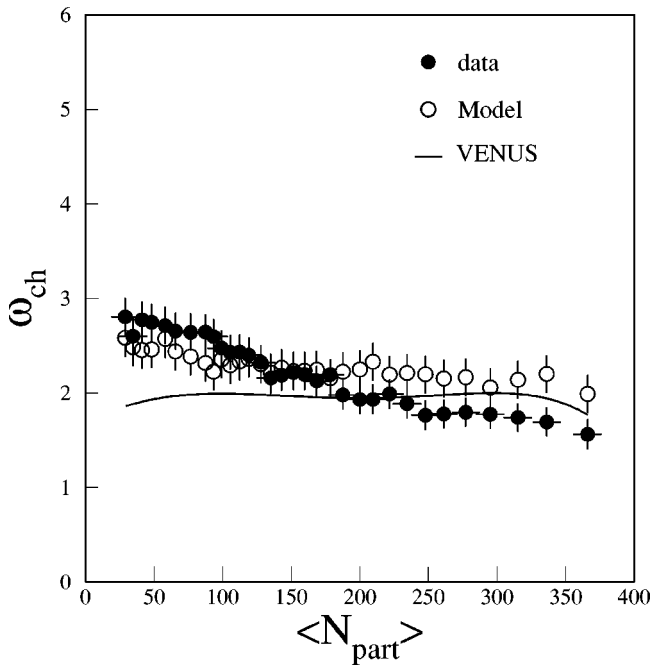

FIG. 10. The relative fluctuations ω_{ch} of the charged particle multiplicity as a function of number of participants. The experimental data are compared to calculations from a participant model and those from VENUS event generator.

nucleon interactions, the error in the number of participants calculated, and the uncertainty in the simulation of the calculated transverse energy. For clarity of presentation we have given results corresponding to alternate 2% centrality bins, i.e., 0–2 %, 2–4 %, . . . ,62–64 %. The results from VENUS are also shown in the form of a solid line in Fig. 10, and are found to remain almost constant over the entire centrality range. Charged particle fluctuations determined from data and the participant model decrease in going from peripheral to central collisions, although the dependence on centrality is weaker for the model calculation.

Figure 11 shows fluctuations in the γ-like clusters as well as N_γ after the correction. The results, plotted as a function of the number of participants, are compared to those of the participant model calculations for photons and results from VENUS. Using the estimated values of efficiency (ϵ_γ) and purity (f_p), the number of photons in an event is calculated by using the relation

$$N_\gamma = \frac{f_p}{\epsilon_\gamma}\ N_{\gamma\text{-like}}. \tag{8}$$

The photon counting efficiency in PMD varies from 68% to 73% for central to peripheral collisions. The purity of the measured photon sample varies from 65% to 54% for central to peripheral collisions.

The systematic errors associated with $N_{\gamma\text{-like}}$ have already been discussed in Sec. II. The additional errors in the conversion from $N_{\gamma\text{-like}}$ to N_γ are mainly due to errors in estimation of photon counting efficiency and purity. The sources of these errors are given below.

(1) Event-by-event variation in photon counting efficiency (ϵ_γ) and purity of photon sample (f_p). These have been found to vary from 3% to 6% for central to peripheral collisions.

(2) The purity factor depends on the ratio of the number of photons and charged particles within the PMD coverage. The systematic error associated with this ratio has been studied by using the FRITIOF [31] event generator in addition to VENUS. The average photon multiplicity estimated by using FRITIOF is found to be higher by about 4% in peripheral and by 1% in central collisions, compared to the values obtained using VENUS.

(3) The photon counting efficiency determined in the present case relies on the energy spectra of photons as given by the VENUS event generator. As the conversion probability for low-energy photons falls sharply [32] with decreasing energy below 500 MeV, the estimate of ϵ_γ may be affected if the energy spectra in the actual case is different. Photon energy spectra have been measured by the WA98 lead glass calorimeter. By extrapolating these measured spectra to the PMD acceptance we have estimated the photon counting efficiencies for different η bins and centralities. These results turn out to be lower compared to those obtained from VENUS by 2–9 % for central events and 3–13 % for peripheral events, the smaller value corresponds to larger pseudorapidity region of the PMD acceptance. The average difference in efficiencies within the PMD acceptance are 6% for central and 9% for peripheral collisions. These differences add to the systematic errors on the photon counting efficiency.

The total systematic error on the multiplicity of photons (N_γ) are -6.7% and $+12.5\%$ for peripheral collisions and -8.0% and $+9.0\%$ for central collisions.

The fluctuations in the number of photons have been estimated from the fluctuations in the number of photonlike clusters by using Eq. (8):

$$\omega_\gamma = \frac{f_p}{\epsilon_\gamma}\ \omega_{\gamma\text{-like}}. \tag{9}$$

These results are shown in Fig. 11. It is observed that the relative fluctuations of photons from the data are in reasonable agreement with those obtained from VENUS. However, the results for photons from the participant model are somewhat higher than those from the experimental data.

VI. TRANSVERSE ENERGY FLUCTUATIONS

Relativistic nuclear collisions are often described within the participant-spectator picture in which nuclei are spheres that collide with a definite impact parameter. The overlapping volumes that participate in the reaction are violently disrupted while the remaining spectator volumes shear off and suffer comparatively mild excitations. The magnitude of the E_T produced depends on the bombarding energy and the participant volume or equivalently the number of participating nucleons. The cross section for a specific value of E_T production depends to a large extent on the geometric probability of a given impact parameter. Therefore impact param-

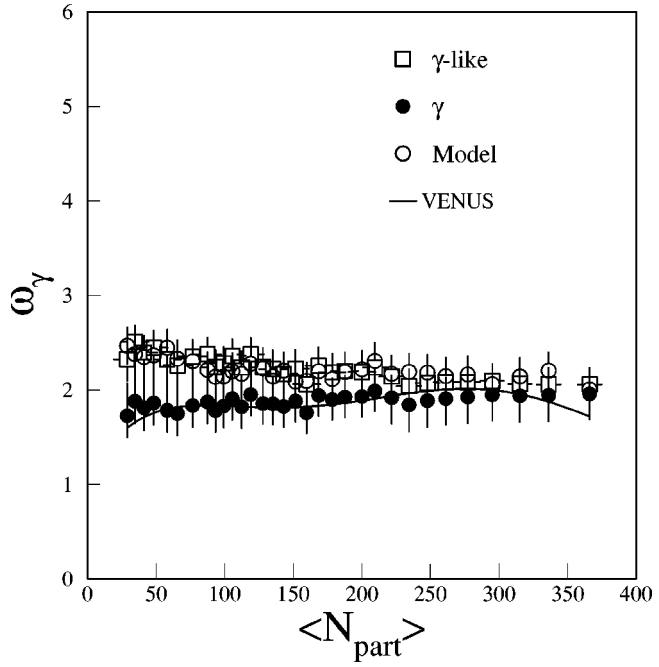

FIG. 11. The relative fluctuations ω_γ of photons as a function of number of participants. The data presented show the fluctuations in γ-like clusters and photons after correction for efficiency and purity. These are compared to calculations from a participant model and those from VENUS event generator.

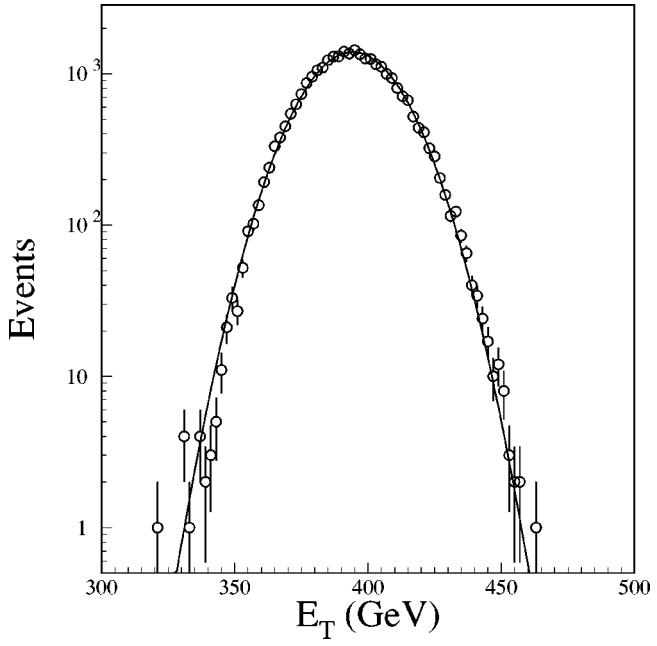

FIG. 12. The transverse energy distribution for the top 2% of the minimum bias cross section.

eter fluctuations are expected to lead to fluctuations in E_T.

Corroboration of the participant-spectator picture comes from the strong anticorrelation of E_T with the energy observed in the zero degree calorimeter, E_F as shown in the Fig. 1(b). The smaller the impact parameter, the larger is the participant volume and E_T, but the smaller is the spectator volume and E_F. E_T also correlates strongly with the produced particle multiplicity. The $d\sigma/dN_{ch}$ and $d\sigma/dN_{\gamma\text{-like}}$ spectra have virtually the same shape as $d\sigma/dE_T$ [Figs. 2(a) and 2(b)].

The study of the average total E_T as measured in the WA98 experiment and its scaling behavior with the number of participants have been discussed earlier in detail in Ref. [28]. Here we concentrate on the second moment, and study the fluctuations in E_T as was done for $N_{\gamma\text{-like}}$ and N_{ch}. For this analysis we have again taken 2% width bins in centrality using the forward energy as measured by the ZDC. Due to the poorer resolution in centrality selection of the ZDC for peripheral collisions, we present the results only up to the 50% centrality class.

The E_T distribution for the top 2% of the minimum bias cross section is shown in Fig. 12. The solid curve shows a Gasussian fit to the distribution. The μ, σ and χ^2/ndf values for such distributions at centrality bins varying from 0–2 % to 48–50 % have been extracted and are shown in Fig. 13. The χ^2/ndf values are seen to be between 1 and 2, which indicates that the distributions are well described by the Gaussians. The fluctuations in E_T have been calculated by using Eq. (1) and are shown in Fig. 14. The relative fluctuations are observed to increase in going from central to peripheral collisions. E_T, measured by the MIRAC was used in the online trigger to define the most central event sample with a threshold that occurred in the region of the top 14–18 % of the total cross section. This region is not analyzed to avoid trigger bias effects in the measured E_T distribution.

E_T has a strong correlation with the number of participant nucleons or the number of effective collisions they undergo [33]. In an attempt to understand the fluctuations in terms of

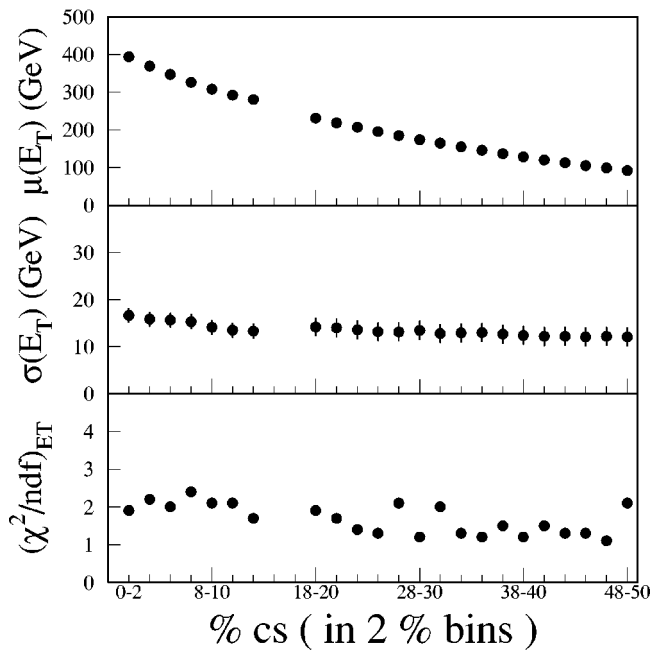

FIG. 13. Centrality dependence of μ, σ, and χ^2/ndf of the transverse energy distribution. The centrality selection is based on E_F measured with the ZDC.

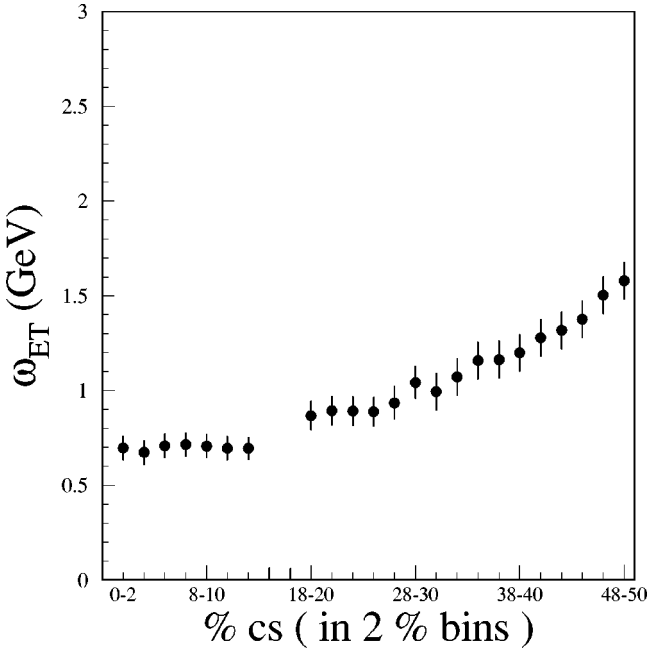

FIG. 14. Centrality dependence of the relative fluctuations in total transverse energy E_T with centrality selected by E_F.

the number of participant nucleons, the VENUS event generator has been used to determine the ratio $\mu(E_T)/\mu(N_{part})$ as a function of centrality. The $\mu(E_T)$ per participant has been found to be ~ 1.1 GeV± 0.2. This is shown in Fig. 15. The main sources of error here are due to the uncertainty in the calculation of the number of participants and the finite resolution of the calorimeters. Similar results were also obtained from WA80 and HELIOS Collaborations of Ref. [11,12].

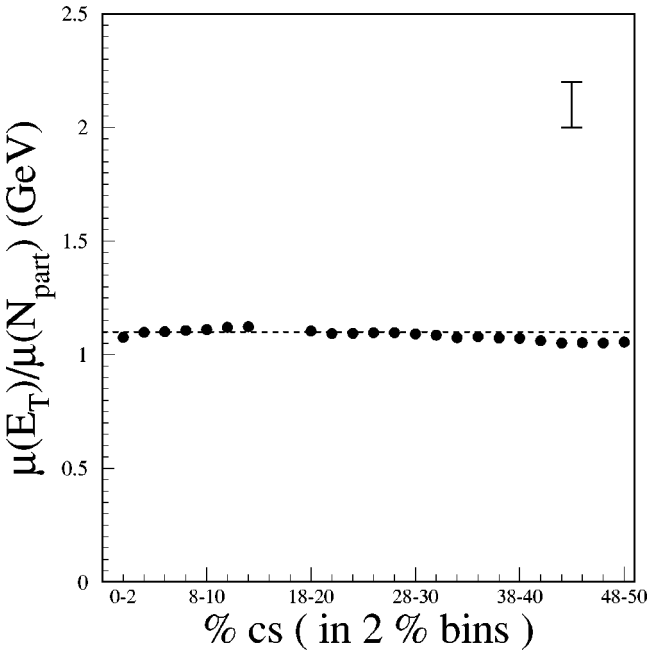

FIG. 15. E_T per participant as a function of centrality. The vertical solid line indicates the estimated systematic error in E_T per participant.

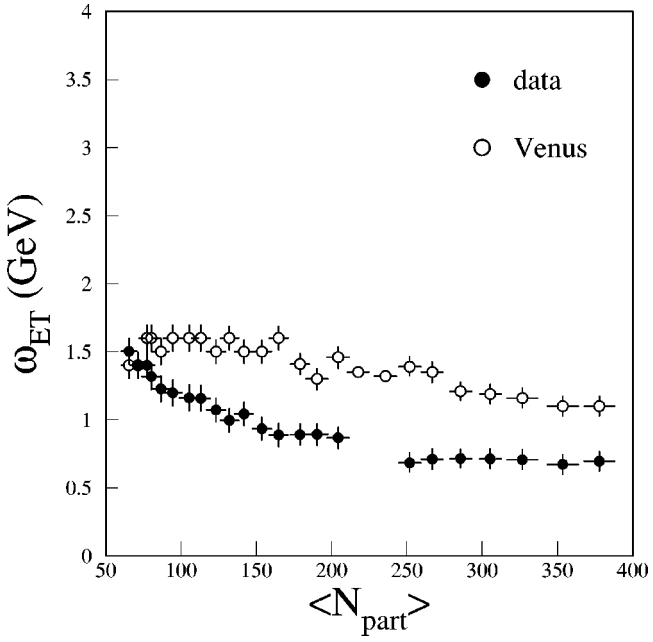

FIG. 16. Centrality dependence of the relative fluctuations in transverse energy E_T with the centrality selected from the E_F. The result is compared to VENUS using similar centrality selection criteria.

While the WA80 Collaboration has shown that E_T per participant is independent of projectile, target, and centrality but depends only on the number of wounded nucleons and the beam energy, the WA98 Collaboration has shown that transverse energy does deviate from a linear dependence on the number of participants for Pb+Pb collisions [28].

The relative fluctuations in transverse energy can be analyzed in a participant picture similar to that employed in the case of photons and charged particles [33]. An expression similar to Eq. (4) can be obtained, where the first term depends on the fluctuations in the transverse energy deposited by each particle produced per participant nucleon, with the second term coming from impact parameter fluctuations within the acceptance of the detector. Since the first term depends greatly on the detector characteristics, we compare the transverse energy fluctuations in data to those obtained from a fast simulation of the MIRAC and ZDC characteristics in VENUS in which the energy resolution for each particle was applied separately when computing the total transverse energy [23]. Figures 1(a) and 1(b) show the comparison of the simulated E_T and E_F distributions with those from data. The agreement is seen to be quite reasonable.

Figure 16 shows the comparison of E_T fluctuations from data to those obtained from simulated events using VENUS. The fluctuations are plotted as a function of the mean number of participants in various 2% bins of centrality obtained from E_F. Errors shown in the data are mainly due to uncertainties in the determination of number of participants and the finite energy resolution of the calorimeters as discussed earlier. It is seen that the fluctuation in data are systematically smaller than those obtained form VENUS. As discussed in Ref. [33] many effects like energy-momentum degradation

of nucleonic objects in successive scatterings and short-range correlations between nucleons in a nucleus may be responsible for the decrease in fluctuations in E_T of data as compared to those obtained from simulations in VENUS. The role of rescattering has also to be understood in this context.

VII. SUMMARY

A detailed event-by-event study of fluctuations in the multiplicities of charged particles and photons and transverse energy has been carried out using data from the WA98 experiment. This has been done by varying both the centrality and rapidity intervals. It is observed that the relative fluctuations increase with increase in the impact parameter interval. Hence it is important to control the impact parameter dependence by studying narrow bins in centrality. For 2% centrality bins, within which the distributions of charged particle and photon multiplicities, as well as the transverse energy, are well described by the Gaussians, the contribution from impact parameter fluctuations is around 1, as expected. The fluctuations in multiplicities and E_T are found to increase in going from central towards peripheral events. A decrease in acceptance has been found to result in decreased multiplicity fluctuations. Using a simple statistical analysis one can explain the observed decrease in a smaller acceptance knowing the fluctuations in a larger acceptance window. The observed centrality dependence of the multiplicity fluctuations of charged particles has been found to agree reasonably well with results obtained from a simple participant model that takes into account impact parameter fluctuations from VENUS and multiplicity fluctuations from *NN* data, within the quoted systematic errors. For photons the fluctuations are found to be slightly lower compared to those obtained from the participant model.

Similar calculations have been performed for the transverse energy and multiplicity distributions using VENUS. The transverse energy fluctuations from experimental data are found to be smaller than those observed in VENUS. On the other hand, after corrections for charged particle contamination in the photonlike clusters, the relative fluctuations of photons appear to be in rather good agreement with VENUS.

ACKNOWLEDGMENTS

We wish to express our gratitude to the CERN accelerator division for the excellent performance of the SPS accelerator complex. We acknowledge with appreciation the efforts of all engineers, technicians, and support staff who have participated in the construction of this experiment. This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR and FRN, the Dutch Stichting FOM, the Polish KBN under Contract No. 621/E-78/SPUB-M/CERN/P-03/DZ211/, the Grant Agency of the Czech Republic under Contract No. 202/95/0217, the Department of Atomic Energy, the Department of Science and Technology, the Council of Scientific and Industrial Research and the University Grants Commission of the Government of India, the Indo-FRG Exchange Program, the PPE division of CERN, the Swiss National Fund, the INTAS under Contract No. INTAS-97-0158, ORISE, Grant-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science and Culture, the University of Tsukuba Special Research Projects, and the JSPS. ORNL is managed by UT-Battelle, LLC, for the U.S. Department of Energy under Contract No. DE-AC05-00OR22725. The MIT group has been supported by the U.S. Department of Energy under cooperative agreement No. DE-FC02-94ER40818.

Abstract. Results on transverse mass spectra of neutral pions measured at central rapidity are presented for impact parameter selected 158·A GeV Pb + Pb, and Pb + Nb collisions. The distributions cover the range $0.5\,\mathrm{GeV}/c^2 \leq m_T - m_0 \leq 4\,\mathrm{GeV}/c^2$. The change of the spectral shape and the multiplicity with centrality is studied in detail. In going from p+p to semi-peripheral Pb+Pb collisions there is a nuclear enhancement increasing with transverse mass similar to the well known Cronin effect, while for very central collisions this enhancement appears to be weaker than expected.

1 Introduction

Heavy ion reactions at ultrarelativistic energies provide information on nuclear matter at high energy density (for reviews see e.g. [1–3]). Hadron production is generally considered to be sensitive to the late freeze-out stage of the collision, when hadrons decouple from one another. Already from the experimentally determined shape of the transverse mass spectra it is evident that heavy ion reactions are not merely a superposition of nucleon-nucleon collisions [4–6].

The broadening of the transverse mass spectra in p+A collisions compared to p+p (Cronin-effect [7]) has been attributed to *initial state* multiple scattering of partons [8, 9]. However, models which attempt to describe nucleus-nucleus reactions, like the Monte-Carlo programs VENUS [10] or RQMD [11] rely on the assumption that *final state* rescattering plays an important role in determination of the momentum distributions of the hadrons. If final state rescattering is very strong, the notion of local kinetic equilibrium may be valid, which is the basic assumption for a hydrodynamical description (see e.g. [12,13]).

It remains unclear, whether equilibration is attained. If it occurs, it will be important to isolate the contributions of thermal, pre-equilibrium, and initial state processes to the hadron yield. Since the latter are expected to dominate at large transverse momenta, it is hoped that systematic studies of hadron spectra over a large range in momentum might allow to disentangle these contributions. In the analysis of central reactions of Pb + Pb at 158·A GeV it is seen that both predictions of perturbative QCD [17,18] and hydrodynamical parameterizations [19] can describe the measured neutral pion spectra reasonably well. It is particularly surprising to observe that, on the one hand, a pQCD calculation gives a reasonable description also at relatively low momenta, while on the other hand, a hydrodynamical parameterization can provide a good description, even at very high momenta.

The understanding of the relative contributions of the various soft and hard processes in particle production is especially important in view of the recent interest in the energy loss of partons in dense matter [14,15], generally referred to as *jet quenching*, as a possible probe for the quark-gluon-plasma. One of the suggested experimental hints of jet quenching is the suppression of particle production at high transverse momenta [16]. In order to confirm such an interpretation, it is important to study other possible nuclear modifications of particle production in detail. More information in this respect may be gathered from the variation of the particle spectra for different reaction systems or different centralities. First attempts in this respect have been discussed in [17], where the neutral pion average p_T as a function of the centrality was shown to rise from p+p collisions to peripheral Pb+Pb collisions and to saturate for medium central and central Pb+Pb collisions. It was also seen that the neutral pion yield for reactions with more than about 30 participating nucleons N_{part} exhibits a scaling as N_{part}^{α} with a power $\alpha \approx 1.1$ which is approximately independent of p_T.

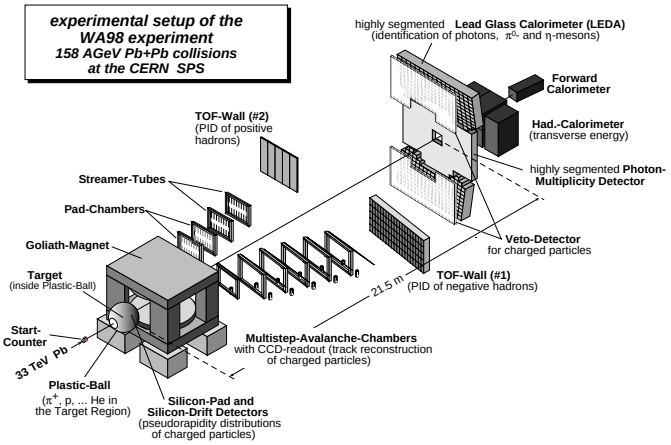

Fig. 1. The WA98 experimental setup

In the present paper we will present a detailed study of neutral pion transverse mass spectra in the range $0.5\text{GeV}/c^2 \leq m_T - m_0 \leq 4.0\text{GeV}/c^2$ and $2.3 \leq y \leq 3.0$ for collisions of Pb+Pb and Pb+Nb at 158·A GeV for different centralities.

2 Experiment

The CERN experiment WA98 [20] is a general-purpose apparatus which consists of large acceptance photon and hadron spectrometers together with several other large acceptance devices which allow to measure various global variables on an event-by-event basis. The experiment took data with the 158·A GeV ^{208}Pb beams from the SPS in 1994, 1995, and 1996. The data presented here were taken during the 1995 and 1996 beamtimes at the CERN SPS. The layout of the WA98 experiment as it existed during the final WA98 run period in 1996 is shown in Fig. 1.

Neutral pions are reconstructed on a statistical basis from their two-photon decay, using photons measured with the LEDA spectrometer in the pseudorapidity interval $2.3 < \eta < 3.0$. This detector is located 21.5 m from the target and consists of 10,080 modules. Each module is a $4 \times 4 \times 40$ cm^3 (14.3 radiation lengths) TF1 lead-glass block read out by an FEU-84 photomultiplier. The high voltage is generated on-base with custom developed [22] Cockcroft-Walton voltage-multiplier type bases which are individually controlled by a VME processor. The photomultiplier signals are digitized with a custom-built ADC system [23]. Twenty-four lead-glass modules are epoxied together in an array 6 modules wide by 4 modules high to form a super-module. Each super-module has its own calibration and gain monitoring system based on a set of 3 LEDs and a PIN-photodiode mounted inside a sealed reflecting front cover dome [24]. The photon spectrometer is separated into two nearly symmetric halves above and below the beam plane in the two regions of reduced charged-particle density which result from the sweeping action of the GOLIATH magnet. More details about the experimental setup and the photon spectrometer can be found in [25].

The acceptance of the photon spectrometer for π^0 detection in rapidity and transverse mass is shown in Fig. 2. The acceptance covers the region $2.3 < y < 3.0$, near mid-rapidity ($y_{cm} = 2.9$).

The minimum bias trigger requires a valid signal of the beam counters and a minimum amount of transverse energy $E_T \gtrsim 5\,\mathrm{GeV}$, detected by the Mid-Rapidity Calorimeter, MIRAC [21], which is located 24 m downstream of the target. MIRAC consists of a hadronic and an electromagnetic section and covers the pseudorapidity interval $3.5 < \eta < 5.5$. Data have been taken with the 158·A GeV lead beam on targets of Pb (495 and 239 mg/cm^2) and Nb (218 mg/cm^2). For the present analysis 9.7 million Pb+Pb and 0.23 million Pb+Nb minimum bias events were accumulated. The minimum bias cross sections have been calculated from the number of beam triggers and minimum bias triggers and the target thicknesses. The yields have been corrected for small non-target background contributions (typically a few percent) to obtain $\sigma_{\mathrm{mb}} \approx 6300\,\mathrm{mb}$ and 4400 mb for Pb + Pb and Pb + Nb reactions, respectively. These absolute cross sections are estimated to have an overall systematic error of less than 10%.

3 Pion reconstruction and efficiency

The method for pion reconstruction is similar to that used by the WA80 collaboration as discussed in [6]. It is also discussed at length in [25,26] so we will only briefly sketch the basics of the method.

The showers used for the extraction of the neutral pion yield via the $\gamma\gamma$ decay branch can be selected with different criteria. It has been demonstrated that the extracted yield does not depend significantly on the choice of these photon identification cuts [25]. For the present analysis, showers with a small lateral dispersion [27] have been selected as photon candidates.

Hits in LEDA are combined pairwise to provide distributions of pair mass vs. $m_T - m_0$ (where $m_T = \sqrt{p_T^2 + m_0^2}$ is the transverse mass and m_0 is the π^0 rest mass) for all possible combinations. These distributions are obtained both for real events, $R(m_{\mathrm{inv}}, m_T)$, and for so-called mixed events, $M(m_{\mathrm{inv}}, m_T)$, where a hit from one event is combined with a hit from another event with similar multiplicity. $M(m_{\mathrm{inv}}, m_T)$ provides a good description of the combinatorial background and is subtracted from $R(m_{\mathrm{inv}}, m_T)$ to obtain the mass distribution of neutral pions (see Fig. 3).

The large multiplicities, especially in central reactions of Pb + Pb, lead to a considerable probability that showers in the detector overlap and influence each other. Particles may be lost for reconstruction. In other cases the particle might be measured with an incorrect energy. These effects lead to a detector efficiency for pion reconstruction which depends on particle density. To study this detection efficiency, the GEANT [28] simulation package has been used to create artificial signals for the lead glass modules corresponding to neutral pions incident on the detector. The effects of detector noise and the digitization of the photomultiplier signals are also implemented. To obtain the π^0

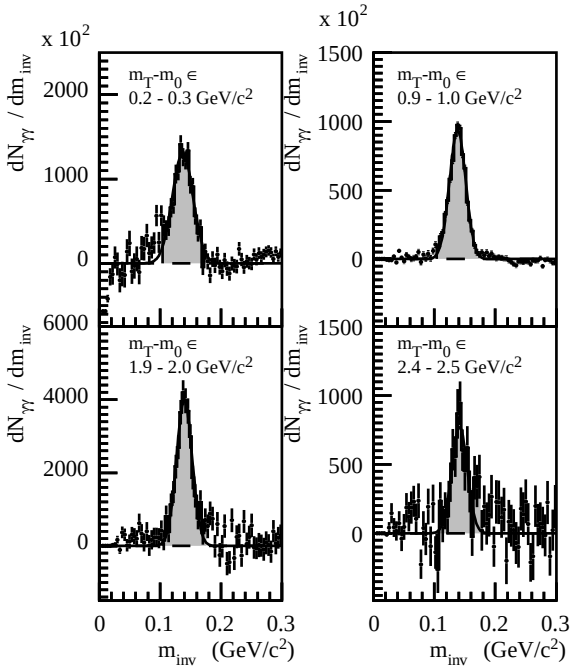

Fig. 3. Invariant mass distributions of photon pairs for minimum bias Pb + Pb collisions in different intervals of $m_T - m_0$. The combinatorial background has been calculated using mixed-event distributions and subtracted

reconstruction efficiency, these simulated photon shower pairs have been superimposed onto the measured events. The simulation provides the means to extract the probability that a pion at a given input transverse mass $m_T^{(0)}$ will be measured with $m_T^{(1)}$. These probabilities, extracted as a function of $m_T^{(0)}$, can be understood as a matrix which transforms the real physical distributions into the mea-

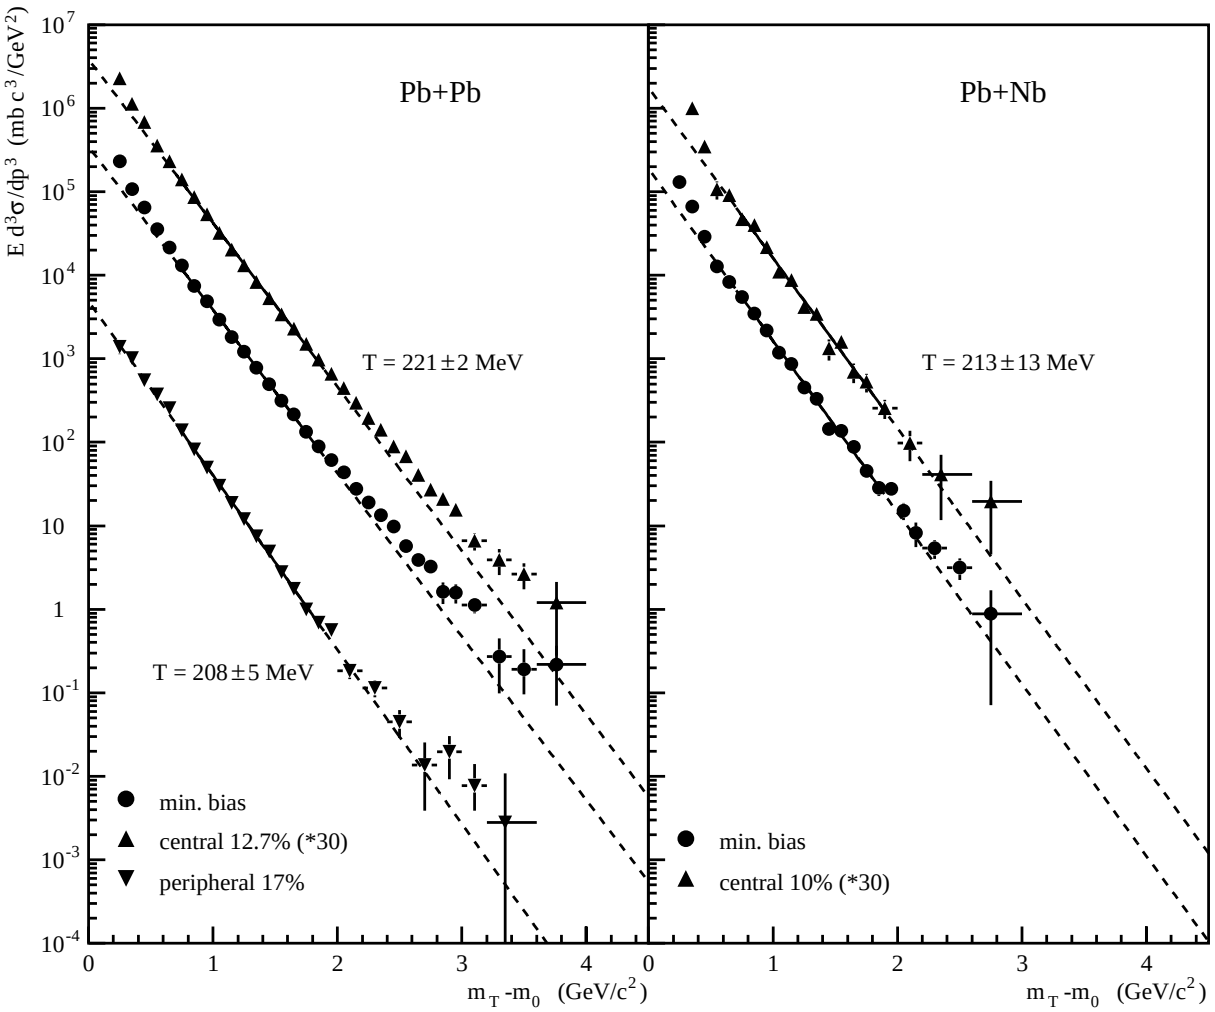

Fig. 4. Invariant cross sections of neutral pions for Pb + Pb (left) and Pb + Nb collisions (right) of different centralities as a function of $m_T - m_0$

sured ones. These correction matrices are used to correct the measured distributions. A detailed description of the efficiency correction can be found in [25].

The distributions have then been corrected for contributions from reactions of Pb projectiles with material other than the target (e.g. residual gas, exit windows, etc.). The corresponding corrections were obtained by measurements performed without target. The corrections are negligible for medium-central and central reactions.

The systematic errors on the measured transverse mass spectra are dominated by the following contributions:

- An uncertainty in the absolute calibration of the momentum scale of 1%. This may be translated into an uncertainty in the yields of a few% at low m_T rising to $\approx$ 13% at $m_T - m_0 = 3.5\,\mathrm{GeV}/c^2$, which is independent of centrality or reaction system.
- Uncertainties in the π^0 extraction which include the error in the determination of the invariant mass peak content and the propagation of the energy resolution through the acceptance and efficiency corrections. This is largest in central collisions. It leads to an error below 10% for $m_T - m_0 \geq 0.5\,\mathrm{GeV}/c^2$ for most samples.
- Uncertainties in the correction for contributions from no-target reactions, which are only relevant for peripheral reactions. This leads to an error below 10% for $m_T - m_0 \geq 0.5\,\mathrm{GeV}/c^2$.

The total centrality dependent systematic error is below 10% for $m_T - m_0 \geq 0.5\,\mathrm{GeV}/c^2$ for most centrality classes and below 20% for the most central sample.

4 Results

4.1 Neutral pion spectra

Neutral pion spectra for Pb + Pb and Pb + Nb collisions for minimum bias and selected centralities are presented in Fig. 4. On the left hand side results for Pb + Pb minimum bias as well as for the 12.7% most central and the 17% most peripheral event selections are shown. Included also are results of exponential fits:

$$f(m_T - m_0) = C \cdot \exp\left(-\frac{m_T - m_0}{T}\right) \qquad (1)$$

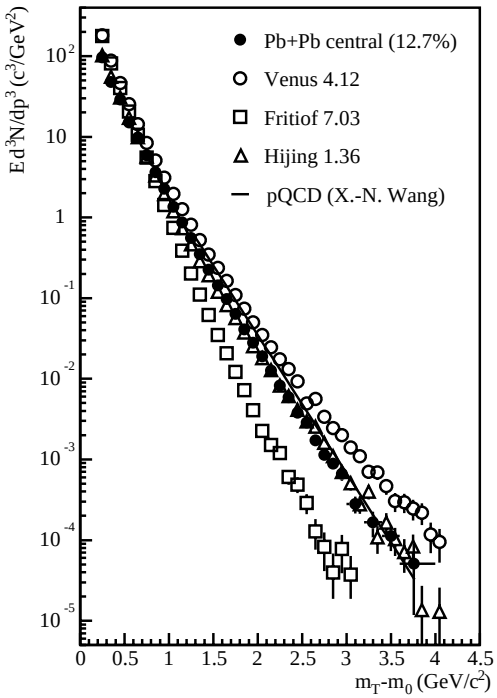

Fig. 5. Invariant multiplicities of neutral pions for central Pb + Pb collisions as a function of $m_T - m_0$ compared to predictions of Monte Carlo event generators

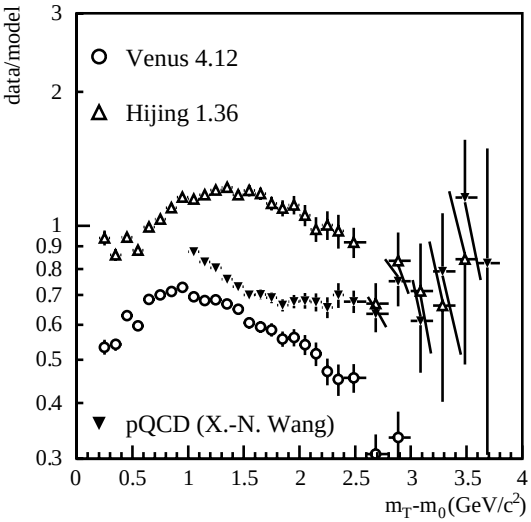

Fig. 6. Ratios of measured invariant multiplicities of neutral pions to those from Monte Carlo event generators for central Pb + Pb collisions as a function of $m_T - m_0$

fitted over the range $0.7\,\mathrm{GeV}/c^2 \leq m_T - m_0 \leq 1.9\,\mathrm{GeV}/c^2$. As noted previously [6,17], the data clearly deviate from the exponential shape when considered over the full range of transverse masses. The fit in the limited transverse mass range can, however, still be used to extract slope parameters T. For the 12.7% most central collisions one finds $T = 221 \pm 2\,\mathrm{MeV}$ which is significantly larger than the value of $T = 208 \pm 5\,\mathrm{MeV}$ for peripheral collisions. Spectra for reactions of Pb + Nb (minimum bias and 10% central) are shown on the right hand side. The spectral shapes are very similar to those for Pb + Pb collisions. For central collisions a slope parameter of $T = 213 \pm 13\,\mathrm{MeV}$ is extracted which is intermediate compared to that of peripheral and central Pb + Pb collisions. Since the statistics for the Pb + Nb dataset is limited, we will concentrate on the Pb + Pb reactions in the rest of the paper.

In Fig. 5 the multiplicity distribution for central collisions is compared to predictions of the event generators FRITIOF 7.03 [29], VENUS 4.12 [10], and HIJING 1.36 [30]. Clearly FRITIOF does not describe the data at all, while VENUS and HIJING yield a more reasonable description. The prediction of the pQCD calculation from [18] is included as a solid line, which also shows a reasonable agreement with the data. The degree of agreement of the models can be better seen in Fig. 6 where the ratio of the experimental data to the generator results is shown. FRITIOF is not included as the discrepancies are already evident from Fig. 5. VENUS overpredicts the pion production at high m_T by about a factor of two. HIJING shows the best agreement at large momenta but underpredicts the data slightly at intermediate m_T. Also the Monte Carlo models lead to a stronger concave curvature than the data. The pQCD calculation overpredicts the data by $\approx 30\%$ in the range $1.5\,\mathrm{GeV}/c \leq m_T - m_0 \leq 3.0\,\mathrm{GeV}/c$.

The momentum spectra for central collisions have been published already in [17]. As discussed in the corresponding erratum, cross section estimates had turned out to be incorrect. In the course of the present analysis it was realized that for the presentation of the results in Fig. 1 of [17], the π^0 multiplicities were incorrectly normalized. All other results and conclusions of [17] are unchanged. Unfortunately, the same improperly normalized distributions were analyzed in [18]. The correct normalization reduces the π^0 mulitiplicities by 27% with the result that the pQCD calculations presented there would overpredict the measured WA98 π^0 result, as shown in Fig. 6. Still different parameters for the p_T-broadening in these calculations might possibly enable the model to describe the central distributions better. More stringent tests of such a model can be performed when looking at the detailed centrality dependence of the pion production which has been done in the following.

The minimum bias sample has been subdivided into eight centrality samples summarized in Table 1. Measurements were performed with and without magnetic field, which does not affect the neutral pion distributions, but alters the transverse energy used to determine the centrality. The corresponding cuts have been adjusted so that always the same fractions of the minimum bias cross section were selected. The data samples with and without magnetic field agree well with each other and have been combined in the present analysis. Table 1 shows the transverse energy cuts for one particular data set as an example.

All the transverse mass distributions for Pb + Pb collisions for the different centrality classes as a function of $m_T - m_0$ have a very similar shape (see Fig. 7). The distributions are compared more closely in Fig. 8 where the spectra for given centrality classes are divided by the min-

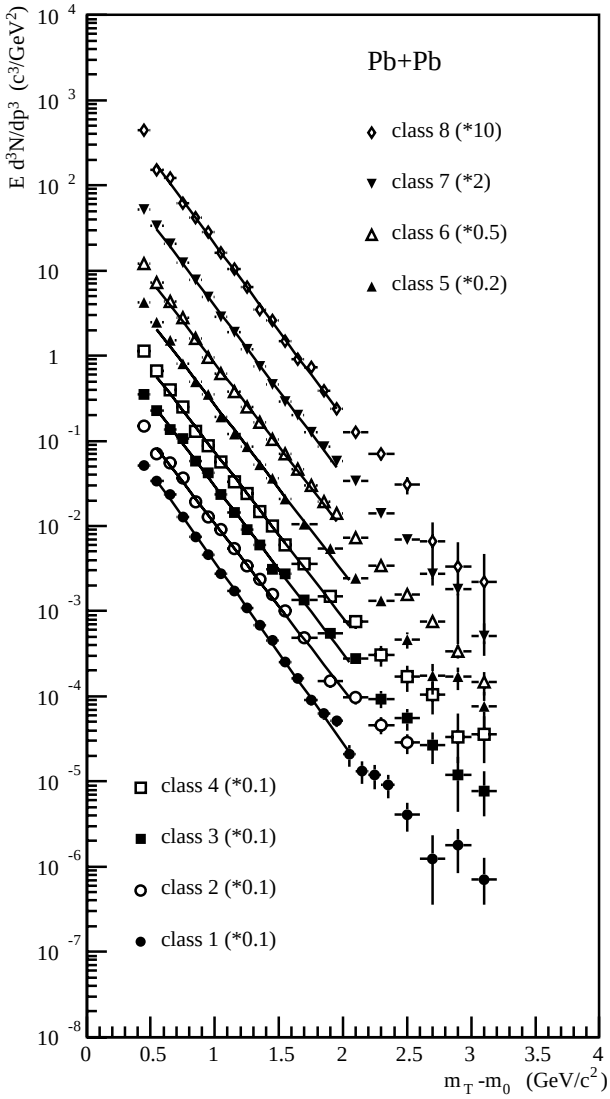

Fig. 7. Invariant multiplicities of neutral pions for Pb + Pb collisions of different centralities as a function of $m_T - m_0$. The solid lines show exponential fits to the spectra

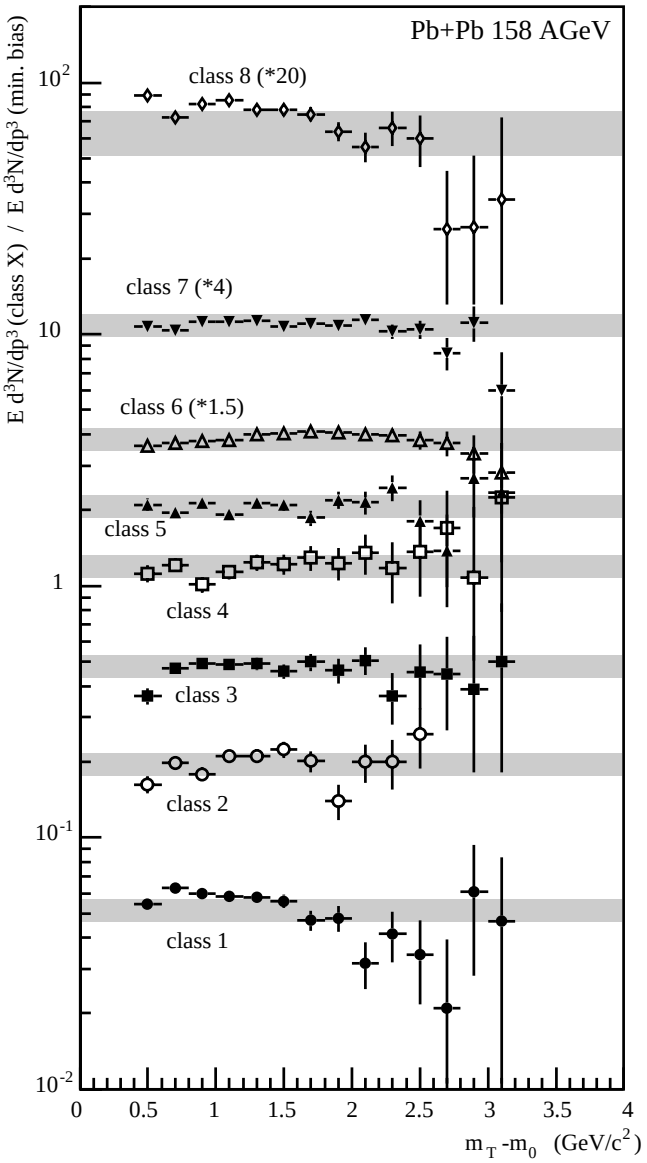

Fig. 8. Ratios of invariant multiplicities of neutral pions for Pb + Pb collisions of different centralities to minimum bias distributions as a function of $m_T - m_0$, with class 1 being the most peripheral and class 8 the most central sample. The grey bands show the estimate of the centrality dependent systematic error

imum bias spectrum. Still in these ratios no drastic variations are seen when displayed in logarithmic scale. The spectral shapes, especially for the intermediate centrality classes, are very similar. The spectra are broadened when going from peripheral reactions to semi-peripheral reactions, consistent with the nuclear enhancement seen in p + A [7] and in S + Au collisions [6]. However, the enhancement does not continue to grow for central collisions. Instead there is an indication of a stronger fall off in the most central class.

This observation is surprising, because both initial state (parton multiple scattering) and final state (hadron rescattering) mechanisms are expected to yield a further broadening of the spectra with decreasing impact parameter, i.e. increasing thickness or volume.

The change in the spectrum for the most stringent centrality selection of 1% of the minimum bias cross section appears to be relatively strong, and the question arises whether this cut is really significant enough and whether this sample should not behave similarly to the adjacent sample. We have therefore performed detailed investigations of possible backgrounds and biases with respect to this particular sample. Pile-up of multiple beam interactions is effectively suppressed by strong time and amplitude cuts on the trigger level. In addition, the total calorimeter coverage of MIRAC and the ZDC is sufficient to reject all possible pile-up events, as the measured energy would exceed the beam energy.

Also, simulations of the centrality selections including realtistic fluctuations in the detectors show that e.g. classes 7 and 8 are significantly different. This can e.g.

Table 1. Centrality classes, as selected by the amount of transverse energy measured in MIRAC, for Pb + Pb collisions. The average number of participants and binary nucleon-nucleon collisions as calculated with VENUS 4.12 with an estimate of the systematic error. Please note that the systematic error in the number of collisions is correlated for all samples

class	E_T (GeV)	$\sigma/\sigma_{\rm mb}$	$\langle N_{part}\rangle$	$\langle N_{coll}\rangle$
1	$\leq$ 24.35	17.2%	12 ± 2	9.9 ± 2.5
2	24.35 – 55.45	15.8%	30 ± 2	30 ± 5
3	55.45 –114.85	18.2%	63 ± 2	78 ± 12
4	114.85 –237.35	23.5%	132 ± 3	207 ± 21
5	237.35 –326.05	12.3%	224 ± 1	408 ± 41
6	326.05 –380.35	6.2%	290 ± 2	569 ± 57
7	380.35 –443.20	5.8%	346 ± 1	712 ± 71
8	>443.20	1.0%	380 ± 1	807 ± 81
6–8	>326.05	12.7%	323 ± 1	651 ± 65

be expressed by the mean (rms) of the distribution of the number of participating nucleons which are 346 (20) and 380 (10), respectively.

As the centrality selection is performed with the transverse energy measured slightly off midrapidity, one might suspect that midrapidity particle production could suffer a different bias, if e.g. the pseudorapidity distribution would change significantly over the small range relevant here. This is, however, not observed. The charged particle pseudorapidity density at $\eta = 0$ increases in a fashion identical to the transverse energy as can be seen in [31].

While this leads us to expect no additional bias from the event selection, the direct comparison of the spectra obtained with different analysis cuts for the most central sample (class 8) shows slightly larger variations than the other samples. We have therefore assigned a larger systematic error of 20% to this sample, as was discussed in Sect. 3.

4.2 Average p_T and inverse slopes

Another means to characterize the spectral shape is via the average transverse momentum $\langle p_T\rangle$, or via the inverse slopes T of the spectra. The truncated average transverse momentum has already been presented in [17], where it was shown that the values of $\langle p_T(p_T^{min})\rangle$, with a lower cutoff of $p_T^{min} = 0.4\,\mathrm{GeV}/c^2$, increase from peripheral to medium central collisions but seem to saturate for still smaller impact parameters. Since the $\langle p_T(p_T^{min})\rangle$ is dominated by the momentum region near the cutoff, this is not in contradiction with the dependence observed in Fig. 8. A similar analysis has been performed with inverse slope parameters which were obtained by fitting exponentials (1) to the spectra in limited regions of transverse mass. The extracted slope parameters as a function of the number of participants are shown in Fig. 9. Fits in the lowest m_T interval yield a slope of $T = 204\,\mathrm{MeV}$ for peripheral reactions. In the intermediate centrality range the slope appears to be constant at $T \approx 220\,\mathrm{MeV}$.

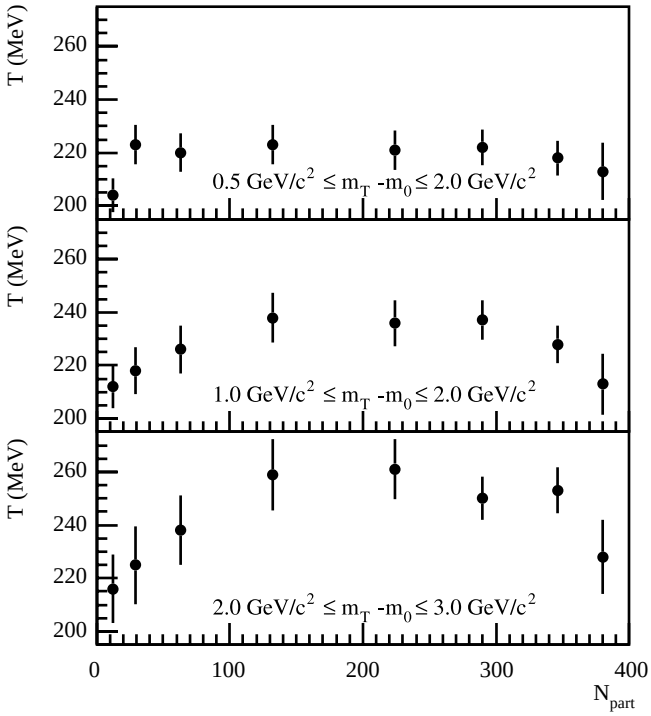

Fig. 9. Inverse slope parameters T of neutral pion transverse mass distributions as a function of the number of participants in Pb + Pb collisions. The exponential fits are performed in different regions $m_T - m_0$ as indicated. The error bars shown contain statistical and systematic errors added in quadrature

Inverse slopes have also been extracted for other intervals of transverse mass (see Fig. 9). For all centralities the slopes increase with larger transverse mass, which is another demonstration of the curvature of the spectra. The centrality dependence is more pronounced for the higher m_T regions ($1 - 2$ GeV/c^2 and $2 - 3$ GeV/c^2). There is a continuous rise in the inverse slope from very peripheral reactions up to reactions with $N_{part} \approx 130$, the highest slopes reaching $T \approx 240\,\mathrm{MeV}$ and $T \approx 260\,\mathrm{MeV}$, respectively. There is an indication of a decrease in the slope for very central collisions which is however not conclusive in view of the systematic errors.

From this analysis of the spectral shapes by looking at spectral ratios or inverse slopes one may conclude, that apart from the broadening in going from peripheral to semi-peripheral collisions, no striking features are observed. Apparently these analysis tools are not suited to extract information on possible more subtle variations.

4.3 Scaling with system size

In addition to variations of the shape of the momentum spectra it is of interest to study the variations in absolute multiplicities. Especially at high transverse momentum one naïvely expects an increase of the cross section proportional to the mass number of the nuclei and, correspondingly, an increase of the multiplicity proportional to the number of binary collisions due to the importance

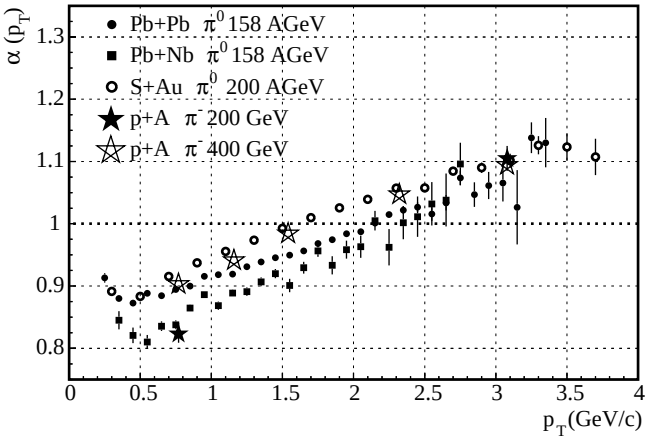

Fig. 10. Exponent α of the mass dependence of neutral pion cross sections as a function of transverse momentum. Values are obtained from ratios of minimum bias Pb + Pb and Pb + Nb collisions to a parameterization of p+p collisions. Included for comparison are results for S+Au collisions at 200·AGeV [6] and the proton induced data from [7]

of hard scattering. In fact, it was already observed in pA collisions at beam energies of $200 - 400\,\mathrm{GeV}$ [7] that the increase in cross section at high transverse momenta is even stronger than the increase in the target mass.

This behaviour can be investigated by parameterizing the data according to the phenomenological expression:

$$E\frac{d^3\sigma}{dp^3}(\mathrm{A+B}) = (A\cdot B)^{\alpha(p_T)}\, E\frac{d^3\sigma}{dp^3}(\mathrm{p+p}), \qquad (2)$$

where A and B are the mass numbers of the projectile and target nuclei. For this purpose the experimental data have been compared to a parameterization [26] of pp reactions [32–39] scaled to the same $\sqrt{s}$:

$$E\frac{d^3N}{dp^3} = C\cdot\left(\frac{p_0}{p_T+p_0}\right)^n, \qquad (3)$$

with $C = 4.125c^3/\mathrm{GeV}^2$, $p_0 = 9.02\,\mathrm{GeV}/c$ and $n = 55.77$. We have assigned a systematic error of 20% to this reference distribution. The values of the exponents α for minimum bias reactions of Pb+Pb and Pb+Nb are shown in Fig. 10. Included for comparison are results for S+Au collisions at 200·AGeV [6] and the proton induced data from [7]. All data follow the same trend, i.e. the exponent is considerably lower than one for low transverse momenta and increases monotonically with p_T finally reaching values > 1 for high p_T. However, the values differ by about 10% for the different systems and the point where they cross the line $\alpha = 1$ ranges from $p_T = 1.5\,\mathrm{GeV}/c^2$ to $2.5\,\mathrm{GeV}/c^2$. It should be noted that the different experimental trigger biases may influence these results.

This form of scaling analysis is only applicable to minimum bias reactions. To study the scaling behaviour for heavy ion reactions of different centralities the scaling with the number of participants or nucleon-nucleon collisions is more appropriate. An analysis of the scaling of the charged multiplicity with the number of participants has been performed in [40]. A more general analysis of the scaling behaviour of transverse energy and particle production in Pb + Pb collisions has been presented in [31] and the scaling of neutral pion production with the number of participants in [17]. For the present paper the number of participants and collisions have been obtained as described in [31]. The values are given in Table 1. The systematic errors of these quantities have been obtained by comparing calculations with different assumptions. In addition to VENUS and FRITIOF calculations with default parameter settings, we have investigated VENUS calculations with a modified nuclear density distribution, with a significantly worsened energy resolution of the calorimeter, with different assumptions on the size of the minimum bias cross section and ignoring the target-out contribution. These calculations are described in [31]. Moreover we have also investigated independently results of a toy model calculation of nuclear geometry and also the influence of modest variations of the nucleon-nucleon cross section entering into the calculations. The maximum deviation of any of these other calculations from the default one is within the error given in Table 1. As expected, the relative error is largest in the most peripheral sample. This is due to the uncertainty in modelling the E_T-fluctuations and the trigger threshold —effects which have been included in our error estimate.

It should be noted that the most peripheral data set in this analysis does not correspond to the most peripheral collisions theoretically possible from nuclear geometry, as they are rejected by the minimum bias trigger. Our minimum bias trigger cross section of $\approx$ 6300 mb corresponds to $\approx$ 85% of the expected total geometrical cross section. The more peripheral reactions rejected by our trigger would of course have a still larger uncertainty due to e.g. the uncertainties in the nuclear density distribution. In our samples the error is still at a reasonable level as quoted in the table.

Furthermore, the error in ratios of e.g. the number of collisions for different samples is considerably smaller, since some of the systematic effects are correlated, as is obvious e.g. for the size of the nucleon-nucleon cross section.

The scaling of the neutral pion production is analyzed both as a function of the number of collisions and as function of the number of participants. As in the earlier publications the yield is parameterized as:

$$E\frac{d^3N}{dp^3}(N_{part}) \propto (N_{part})^{\alpha_p} \qquad (4)$$

or

$$E\frac{d^3N}{dp^3}(N_{coll}) \propto (N_{coll})^{\alpha_c}. \qquad (5)$$

The results are presented in Fig. 11 where the upper panel shows the scaling with the number of participants and the lower panel with the number of collisions. The open circles represent the exponents calculated from the ratio of semi-peripheral collisions (class 2) to the parameterization of pp collisions (3). In this case a behaviour very similar

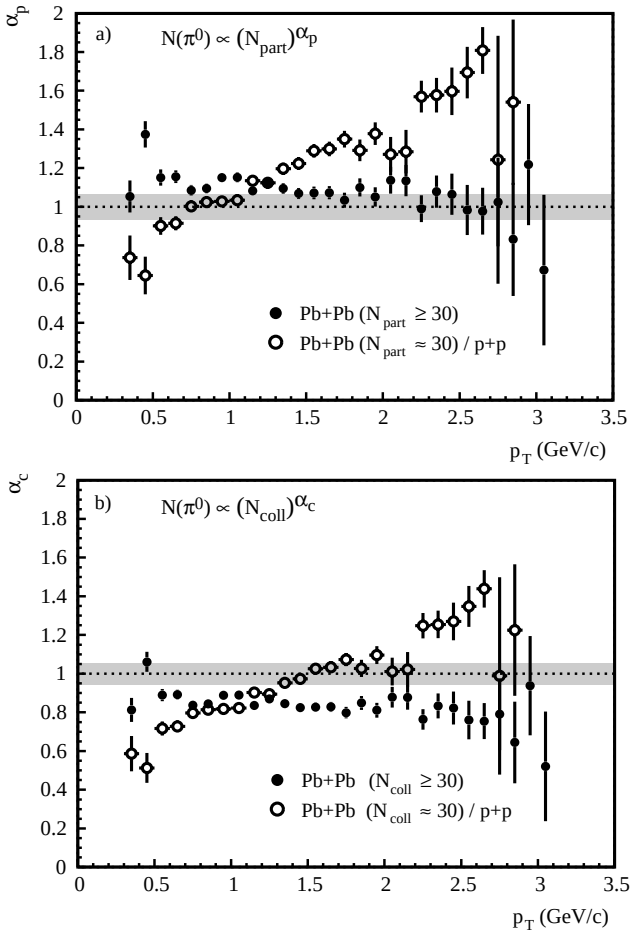

Fig. 11a,b. Exponent α of neutral pion transverse mass distributions parameterized as a function of the number of participants **a** and collisions **b** in Pb + Pb collisions. The exponents are shown as a function of p_T. The open circles are obtained from the ratio of semi-peripheral Pb+Pb data to p+p data, while for the filled circles fits of a power law to the seven most central classes are performed. The grey bands indicate the systematic error relevant for this fit from the calculation of the number of participants and collisions and from the centrality dependent systematic error of the neutral pion multiplicity. The error bars are only statistical

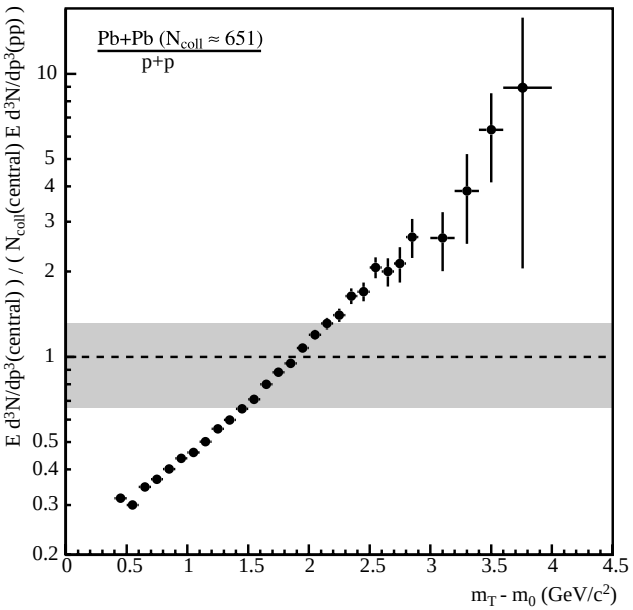

Fig. 12. Ratios of invariant multiplicity distributions of neutral pions for central Pb+Pb reactions to the parameterization of p+p reactions normalized to the number of binary collisions, also called the nuclear modification factor. The grey band shows the estimate of the systematic error due to the calculation of the number of collisions and the absolute cross section normalization relative to p+p

to the original Cronin-effect is observed: The exponents increase monotonically with increasing p_T reaching values > 1 for large p_T. A scaling of the particle yields with $(N_{coll})^{\alpha_c=1}$ is equivalent to a scaling of the minimum bias cross sections with $A^{\alpha=1}$. This value is reached in Fig. 11b at $p_T \approx 1.5\,\mathrm{GeV}/c^2$, similar to where the scaling exponents of the p+A and S+Au data in Fig. 10 reach the value of 1. However, the minimum bias Pb+Pb data in Fig. 10 show a weaker scaling exponent at intermediate and higher p_T.

Fits to the centrality classes 2-8 (displayed as filled circles in Fig. 11), i.e. up to the most central collisions, show almost constant exponents for all transverse momenta. In fact, the values even indicate a slight decrease with increasing p_T. At the highest p_T the exponents appear to be $\alpha_p \approx 1$ and $\alpha_c \approx 0.8$. They are considerably below the scaling exponents for semi-peripheral Pb+Pb relative to p+p. Noticeably the scaling exponent α_c is also significantly below the value of 1 expected as a naïve scaling for hard scatterings.

Ratios of the measured pion multiplicity distributions for two different samples (labeled X and Y) normalized to the number of collisions given in Table 1:

$$R_{XY}(m_T) \equiv \frac{\left(E\frac{d^3N}{dp^3}(m_T)/N_{coll}\right)_X}{\left(E\frac{d^3N}{dp^3}(m_T)/N_{coll}\right)_Y} \qquad (6)$$

are shown in Figs. 12, 13 and 14. In Fig. 12 the ratio of the 12.7% most central collisions to the parameterization of p+p is shown:

$$R_X(m_T) \equiv \frac{\left(E\frac{d^3N}{dp^3}(m_T)/N_{coll}\right)_X}{\left(E\frac{d^3N}{dp^3}(m_T)\right)_{pp}}. \qquad (7)$$

This special case of (6) is sometimes referred to as the *nuclear modification factor* [42]. The ratio is ≈ 0.3 at low m_T and increases exponentially towards higher m_T approaching values close to 10 [1]. This is in line with the earlier

[1] The same ratio for central Pb+Pb(Au) collisions is shown in [42]. There a curve is drawn which saturates at $R = 2$ for high p_T. It is actually dominated by data points at $p_T = 2 - 3\,\mathrm{GeV}/c$, and the WA98 data points can be seen to lie above the curve at high p_T. Remaining differences in the two figures might be due to different estimates for the pp-spectra being used in the ratios

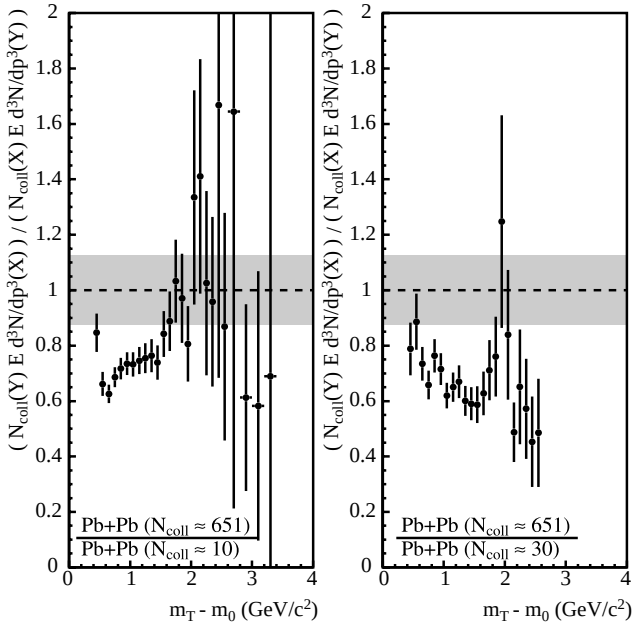

Fig. 13. Ratios of invariant multiplicity distributions of neutral pions for central to peripheral Pb+Pb collisions normalized to the number of binary collisions. The left plot shows the ratio using the most peripheral sample, the right plot a similar ratio with the second most peripheral sample. The grey bands show the estimate of the systematic error due to the calculation of the number of collisions and due to the systematic error in the π^0 distribution

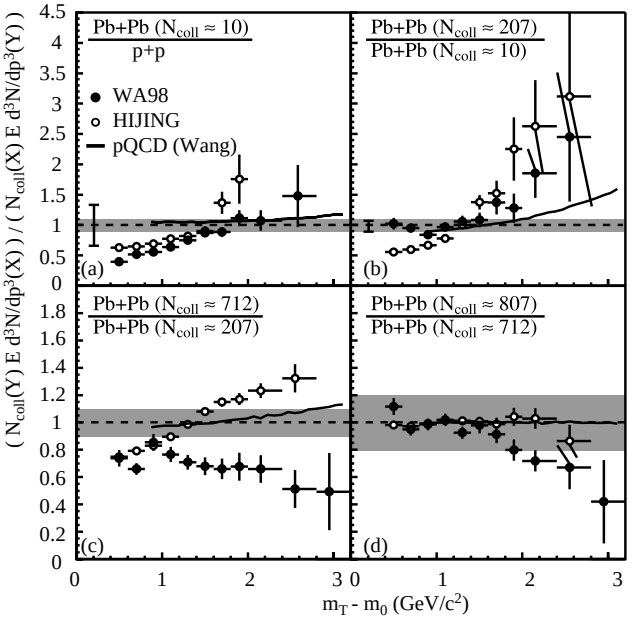

Fig. 14a–d. Ratios of invariant multiplicity distributions of neutral pions normalized to the number of binary collisions. The upper left plot **a** shows the ratio of peripheral Pb+Pb collisions to the parameterization of p+p [3]. The other plots **b**–**d** show different ratios of a more central sample to a more peripheral sample of Pb+Pb collisions. The filled circles show the experimental results, the open circles are results from the HIJING event generator and the solid lines similar ratios from pQCD calculations including p_T broadening [42]. The grey bands show the estimate of the systematic error due to the systematic error in the π^0 distribution. The additional error bar in **a** and **b** shows the normalization uncertainty due to the calculation of the number of collisions and the absolute cross section normalization relative to p+p

observations and demonstrates again that relative to p+p reactions there is a strong Cronin effect in heavy ion collisions for all centralities. However, as evident from Fig. 11b, most of the anomalous enhancement is already present in peripheral reactions, and the additional enhancement in central reactions is much weaker. In the following we will concentrate on this particular observation.

Figure 13 shows ratios of the 12.7% most central collisions to the two most peripheral samples. Both ratios are below 1 for low m_T. In comparison to the most peripheral sample (left part) the spectra are compatible with a scaling with the number of collisions in central reactions at higher m_T, while relative to the semi-peripheral class (right part) the enhancement is significantly weaker even at high m_T. Similar ratios for more detailed centrality selections are shown in Fig. 14. The ratio of peripheral Pb+Pb collisions to p+p (3) (Fig. 14a) increases strongly with increasing transverse mass – this is in line with the Cronin effect discussed above. A similar trend is observed when going from peripheral to medium-central data (Fig. 14b). In addition, the pion production is seen to increase roughly proportional to the number of collisions even at low transverse masses. Going from medium central to central (Fig. 14c) the trend is reversed: the ratio decreases with increasing transverse mass as was already seen in Fig. 8 and the pion multiplicities increase more weakly than the number of collisions. The ratio of very central to central collisions shows an indication of a similar effect although not very significant.

Included in Fig. 14 are results of HIJING calculations (open circles) for the same centralities. They show a very different trend: For all but the most central case the ratios increase with increasing transverse mass, for high transverse masses the ratio is always larger than one. HIJING does not describe p+p data well at these energies while a reasonable description of central Pb+Pb collisions is obtained by an implementation of the Cronin effect via a soft transverse momentum kick model which introduces a very strong A dependence, as was pointed out already in [41]. Thus the reasonable description of central Pb+Pb collisions by HIJING appears to be fortuitous. The authors of [41] stated that a better implementation of the Cronin effect should use an additional intrinsic p_T of the incoming partons and a likely weaker p_T broadening. Still, in any model of the Cronin effect one would expect the ratios of central to less central spectra, as shown in Fig. 14c, to be larger than one at high transverse mass. Similarly, one would expect the scaling exponent shown in Fig. 11 to be $\alpha_c > 1$ at high transverse momentum. A more refined calculation including intrinsic p_T was performed in [42] using the same model as in [18]. The results are also shown in Fig. 14 as solid lines. As expected, the ratios show a

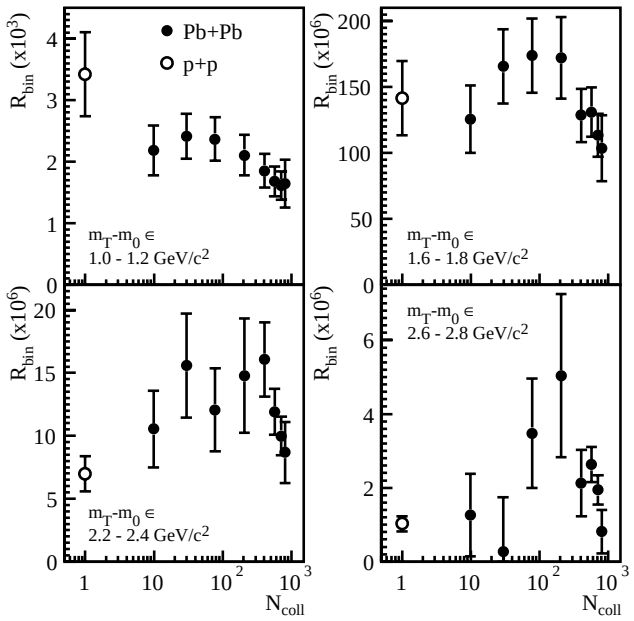

Fig. 15. Multiplicities of neutral pions normalized to the number of binary collisions $R_{bin} = (Ed^3N/dp^3)/N_{coll}$ as a function of N_{coll} for different ranges of transverse mass as indicated in the pictures. The filled circles show the experimental results for Pb+Pb reactions, the open circles the parameterization for p+p reactions (3). The error bars contain statistical and systematic errors added in quadrature

weaker increase at high m_T compared to HIJING, but are all ≥ 1 and thus do not explain the centrality dependence as seen in Fig. 14c.

With these observations in mind one can revisit the evolution of the particle yields with system size at given transverse mass. This is done in Fig. 15 where the neutral pion yield per binary collision:

$$R_{bin} \equiv E\frac{d^3N}{dp^3}/N_{coll} \tag{8}$$

is shown as a function of the number of collisions for four different transverse mass intervals. In addition to Pb+Pb reactions also the parameterization of p+p is included. At relatively low transverse mass the yield per collision decreases as expected from the scaling exponent $\alpha_c < 1$. With increasing transverse mass a rise of R_{bin} develops which is most prominent for the highest m_T. However, it is also clear that R_{bin} decreases significantly with N_{coll} for $N_{coll} > 200$. The exact point of turnover of the evolution of the pion yields could not be so easily observed in the investigation of the scaling exponents above – it is much more clearly born out when normalizing to the number of binary collisions as in R_{bin}.

5 Summary

We have presented transverse mass spectra of neutral pions in Pb+Pb reactions at 158·A GeV for different centralities. A comparison to several event generators found none of them able to adequately describe the spectra.

While there is a strong broadening of the transverse mass spectra in going from p+p to peripheral Pb+Pb reactions, and further to semi-peripheral reactions, there is an indication of a stronger fall off of the spectra when going to the most central selections. The absolute yields at high transverse momenta show an enhancement which grows stronger than with the number of collisions up to medium central Pb+Pb collisions, which is qualitatively similar to the Cronin effect observed in p+A collisions. For central collisions, however, the further increase in multiplicity at high p_T is weaker than with the number of collisions. This is in qualitative contradiction to conventional explanations of the Cronin effect (p_T-broadening) which is expected to cause a further strengthening of the nuclear enhancement with more central collisions. As a possible explanation of this behaviour one may consider that the multiple scattering mechanisms which are expected to be responsible for the apparent p_T-broadening in pA and peripheral Pb+Pb might be modified in central Pb+Pb collisions. This might be possible if both *initial* and *final* state scatterings are relevant for the enhancement, and the relative contributions are shifted more towards final state contributions in central collisions, reminiscent of a more and more thermalized system. Alternative explanations might involve suppression mechanisms independent of the nuclear enhancement in question, e.g. an onset of quenching via energy loss of produced particles (partons or hadrons) in central Pb+Pb collisions.

Acknowledgements. We wish to express our gratitude to the CERN accelerator division for excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians and support staff who have participated in the construction of the experiment. This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR and FRN, the Dutch Stichting FOM, the Polish KBN under Contract No 621/E-78/SPUB-M/CERN/P-03/DZ211/, the Grant Agency of the Czech Republic under contract No. 202/95/0217, the Department of Atomic Energy, the Department of Science and Technology, the Council of Scientific and Industrial Research and the University Grants Commission of the Government of India, the Indo-FRG Exchange Program, the PPE division of CERN, the Swiss National Fund, the INTAS under Contract INTAS-97-0158, ORISE, Research-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science and Culture, the University of Tsukuba Special Research Projects, and the JSPS Research Fellowships for Young Scientists. ORNL is managed by Lockheed Martin Energy Research Corporation under contract DE-AC05-96OR22464 with the U.S. Department of Energy. The MIT group has been supported by the US Dept. of Energy under the cooperative agreement DE-FC02-94ER40818.

(Received 18 April 2001; published 17 July 2001)

The first measurement of energy produced transverse to the beam direction at the Relativistic Heavy-Ion Collider at Brookhaven National Laboratory is presented. The midrapidity transverse energy density per participating nucleon rises steadily with the number of participants, closely paralleling the rise in charged-particle density, such that $\langle E_T\rangle/\langle N_{ch}\rangle$ remains relatively constant as a function of centrality. The energy density calculated via Bjorken's prescription for the 2% most central Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV is at least $\epsilon_{Bj} = 4.6\ \mathrm{GeV/fm^3}$, which is a factor of 1.6 larger than found at $\sqrt{s_{NN}} = 17.2$ GeV (Pb + Pb at CERN).

DOI: 10.1103/PhysRevLett.87.052301 PACS numbers: 25.75.–q, 12.38.Mh, 13.60.Le, 13.85.Hd

The PHENIX detector [1] at RHIC, the Relativistic Heavy-Ion Collider at Brookhaven National Laboratory, is designed to measure the properties of nuclear matter at the highest temperatures and energy densities. For example, a transition to a quark-gluon plasma has been predicted for energy densities on the order of a few $\mathrm{GeV/fm^3}$ [2]. The spatial energy density (ϵ) in a relativistic collision can be estimated (following Bjorken [3]) by measuring the transverse energy density in rapidity, dE_T/dy, which is effectively the comoving energy density in a longitudinal expansion:

$$\epsilon_{Bj} = \frac{dE_T}{dy}\,\frac{1}{\tau_0 \pi R^2}\,, \tag{1}$$

where τ_0, the formation time, is usually taken as 1 fm/c, and πR^2 is the effective area of the collision. The transverse energy (E_T) is a multiparticle variable defined as

$$\begin{aligned} E_T &= \sum_i E_i \sin\theta_i\,, \\ dE_T(\eta)/d\eta &= \sin\theta(\eta)\, dE(\eta)/d\eta\,, \end{aligned} \tag{2}$$

where θ is the polar angle, $\eta = -\ln\tan\theta/2$ is the pseudorapidity, E_i is by convention taken as the kinetic energy for nucleons and the total energy for all other particles [4], and the sum is taken over all particles emitted into a fixed solid angle for each event. E_T measurements, even in limited apertures at midrapidity, provide excellent characterization of the nuclear geometry of a reaction on an event-by-event basis and are sensitive to the underlying reaction dynamics [2].

During the RHIC run in the summer of 2000, PHENIX accumulated close to 5×10^6 interaction triggers for Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV using zero degree calorimeters and beam-beam counters (BBC) as triggering devices. The events were selected with a requirement on the collision vertex position along the beam axis, $|z| \leq 20$ cm, as in the recent PHENIX publication on midrapidity multiplicity distributions [5], where further details are given.

The present measurement uses a section of the electromagnetic calorimeter (EMCal) from the PHENIX central spectrometer, with front face 5.1 m from the beam axis. This section is part of a sampling calorimeter, custom developed and built for PHENIX [6], composed of alternating Pb and scintillator tiles (PbSc) with readout of individual towers, 5.54×5.54 cm^2 in cross section, via wavelength shifting fibers in a "shashlik" geometry. The depth of the PbSc calorimeter is 18 radiation lengths (X_0) which corresponds to 0.85 interaction lengths. The PbSc calorimeter has an energy resolution of $8.2\%/\sqrt{E(\mathrm{GeV})} \oplus 1.9\%$ for test beam electrons, with measured response proportional to incident electron energy to within $\pm 2\%$ over the range $0.3 \leq E_e \leq 40.0$ GeV [6].

During construction, the calibration of the calorimeter was set by simultaneously recording the response to laser excitation and to cosmic-ray muons penetrating transversely to the tower axis. The calibration was maintained *in situ* during the run by monitoring relativistic charged particles from Au + Au collisions. The absolute energy scale was determined by test-beam measurements normalized to electrons with known energy. A final adjustment of the absolute energy scale was performed using *in situ* identified electrons ($p > 500$ MeV/c) by shifting the originally measured energy/momentum (E/p) peak from 1.02 ± 0.01 to 1.00. The accuracy of the absolute energy scale was cross-checked *in situ* against both the minimum ionizing peak (MIP) of charged particles penetrating along the tower axis and the mass of the π^0. The corrected energy distribution of EMCal clusters from 1.0 ± 0.1 GeV/c charged tracks (mostly pions) measured in the drift chamber [1] exhibits a clear MIP (Fig. 1a), as well as energy due to nuclear interactions in the material of the EMCal. The MIP position is in agreement within 2% to the value obtained in the test beam (270 MeV). The mass of the π^0, reconstructed from pairs of EMCal clusters (assumed to be photons [7]) of total energy greater than 2 GeV (Fig. 1b), is within 1.5% of the published value. This sets the systematic error of the absolute energy scale at less than 1.5%.

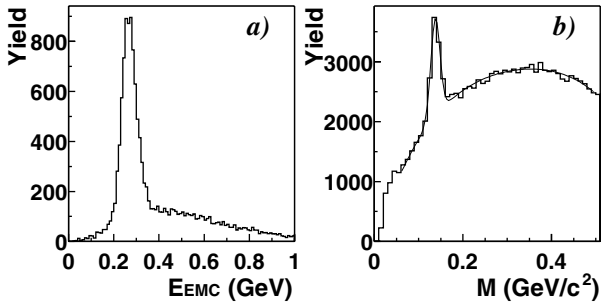

FIG. 1. (a) The distribution of EMCal clusters corresponding to 1 GeV/c charged tracks (mostly pions) from Au + Au collisions. (b) The reconstructed π^0 mass from pairs of EMCal clusters with total energy >2 GeV.

The data sample for the present E_T measurement is taken from the same runs used in our multiplicity measurement [5] (no magnetic field) and comprises about 140 000 events from the BBC trigger which detects $[92 \pm 2(\mathrm{syst})]\%$ of the nuclear interaction cross section of 7.2 b with a background contamination of $[1 \pm 1(\mathrm{syst})]\%$ [5]. The transverse energy was measured using the PbSc EMCal in a fiducial aperture $|\eta| \leq 0.38$ in pseudorapidity and $\Delta\phi = 44.4°$ in azimuth. E_T was computed for each event [Eq. (2)] using clusters of energy greater than 20 MeV, composed of adjacent towers with deposited energy of more than 3 MeV. The angle θ_i is computed from the centroid of the cluster of energy E_i assuming a particle originating from the event vertex.

The raw spectrum of measured transverse energy, $E_{T\mathrm{EMC}}$, in the fiducial aperture of the PHENIX EMCal for Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV is shown in Fig. 2, upper scale. The lower scale in Fig. 2 represents a correction of the raw $E_{T\mathrm{EMC}}$ by a factor of 12.8 to correspond to the hadronic $dE_T/d\eta|_{\eta=0}$ in the full azimuth. The 12.8 is composed of a factor of 10.6 for the fiducial acceptance, a factor of 1.03 for disabled calorimeter towers and a factor, $k = 1.17 \pm 0.01$, which is the ratio of the hadronic E_T in the fiducial aperture to the measured $E_{T\mathrm{EMC}}$. The k factor includes the response of the detector to charged and neutral particles emitted from the event vertex into the fiducial aperture, and additional corrections for energy inflow from outside the fiducial aperture and for losses [8]. These factors were calculated with a GEANT [9] based Monte Carlo (MC) simulation of the detector using HIJING as the event generator [10].

For E_T measurements at midrapidity at a collider, the EMCal acts as a thin but effective hadronic calorimeter. Charged pions with $p_T \leq 0.35$ GeV/c, kaons ($p_T \leq 0.64$ GeV/c), and protons ($p_T \leq 0.94$ GeV/c)—p_T values which are near or above the $\langle p_T \rangle$ for all three cases—stop (i.e., deposit all their kinetic energy) in the EMCal. For higher p_T hadrons, 43% leave the MIP and 57% interact, leaving an average of ~65% of their energy.

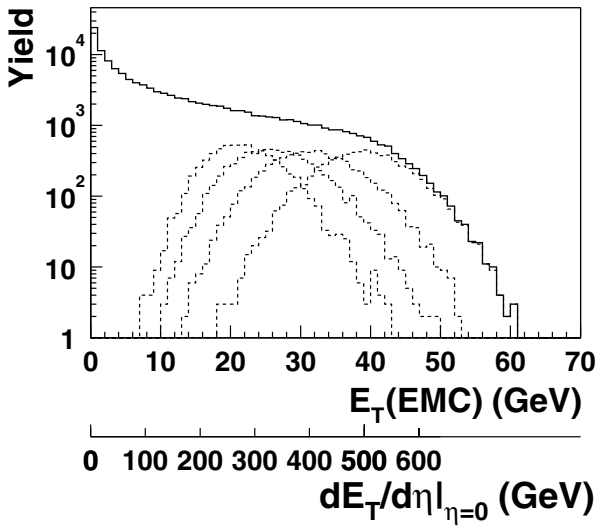

FIG. 2. The raw $E_{T\mathrm{EMC}}$ distribution measured in the $\Delta\phi = 44.4°$ azimuthal and $|\eta| \leq 0.38$ polar angle fiducial acceptance for Au + Au at $\sqrt{s_{NN}} = 130$ GeV (upper scale) and total hadronic $dE_T/d\eta|_{\eta=0}$ (lower scale); see text. The solid line is the minimum bias distribution with the BBC trigger; the dashed lines correspond to the distributions for the four most central bins in Table I.

The measured $E_{T\mathrm{EMC}}$ is 0.79 ± 0.01 of the total E_T striking the EMCal, which is composed roughly of 40% produced by charged pions, 40% by photons (from π^0 and other decays), and 20% by all other particles (including decay muons). The particle composition and $\langle p_T \rangle$ in HIJING are close to the observed values, and furthermore, the k factor is insensitive to reasonable variations (for instance, varying the momenta of all particles by $\pm 15\%$ changes the overall k by less than $\pm 2\%$), leading to an estimated systematic uncertainty in k of less than $\pm 3\%$ due to particle composition and momentum.

The main issues for the MC are the inflow contribution and losses. The losses are due to particles which originate within the aperture but whose decay products miss the EMCal (10%), or whose energy is lost due to edge effects (6%) or clustering (2%). The inflow, $(24 \pm 1)\%$ of the E_T striking the EMCal, is principally of two types: (i) albedo from the magnet poles and (ii) particles which originate outside the aperture of the calorimeter but whose decay products hit the calorimeter. The inflow component of k was checked by comparing the MC and the measurements for events with a vertex outside the normal range, just at and inside a pole face of the axial central-spectrometer magnet, $38 \leq z \leq 42$ cm, for which the calorimeter aperture is partly shadowed. The fraction of the total energy, $dE_{\mathrm{EMC}}/E_{\mathrm{EMC}}$, in bins of width 2 towers along the z coordinate of the EMCal, z_{EMC}, is shown in Fig. 3a. The HIJING MC simulation agrees with the measured data everywhere except in the range $z_{\mathrm{EMC}} > 100$ cm, which is fully shadowed by the pole, where the simulation shows $\sim 20\%$ less energy than the data. In Fig. 3b, the distributions of the cluster energy, E_{cl}, for the open aperture, $z_{\mathrm{EMC}} < -50$ cm, are shown for both HIJING and the data and are in excellent agreement. The inflow component of HIJING is also indicated as a dotted line and falls much more sharply than the total E_{cl} spectrum. The residual discrepancy of the energy in the shadowed region, which contributes roughly 10% of the total signal, results in a $\pm(2 - 3)\%$ systematic uncertainty in E_T due to the uncertainty in the inflow. Combining this with the uncertainty due to particle composition and momentum yields an overall factor $k = [1.17 \pm 0.01] \pm 4\%$ (syst), which, according to the MC, is independent of centrality.

Returning to Fig. 2, the shape of the measured transverse energy spectrum shows the characteristic form of E_T distributions in limited apertures: a peak and a sharp dropoff at low values of E_T corresponding to peripheral collisions with grazing impact; a broad, gently sloping plateau at the midrange of impact parameters, dominated by the nuclear geometry; and then at higher values of E_T, which correspond to the most central collisions where the nuclei are fully overlapped, a "knee" leading to a falloff which is very steep for large apertures and which becomes less steep, the smaller the aperture [11]. It should be emphasized that the correction of $E_{T\mathrm{EMC}}$ to $dE_T/d\eta|_{\eta=0}$

TABLE I. Average transverse energy density vs centrality. The statistical errors are negligible. Errors on $\langle dE_T/d\eta|_{\eta=0} \rangle$ are the N_{part}-dependent systematic errors from the uncertainty of the BBC cross section [5] such that all points move together. There is an additional overall (N_{part}-independent) systematic uncertainty of $\pm 4.5\%$.

Centrality	$\langle dE_T/d\eta|_{\eta=0} \rangle$ (GeV)	$\langle dN_{ch}/d\eta|_{\eta=0} \rangle$ [5]	$\langle N_{\mathrm{part}} \rangle$ [5]
0%–5%	503 ± 2	622 ± 41	347 ± 10
5%–10%	409 ± 4	498 ± 31	293 ± 9
10%–15%	340 ± 5	413 ± 25	248 ± 8
15%–20%	283 ± 7	344 ± 21	211 ± 7
20%–25%	233 ± 7	287 ± 18	177 ± 7
25%–30%	191 ± 8	235 ± 16	146 ± 6
30%–35%	154 ± 8	188 ± 14	122 ± 5
35%–40%	123 ± 7	147 ± 12	99 ± 5
40%–45%	98 ± 7	115 ± 11	82 ± 5
45%–50%	76 ± 6	89 ± 9	68 ± 4

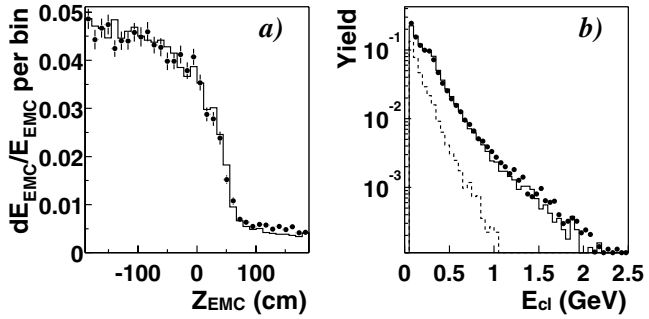

FIG. 3. (a) The fraction of $E_{T\mathrm{EMC}}$ in bins of 11.08 cm along the EMCal z_{EMC} direction for event vertex near a pole face; histogram from MC simulation and solid points from beam data. (b) EMCal cluster energy spectrum from HIJING MC (solid line), with inflow component (dotted line) compared to data (solid points).

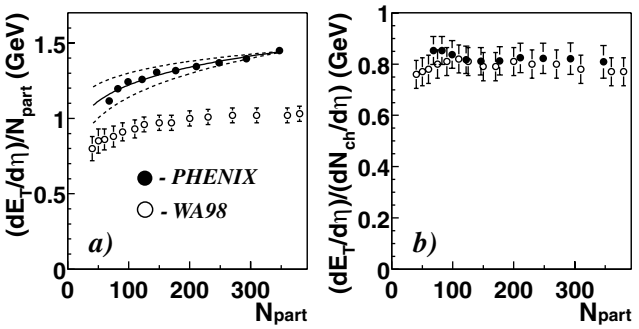

FIG. 4. (a) PHENIX transverse energy density per participant $dE_T/d\eta|_{\eta=0}/N_{\mathrm{part}}$ for Au + Au collisions at $\sqrt{s_{NN}} =$ 130 GeV as a function of N_{part}, the number of participants, compared to data from WA98 [12] for Pb + Pb collisions at $\sqrt{s_{NN}} = 17.2$ GeV. The solid line is the $N_{\mathrm{part}}^{\alpha}$ best fit and the dashed lines represent the effect of the $\pm 1\sigma$ N_{part}-dependent systematic errors for $dE_T/d\eta|_{\eta=0}$ and N_{part}. There is an additional overall (N_{part}-independent) systematic uncertainty of $\pm 4.5\%$ from $dE_T/d\eta|_{\eta=0}$ and $\pm 2.0\%$ from N_{part}. (b) PHENIX $dE_T/d\eta|_{\eta=0}/dN_{ch}/d\eta|_{\eta=0}$ versus N_{part}, including all systematic errors, compared to WA98. Note that the WA98 data in both (a) and (b) have an additional $\pm 20\%$ overall systematic error which is not shown.

by a single scale factor (predominantly acceptance) is valid up to the knee of the distribution, roughly the upper 1 percentile. Above the knee, the falloff depends on the aperture and is sensitive to detector effects as well as statistical and dynamical fluctuations. Thus an actual measurement of $dE_T/d\eta|_{\eta=0}$ for $\Delta\eta = 1.0$ and full azimuth would have a sharper falloff above the knee. With this caveat, the uncertainty in the absolute energy scale ($\pm 1.5\%$) and the uncertainty in k of $\pm 4\%$ are combined to yield an overall uncertainty in the hadronic $dE_T/d\eta|_{\eta=0}$ of $\pm 4.5\%$ (syst), independent of E_T, where the statistical error is negligible.

Midrapidity E_T distributions are a standard method of defining centrality [2,11–13]. Thus, it is important to determine for the present data the detailed relationship of transverse energy production to N_{part}, the number of nucleons participating in the collision (participants), which in earlier fixed target experiments was deduced straightforwardly by measuring the energy of spectator nucleons and fragments in a zero degree calorimeter at beam rapidity. Following a procedure used in our previous publication on the midrapidity charged multiplicity (N_{ch}) distribution, in which a clear increase of $\langle dN_{ch}/d\eta|_{\eta=0}\rangle$ per participant with the number of participants was demonstrated [5], we calculate $\langle dE_T/d\eta|_{\eta=0}\rangle$ as a function of centrality in upper percentile ranges of the 7.2 b Au + Au interaction cross section (see Table I). Figure 4a shows that $\langle dE_T/d\eta|_{\eta=0}\rangle$ per participant also increases with N_{part}, closely paralleling the rise in charged particle density (Table I). This is better illustrated in Fig. 4b where the ratio $\langle dE_T/d\eta|_{\eta=0}\rangle/\langle dN_{ch}/d\eta|_{\eta=0}\rangle$ remains constant at a value of ~ 0.8 GeV, independent of centrality. Comparison to the measurements of WA98 [12] from Pb + Pb collisions at $\sqrt{s_{NN}} = 17.2$ GeV is instructive. The WA98 data for midrapidity $\langle dE_T/d\eta|_{\mathrm{mid}}\rangle$ per participant are shown in Fig. 4a and are essentially independent of N_{part} for $N_{\mathrm{part}} > 200$ [14]. WA98 parametrizes their data as $dE_T/d\eta|_{\mathrm{mid}} \propto N_{\mathrm{part}}^{\alpha}$ with $\alpha = 1.08 \pm 0.06$ while the same parametrization for our data yields $\alpha = 1.13 \pm 0.05$. Figure 4 also shows that $\langle dE_T/d\eta|_{\eta=0}\rangle$ for central Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV is about 40% larger than found by WA98, yet, for both c.m. energies, $\langle dE_T/d\eta\rangle/\langle dN_{ch}/d\eta\rangle$ remains constant versus centrality at roughly the same value, ~ 0.8 GeV (Fig. 4b).

The Bjorken energy density for Pb + Pb collisions at $\sqrt{s_{NN}} = 17.2$ GeV was given by the NA49 Collaboration [13]. NA49 reported a value of midrapidity $dE_T/d\eta|_{\mathrm{mid}} = 405$ GeV for the most central 2% of the inelastic cross section, in agreement with WA98. This corresponds [13] to a value of $\epsilon_{Bj} = 2.9\ \mathrm{GeV/fm^3}$. A straightforward derivation of ϵ_{Bj} from our measured $dE_T/d\eta|_{\eta=0}$ of 578^{+26}_{-39} GeV for the same centrality cut, corrected to $dE_T/dy|_{y=0}$ by a factor of 1.19 ± 0.01 from our HIJING MC, and taking $\pi R^2 = 148\ \mathrm{fm^2}$ (i.e., $R = 1.18\ \mathrm{fm}\, A^{1/3}$) gives $\epsilon_{Bj} = 4.6\ \mathrm{GeV/fm^3}$, an increase of 60% over the NA49 value.

In conclusion, the midrapidity transverse energy density for central Au + Au collisions, and likely the spatial energy density, is at least 1.6 times larger at $\sqrt{s_{NN}} =$ 130 GeV (RHIC) than at $\sqrt{s_{NN}} = 17.2$ GeV (CERN). The variation of the E_T density per participant with centrality is very similar to the previously reported dependence of charged multiplicity density per participant at RHIC energies. These results, together with the observed constancy of $\langle E_T\rangle/\langle N_{ch}\rangle$ at a value ~ 0.8 GeV, indicate that the additional energy density at RHIC energies is achieved mainly by an increase in particle production rather than by an increase in transverse energy per particle.

We thank the staff of the RHIC project, Collider-Accelerator, and Physics Departments at BNL and the staff of PHENIX participating institutions for their vital

contributions. (Received 21 December 2000)

We present results for the charged-particle multiplicity distribution at midrapidity in Au-Au collisions at $\sqrt{s_{NN}} = 130$ GeV measured with the PHENIX detector at RHIC. For the 5% most central collisions we find $dN_{ch}/d\eta_{|\eta=0} = 622 \pm 1(\text{stat}) \pm 41(\text{syst})$. The results, analyzed as a function of centrality, show a steady rise of the particle density per participating nucleon with centrality.

DOI: 10.1103/PhysRevLett.86.3500 PACS numbers: 25.75.Dw

The Relativistic Heavy-Ion Collider (RHIC) at Brookhaven National Laboratory started regular operation in June 2000, opening new frontiers in the study of hadronic matter under unprecedented conditions of temperature and energy density. The research is focused on the phase transition associated with quark deconfinement and chiral symmetry restoration expected to take place under those conditions.

In this Letter, we report results for the charged-particle multiplicity distribution at midrapidity in Au-Au collisions at $\sqrt{s_{NN}} = 130$ GeV, as measured with the PHENIX detector. These are the first RHIC results to span a broad impact parameter range.

Particle density at midrapidity is an essential global variable for the characterization of high energy nuclear collisions, providing information about the initial conditions, such as energy density. The results presented here should help to constrain the wide range of theoretical predictions [1] available at RHIC energies and to discriminate among various mechanisms of entropy and particle production. In particular, we analyze the particle density as a function of centrality, expressed by the number of participating nucleons. Such an analysis may shed light on the relative importance of soft versus hard processes of particle production and test the assumption of gluon saturation expected at RHIC energies [2,3]. Our results are compared to

different models, to similar studies obtained in Pb-Pb collisions at the CERN SPS [4–6] and to a recent measurement performed at RHIC by PHOBOS [7].

The PHENIX detector is described in Ref. [8]. The present analysis relies primarily on three PHENIX subsystems: two layers of pad chambers (PC), called PC1 and PC3, used to determine the charged particle multiplicity, the zero degree calorimeters (ZDC) and the beam-beam counters (BBC), used to derive the trigger and the off-line event selection. The PC provide three-dimensional coordinates along the charged-particle trajectories [9]. The two layers are mounted at radial distances of 2.49 m and 4.98 m, respectively, from the interaction region. Each layer has 8 wire chambers with cathode pad readout (see Fig. 1) and covers 90° in azimuth (ϕ) and ± 0.35 units of pseudorapidity (η). The ZDC are small transverse-area hadron calorimeters that measure neutron energy within a 2 mrad ($|\eta| > 6$) cone around the beam direction and are located at ± 18.25 m from the center of the interaction region [10]. The BBC comprise two arrays of 64 photomultiplier tubes, each equipped with quartz Cherenkov radiators. The BBC are located around the beam direction at ± 1.44 m from the center of the interaction region covering the full 2π azimuth and the range $\eta = \pm(3.0-3.9)$ [11].

The primary interaction trigger is generated by a coincidence between the two BBC with at least two photomultipliers fired in each of them and a requirement on the collision vertex position, usually $|z| \leq 20$ cm. Based on detailed simulations of the BBC, this trigger reflects [92 $\pm$ 2(syst)]% of the nuclear interaction cross section of 7.2 b [12]. Another trigger is generated by a coincidence between the two ZDC, each one with an energy signal larger than 10 GeV. This trigger reflects the nuclear interaction plus the mutual Coulomb dissociation cross sections. Most BBC triggers (97.8%) also satisfy the ZDC trigger requirement. The small percentage of exclusive BBC triggers is due to inefficiencies of the ZDC trigger and background interactions. These two sources are difficult to distinguish and we estimate a background event contamination of [1 $\pm$ 1(syst)]% of the total event sample.

This analysis is based on a sample of 137 784 events taken without magnetic field, satisfying the BBC trigger and with a reconstructed vertex position $|z| \leq 17$ cm.

The number of primary charged particles per event is determined on a statistical basis by correlating hits in PC1 and PC3. The analysis procedure was developed and corroborated by extensive simulations using the GEANT [13] response of the PHENIX detector to events generated with HIJING [14]. The vertex is reconstructed using the following algorithm: all hits in PC3 are combined with all hits in PC1 and the resulting lines are projected onto a plane through the beam line, perpendicular to the symmetry axis of the chambers (see Fig. 1). For events with more than $\sim$5 tracks, the distribution of these projections along the Z axis produces a distinct peak which defines the vertex position. For low multiplicity events the vertex is reconstructed from the time difference between the two BBC.

Once the vertex is known, all hits in PC3 are again combined with all hits in PC1 and the resulting tracks are projected onto the plane previously defined. The distribution of the distance R of the intersection points to the vertex position, is shown in Fig. 2. This distribution contains real tracks and tracks from the obvious combinatorial background inherent to the adopted procedure of combining all hits in PC3 with all hits in PC1. The latter can be determined by a mixed event technique; in the present analysis, each sector in PC1 was exchanged with its neighbor and the resulting combinatorial background is shown in Fig. 2 by the dotted line. The yield of this background increases quadratically with R (leading to a linear dependence in the differential dN/dR vs R presentation of Fig. 2).

The R distribution of real tracks obtained by subtracting the background (N_B) from the total number of tracks is shown in Fig. 2 by the dashed line. The sharp peak at small R is due to tracks from primary particles originating at the vertex and the long tail is due to decay products of primary particles decaying in flight. In practice, the track counting is performed up to a given R value. The fraction of counted

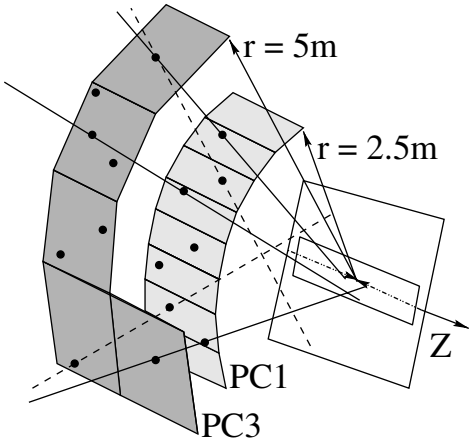

FIG. 1. Sketch of the geometry. For clarity, three PC3 sectors have been removed from the drawing.

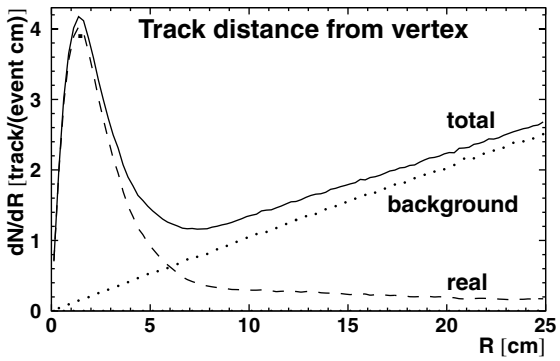

FIG. 2. Tracks per event and per cm as a function of the distance to the event vertex.

tracks as a function of R is obtained from the integral of the dashed curve normalized to the total integral up to $R = \infty$. The tail at large R values is very well described by an exponential function and therefore the extrapolation of the dashed curve to $R = \infty$ is straightforward. The larger the value of R, the smaller is the correction for the fraction of uncounted tracks, but the larger the background to be subtracted. Since the background can be reliably subtracted we performed the track counting up to $R = 25$ cm, thus including 95.9% of all tracks.

After subtracting the background, a raw multiplicity distribution is obtained to which we apply several corrections to obtain the corrected distribution of primary charged particles:

(i) A correction of 15.3% accounts for inactive gaps between the chambers, inactive electronic readout cards, and dead pads in the PC1 and PC3 detectors.

(ii) Using cosmic rays, the pad chamber hit efficiency was measured to be 99.4% for isolated single hits in agreement with an analytical study of the chamber performance [15].

(iii) The track losses due to the finite double hit resolution of the chambers depend on the event multiplicity. The losses occur in the direct counting of tracks and in the combinatorial background subtraction. The two effects were studied in great detail with Monte Carlo techniques. For the first one, the correction amounts to 13.3% for the 5% most central collisions, whereas it is only 4.9% for the 20%–25% bin. The second effect is a reduction of the combinatorial background which leads to an increase in the track multiplicity by $0.036 \times N_B$.

(iv) Finally there is a correction due to uncounted charged tracks. Two sources contribute here. First, there is a correction of 4.3% from tracks missed because the analysis is limited to $R = 25$ cm. The second source has two components. On the one hand there are primary charged particles (mainly $\pi^{\pm}$) which decay in flight. A large fraction of these decays is accounted for since, as discussed above, they produce the tail of the R distribution in Fig. 2. However, there are still a small number of decays which miss altogether PC1 and/or PC3 and those have to be added. On the other hand, there is feed down from neutral particle decays (mainly K_S^o and π^o) which lead to valid tracks. Those have to be subtracted. Both components depend on particle composition and momentum distribution. Lacking precise information about them, we performed Monte Carlo simulations, applying to the GEANT response of the pad chambers the same analysis procedure as to real data and comparing the resulting multiplicity to the original HIJING input. The result is a net correction of only $\sim$2.8%. This correction is quite robust against changes in the input. For example, a uniform 20% increase in momentum p of all pions reduces the net correction to 1%.

The systematic error in the multiplicity due to corrections (i) and (ii) is estimated at less than 2%. To these we have to add the errors associated with the background subtraction, double hit resolution (which are multiplicity dependent) and particle decays (which is multiplicity independent). We estimate the first two uncertainties to be 4.6% at the highest multiplicities, based on Monte Carlo guidance and a comparison with an identical analysis in which we imposed a 50% larger double hit resolution in PC1 and PC3. For the particle decay correction, we assign an error of 4% based on the effect of varying the momentum distribution and the particle composition in the simulations and a comparison with the results obtained with another data set measured while the detectors were retracted by 44 cm from the nominal position. Adding these errors in quadrature results in a total systematic error of 6.5% at the highest multiplicities. An additional error in $dN_{ch}/d\eta$, which enters in the analysis of the multiplicity versus centrality presented below, is the uncertainty in the total number of events due to the BBC trigger ($\pm 2\%$) and the event contamination ($\pm 1\%$).

After applying the appropriate corrections we obtain in the lower panel of Fig. 3 the minimum-bias charged-particle multiplicity distribution, in the track acceptance

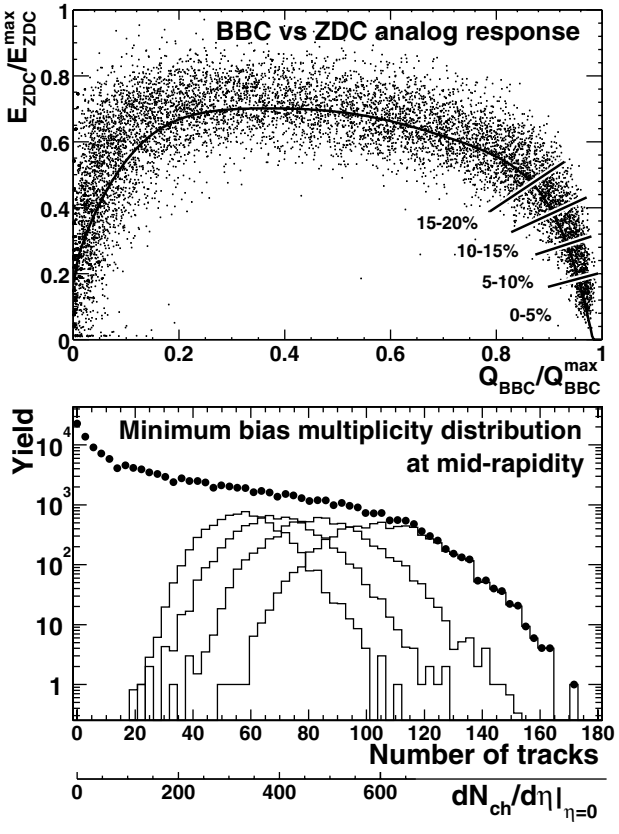

FIG. 3. BBC vs ZDC analog response (top panel) and minimum-bias multiplicity distribution in the PHENIX measurement aperture (lower panel). The lower axis converts the observed distribution to the corresponding average $dN_{ch}/d\eta$ for track multiplicities less than $\sim$120; beyond that value the shape of the distribution has a significant contribution from fluctuations into the measurement aperture.

$|\eta| < 0.35$, $\delta\phi = 88.4°$. A factor of 5.82 thus converts the observed number of tracks to $dN_{ch}/d\eta_{|\eta=0}$ in one unit of pseudorapidity and full azimuth, yielding the lower horizontal scale in Fig. 3.

Figure 3 also shows the multiplicity distributions for the four most central bins, 0%–5% to 15%–20%. The bins were defined by cuts in the space of BBC versus ZDC analog response (see Fig. 3—upper panel) and refer to percentiles of the total interaction cross section of 7.2 b. In order to avoid the ambiguities inherent in the BBC vs ZDC distribution, we selected events with increasing centrality based upon the monotonic response of another PHENIX detector. The centroids of these events projected onto the ZDC-BBC space determine the centrality contour indicated by the solid line. The cuts are made perpendicular to this contour. Simulations of the BBC and ZDC response were used to account for the effect of physics and detector fluctuations in the definition of these event classes and to relate them via a Glauber model [12] to the number of participating nucleons N_p and of binary collisions N_c. The average charged particle density scaled up to one unit of rapidity and the corresponding numbers N_p and N_c are tabulated in Table I for various centrality bins.

The PHOBOS experiment has recently reported an average $dN_{ch}/d\eta_{|\eta=0} = 555 \pm 12(\text{stat}) \pm 35(\text{syst})$ for the 6% most central collisions [7]. For the same centrality bin, we find $dN_{ch}/d\eta_{|\eta=0} = 609 \pm 1(\text{stat}) \pm 37(\text{syst})$. From the preliminary results reported by NA49 in Pb-Pb collisions at $\sqrt{s_{NN}} = 17.2$ GeV [6], we derive a particle density $dN_{ch}/dy_{|y=0} = 410$. Our result, $dN_{ch}/d\eta_{|\eta=0} = 622$ for the same centrality bin (0%–5%), represents an increase of ~80% after scaling it by 1.2 to account for the transformation from η to y.

It has recently been emphasized [2] that the centrality dependence of $dN_{ch}/d\eta$ allows one to discriminate between various models of particle production. We show in Fig. 4 our results for $dN_{ch}/d\eta$ per participant pair as a function of the number of participants N_p. Figure 4 also shows the $p\overline{p}$ value at the same $\sqrt{s}$ taken from the UA5 analysis [16]. It is interesting to note that the extrapolation of our data points to low multiplicities approaches the $p\overline{p}$ value.

TABLE I. Charged-particle density, number of participants, and collisions for various centrality bins expressed as percentiles of $\sigma_{\text{geo}} = 7.2$ b. The statistical errors are negligible and only systematic errors are quoted.

Centrality bin	$\langle dN_{ch}/d\eta_{\|\eta=0}\rangle$	$\langle N_p\rangle$	$\langle N_c\rangle$
0–5	622 ± 41	347 ± 10	946 ± 146
5–10	498 ± 31	293 ± 9	749 ± 116
10–15	413 ± 25	248 ± 8	596 ± 93
15–20	344 ± 21	211 ± 7	478 ± 75
20–25	287 ± 18	177 ± 7	377 ± 61
25–30	235 ± 16	146 ± 6	290 ± 47
30–35	188 ± 14	122 ± 5	226 ± 38
35–40	147 ± 12	99 ± 5	170 ± 30
40–45	115 ± 11	82 ± 5	130 ± 24
45–50	89 ± 9	68 ± 4	101 ± 19

Models such as HIJING predict that there is a component of particle production from soft interactions that scales linearly with N_p and a second component from hard processes (pQCD jets) that scales with N_c. Following that, we fit the data of Fig. 4 with the function $dN_{ch}/d\eta = A \times N_p + B \times N_c$ using the values of N_c and N_p tabulated in Table I. The results of the fit are shown in Fig. 4. Note that the errors in A and B are anticorrelated. In such models, the values of A and B imply a large contribution of hard processes to particle production, which increases with centrality from ~30% at $N_p = 68$ to ~50% for central collisions. HIJING predicts the same trend although the calculated values are lower than the data by ~15%. However, this is not a unique interpretation. At alternating gradient synchrotron energies, where hard processes do not occur, the particle production per participant was also observed to increase with centrality [17]. At the CERN SPS energy of $\sqrt{s_{NN}} = 17.2$ GeV, a similar behavior was observed. Using a different parametrization, $dN_{ch}/d\eta \propto N_p^{\alpha}$, WA98 finds a best fit value of $\alpha = 1.07 \pm 0.04$ [4]. Experiment WA97 quotes a value $\alpha = 1.05 \pm 0.05$, consistent with the result of WA98 but also compatible with their assumption of proportionality between multiplicity and participants [5]. A good fit to our data can also be obtained with this functional form with a higher value of $\alpha = 1.16 \pm 0.04$. One should note that the CERN results are in the lab frame, whereas ours are in the center of mass system.

Other models such as the EKRT [3] predict that at RHIC energies, the large production of semihard gluons in a small volume may saturate the gluon density. The resulting gluon fusion limits the total entropy production and thus lowers the final particle production per participant. The predictions of the EKRT model are also shown in Fig. 4.

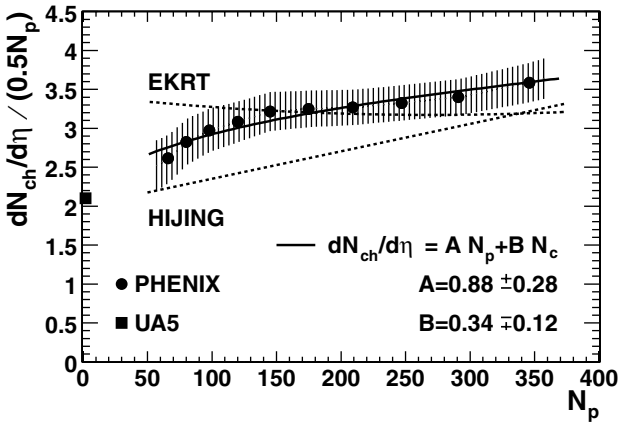

FIG. 4. Charged-particle pseudorapidity density per participant pair vs the number of participants. Predictions from HIJING [2] and EKRT [3] models, and a simple phenomenological fit are also shown. The shaded area represents the systematic errors of $dN_{ch}/d\eta$ and N_p. The errors of N_c are in Table I.

We observe no such saturation effect within our errors for Au + Au collisions at $\sqrt{s_{NN}} = 130$ GeV, but instead see a steady rise in the particle production per participant pair.

We thank the staff of the RHIC project, Collider-Accelerator, and Physics Departments at BNL and the staff of PHENIX participating institutions for their vital contributions. We acknowledge support from the U.S. Department of Energy and NSF, Monbu-sho and STA (Japan), RAS, RMAE, and RMS (Russia), BMBF and DAAD (Germany), FRN, NFR, and the Wallenberg Foundation (Sweden), MIST and NSERC (Canada), CNPq and FAPESP (Brazil), IN2P3/CNRS (France), DAE (India), KRF and KOSEF (Korea), and the U.S.-Israel Binational Science Foundation.

(Received 15 December 2000; published 31 May 2001)

Localized fluctuations in the multiplicity of charged particles and photons produced in central 158*A* GeV/*c* Pb+Pb collisions are studied. The charged versus neutral correlations in common $\eta-\phi$ phase space regions of varying azimuthal size are analyzed by two different methods. The analysis provides a model-independent demonstration of nonstatistical fluctuations in both charged particle and photon multiplicities in limited azimuthal regions. However, no correlated charge-neutral fluctuations are observed, contrary to expectations for the production of a disoriented chiral condensate. The result is not explained by the widely used VENUS model.

The formation of hot and dense matter in high energy heavy-ion collisions offers the possibility to create a new phase where matter is deconfined and chiral symmetry is restored. Indications for the formation of such a quark gluon plasma (QGP) phase are provided by several results from experiments at the CERN SPS [1]. Event-by-event fluctuations in the particle multiplicities and their ratios have recently been predicted to provide information about the nature of the QCD phase transition [2,3]. Fluctuations may also be caused by Bose-Einstein correlations, resonance decays, or more exotic phenomena such as pion lasers [4]. Enhanced fluctuations in neutral to charged pions have been predicted as a signature of the formation of disoriented chiral condensates (DCC) [5–8], which might be one of the most interesting predicted consequences of chiral symmetry restoration.

Theoretical predictions suggest that isospin fluctuations, caused by formation of a DCC, would produce clusters of coherent pions in localized phase space regions or domains. The probability distribution of the neutral pion fraction in such a domain would follow the relation $P(f)=1/2\sqrt{f}$, where $f=N_{\pi^0}/N_{\pi}$. Thus DCC formation in a given domain would be associated with large event-by-event fluctuations in the ratio of neutral to charged pions in that domain. Experimentally, such fluctuations can be deduced from the measurement of fluctuations in the number of photons to charged particles in limited $\eta-\phi$ regions. The anti-Centauro events, reported by the JACEE Collaboration [9], with large charged-neutral fluctuations are possible candidates for DCC events. The studies carried out so far in $p-\overline{p}$ [10] and heavy-ion [11,12] reactions have searched for fluctuations which extend over a large region of phase space. These measurements have provided upper limits on the presence of DCC-like fluctuations.

In this Rapid Communication we present first results on the search for nonstatistical event-by-event fluctuations in the relative number of charged particles and photons in localized $\eta-\phi$ phase space regions for central 158*A* GeV/c Pb+Pb collisions. The data presented here were taken with the 158*A* GeV Pb beam of the CERN SPS on a Pb target of 213 μm thickness during a period of WA98 operation without magnetic field. The analysis makes use of a subset of detectors of the WA98 experiment. Charged particle hits ($N_{\rm ch}$) were counted using a circular silicon pad multiplicity detector (SPMD) [11] located 32.8 cm downstream from the target. It provided uniform pseudorapidity coverage in the region $2.35<\eta<3.75$. The detector was 99% efficient for charged particle detection. The photon multiplicity was measured using a preshower photon multiplicity detector (PMD) [13] placed 21.5 m downstream of the target and covering the pseudorapidity range $2.9<\eta<4.2$. Clusters of hit scintillator pads having total energy deposit above a hadron rejection threshold are identified as photonlike ($N_{\gamma\text{-like}}$). For this analysis the pseudorapidity region of common coverage of the SPMD and PMD was selected ($2.9<\eta<3.75$). The acceptance in terms of transverse momentum (p_T) extends down to 30 MeV/c, although no explicit p_T selection is applied. Strict data selection and cleanup cuts have been applied as described in Refs. [11,14]. After cuts, a total of 85 K central events, corresponding to the top 5% of the minimum bias cross section as determined from the measured total transverse energy, have been analyzed. Average multiplicities of $\langle N_{\rm ch}\rangle=323.8$ and $\langle N_{\gamma\text{-like}}\rangle=335.7$ are obtained for this centrality selection.

The measured results are interpreted by comparison with simulated events and with several types of mixed events. Simulated events were generated using the VENUS 4.12 [15] event generator with default parameters. The output was processed through a WA98 detector simulation package in the GEANT 3.21 [16] framework. The centrality selection for the simulated data has been made in a manner identical to the experimental data by selection on the simulated total transverse energy in the WA98 acceptance ($3.2<\eta<5.4$). The simulated VENUS+GEANT events (referred as V+G) were then processed with the same analysis codes as used for the analysis of the experimental data. The photon counting efficiency and the purity of the γ-like sample were determined from these simulations to be 68% and 65%, respectively, for central events [14].

The effect of nonstatistical DCC-like charged-neutral fluctuations has been studied within the framework of a simple model in which the output of the VENUS event generator has been modified. To implement the DCC effect, the charges of the pions within a localized $\eta-\phi$ region from VENUS are interchanged pairwise ($\pi^+\pi^-\leftrightarrow\pi^0\pi^0$) according to the $P(f)=1/2\sqrt{f}$ probability distribution. The DCC-like fluctuations were generated over $\eta=3$–4 for varying intervals in $\Delta\phi$. Since the probability to produce events with DCC domains is unknown, ensembles of events, here referred to as ''nDCC events,'' were produced as a mixture of normal events with varying fractions of pure DCC-like events. The nDCC events were then tracked through GEANT.

In the search for evidence of nonstatistical charged-neutral fluctuations, two different analysis techniques have been applied. The first method employed in the present analysis is the technique of discrete wavelet transformations (DWT). DWT methods are now widely used in many applications, such as data compression and image processing, and have been shown to provide a powerful means to search for localized domains of DCC [17,18]. While there are several families of wavelet bases distinguished by the number of coefficients and the level of iteration, we have used the frequently employed $D-4$ wavelet basis [20]. The analysis has been performed with the sample function chosen to be the photon fraction, given by $f'(\phi)=N_{\gamma\text{-like}}(\phi)/(N_{\gamma\text{-like}}(\phi)+N_{\rm ch}(\phi))$ as a function of the azimuthal angle ϕ, with highest resolution scale $j_{max}=5$. The input to the DWT analysis is the spectrum of the sample function at the smallest bin size corresponding to the highest resolution scale, j_{max}, where the number of bins is $2^{j_{max}}$. The sample function is then analyzed at different scales j by being rebinned into 2^j bins. The DWT analysis yields a set of wavelets or father function coefficients (FFC) at each scale from $j=1$ to $(j_{max}-1)$. The coefficients obtained at a given scale, j, are derived from the distribution of the sample function at one higher scale, $j+1$. The FFCs quantify the deviation of the bin-to-bin fluctuations in the sample function at that higher scale relative to the average behavior. The presence of localized nonstatistical

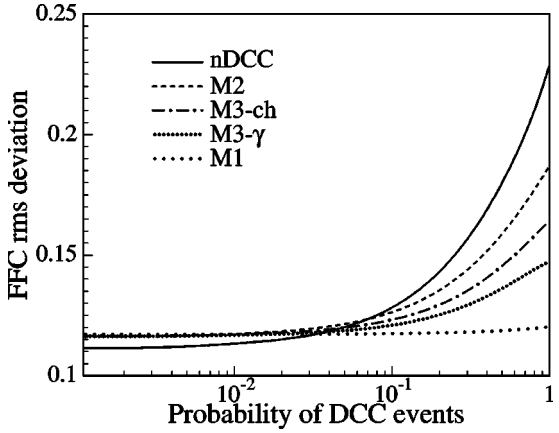

FIG. 1. The rms deviations of the FFC distributions at $j=1$ for simulated nDCC events with extent $\Delta\phi_{\mathrm{DCC}}=90°$ and for various mixed events constructed from those events, as a function of the fraction of DCC-like events present in the nDCC sample.

fluctuations will increase the root mean square (rms) deviation of the distribution of FFCs and may result in non-Gaussian tails [17,18].

The sensitivity of the DWT technique as used in this analysis is demonstrated in Fig. 1 where it has been applied to the simulated nDCC events. The rms deviation of the FFC distribution is shown as a function of the fraction of DCC-like events in the nDCC sample. The rms deviation is observed to increase strongly with increasing DCC-like fraction. Due to the inherent uncertainties in the description of ''normal'' physics and detector response in the V+G simulations, the observation of an experimental result with rms which differs from simulation with zero DCC fraction cannot be taken alone as evidence of DCC observation. For this reason four different types of mixed events have been created from the real or simulated events in order to search for nonstatistical fluctuations by removing various correlations in a controlled manner while preserving the characteristics of the measured distributions as accurately as possible. The first type of mixed events (M1) are generated by mixing hits in both the PMD and SPMD separately, with no two hits taken from the same event. Hits within a detector in the mixed events are not allowed to lie within the two track resolution of that detector. The second kind of mixed events (M2) are generated by mixing the unaltered PMD hits of one event with the unaltered SPMD hits of a different event. Intermediate between the M1 and M2 kinds of mixed events is the case where the hits within the PMD are unaltered while the SPMD hits are mixed (M3-γ), or the SPMD hits are unaltered while the PMD hits are mixed (M3-ch). In each type of mixed event the global (bin 1) $N_{\gamma\text{-like}}-N_{\mathrm{ch}}$ correlation is maintained as in the real event.

The rms deviations of the FFCs for the different kinds of mixed events produced from the nDCC events are also shown in Fig. 1. In the case of vanishing DCC-like fluctuations, the rms values of the various types of mixed events are very close to each other, and higher than the V+G rms values. This is due to the presence of additional correlations between N_{ch} and $N_{\gamma\text{-like}}$, mostly as a result of the charged particle contamination in the $N_{\gamma\text{-like}}$ sample. The rms deviations for the M1 events are found to be almost independent of probability of DCC-like events, while the rms deviations of the M2 events increase similarly, but more weakly, than those of the nDCC events. The rms deviations for the M3 sets of events are found to lie between M2 and M1. Thus, the sequence of the mixed events relative to the simulated events (or data) gives a model independent indication of the presence and source of nonstatistical fluctuations. The simple DCC model used here results in an anticorrelation between $N_{\gamma\text{-like}}$ and N_{ch}. It also results in nonstatistical fluctuations in both $N_{\gamma\text{-like}}$ and N_{ch}. It is seen that the M2 events have only the $N_{\gamma\text{-like}}$-N_{ch} anticorrelation removed while the M1 events have all nonstatistical fluctuations and correlations removed. The M3 mixed events give intermediate results because they contain only the $N_{\gamma\text{-like}}$ (M3-γ) or N_{ch} (M3-ch) nonstatistical fluctuations.

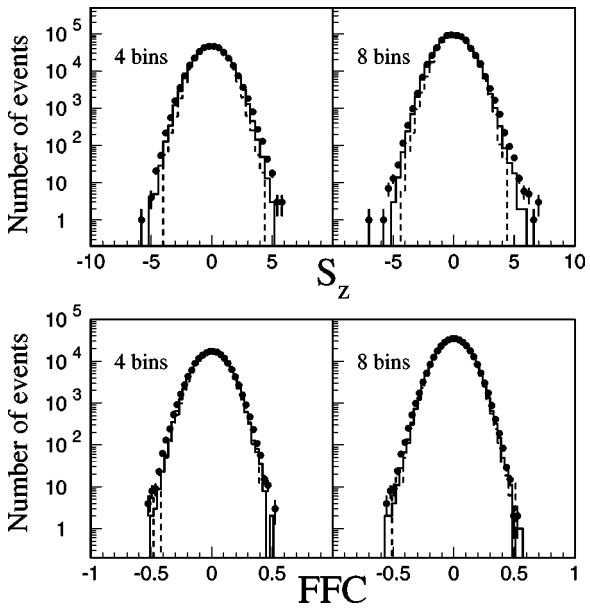

FIG. 2. The S_Z and FFC distributions for four and eight divisions in ϕ. The experimental data, M1, and V+G events are shown by solid circles, solid and dashed histograms, respectively. The number of data and mixed events is the same. The distribution for the V+G events is normalized to the data.

The FFC distributions extracted from the measured $f'(\phi)$ ratio are shown in the bottom panel of Fig. 2 for the experimental data, for M1 events (from data), and for V+G events. The results are shown for scales $j=1$ and 2, which carry information about fluctuations at 90° and 45° in ϕ. The FFC distributions of the experimental distributions are seen to be broader than the V+G and M1 results. This suggests the presence of nonstatistical fluctuations.

A more conventional method similar to that described in Ref. [11] has also been used to search for nonstatistical fluctuations. The correlation between $N_{\gamma\text{-like}}$ and N_{ch} has been studied in varying ϕ intervals, by dividing the entire ϕ space into two, four, eight, and 16 bins. The correlation plot of N_{ch} versus $N_{\gamma\text{-like}}$ [19] is obtained for each ϕ segmentation, and fitted to a second order polynomial to obtain a correlation axis (Z). The distance of separation (D_Z) between the data points and the Z axis has been calculated with the convention

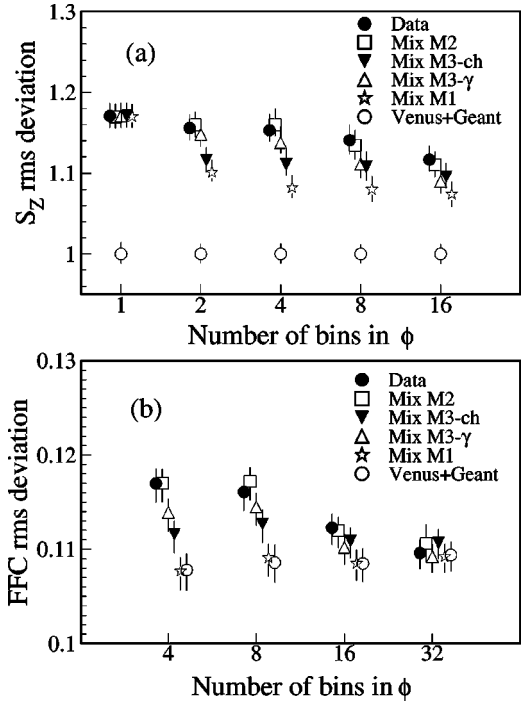

FIG. 3. The rms deviations of the S_Z and FFC distributions for various divisions in the azimuthal angle. For V+G $s(D_Z)=17.2$, 11.8, 8.12, 5.66, and 4.01 for one to 16 bins, respectively.

that D_Z is positive for points below the Z axis (increasing $N_{\gamma\text{-like}}$). In order to compare fluctuations at different bin sizes having different multiplicities we use a scaled variable, $S_Z=D_Z/s(D_Z)$, where $s(D_Z)$ is the rms deviation of the D_Z distributions for V+G events. The presence of events with localized nonstatistical fluctuations would be expected to result in a broader distribution of S_Z compared to those for normal events. The S_Z distributions calculated at four and eight bins in ϕ angle are shown in the top panel of Fig. 2 for data, M1, and V+G events. The experimental distributions are broader than the simulation and M1 results, again indicating the presence of additional fluctuations.

The rms deviations of the S_Z and FFC distributions as a function of the number of bins in azimuth is shown for experimental data, mixed events, and V+G in Fig. 3. As noted in the discussion of Fig. 1, even in the absence of DCCs there exist uninteresting correlations between $N_{\gamma\text{-like}}$ and N_{ch} which are removed by the event mixing procedure and thereby result in a difference between the real and mixed events. The mixed event rms values of Fig. 3 have therefore been rescaled by the percentage difference between the rms deviations of the V+G distributions and those of the corresponding V+G mixed events in order to better illustrate effects in the data beyond those present in V+G. The statistical errors on the values are small and lie within the size of the symbols. The error bars include both statistical and systematic errors. The systematic errors have been estimated by investigation of effects such as the uncertainties in the detection efficiencies, gain fluctuations, backgrounds, binning variations, and fitting procedures. The total systematic error was obtained as the sum in quadrature of the individual error contributions which have been determined from the variation of the final result according to the maximum estimated uncertainty for each effect.

Since the mixed events are constructed to maintain the $N_{\gamma\text{-like}}-N_{\text{ch}}$ correlations for the full azimuth (bin 1), the rms deviations of data and mixed events for this bin are identical. The difference of the S_Z rms deviations between data and V+G for this bin is the same as reported in an earlier WA98 publication [11]. The comparison of V+G and the M1 mixed events demonstrates the utility of the DWT method to normalize out the average behavior when the bin-to-bin fluctuation information is extracted. For two, four, and eight bins the values of the S_Z rms deviations of the data are 2.5σ, 3.0σ, and 2.4σ larger than those of M1 events, respectively, where $\sigma=\sqrt{(\sigma^{data}_{lower})^2+(\sigma^{\text{M1}}_{upper})^2}$ is the sum in quadrature of the total error separating the points. Similarly, the FFC rms deviations at four and eight bins for data are 3.7σ and 2.8σ larger than those of the M1 events. At 16 and 32 bins, the result for mixed events and data agree within the quoted errors. The rms deviations of the M2 events agree with those of the experimental data within error for all bins. The M3-type mixed events are found to be similar to each other within the quoted errors and lie between M1 and M2.

The observation that the rms deviations of the S_Z and FFC distributions for experimental data are larger than those of the M1 events provides model-independent evidence for the presence of localized nonstatistical fluctuations. However, the comparision of the rms deviations for data with those of M2 events implies the absence of event-by-event correlated fluctuations in $N_{\gamma\text{-like}}$ versus N_{ch}. The M3-type mixed events indicate the presence of localized independent fluctuations in $N_{\gamma\text{-like}}$ and N_{ch} of similar magnitude.

If the amount of DCC-like fluctuations in the experimental data were large, then the rms deviations shown in Fig. 3 for data would have been larger compared to those of M2 events. Since this is not the case, we compare the measured results with those obtained from the simulation as shown in Fig. 1 to extract upper limits on the probability of DCC-like fluctuations at the 90% confidence level. Within the context of this simple DCC model, upper limits on the presence of localized nonstatistical DCC-like fluctuations of 10^{-2} for $\Delta\phi$ between 45–90° and 3×10^{-3} for $\Delta\phi$ between 90–135° are extracted.

In summary, a detailed event-by-event analysis of the fluctuations in the $\eta-\phi$ phase space distributions of charged particles and photons has been performed for central Pb+Pb collisions at 158*A* GeV using two complementary analysis methods. The first analysis employed the discrete wavelet transformation technique to investigate the relative magnitude of the $N_{\gamma\text{-like}}/(N_{\text{ch}}+N_{\gamma\text{-like}})$ fluctuations in adjacent ϕ intervals of varying size. The second method studied the magnitude of the $N_{\gamma\text{-like}}$ versus N_{ch} multiplicity fluctuations in decreasing ϕ regions. Both analysis methods provide model-independent evidence for nonstatistical fluctuations at the 3σ level for ϕ intervals of greater than 45°. This is shown to be due to nonstatistical fluctuations in both $N_{\gamma\text{-like}}$ and N_{ch}. However, no significant correlated fluctuations in

$N_{\gamma\text{-like}}$ versus N_{ch} were observed, contrary to naive expectations for a DCC effect. The result is not explained by VENUS+GEANT simulations or by a simple model of DCC-like fluctuations. The interpretation of the result remains an open question.

We wish to express our gratitude to the CERN accelerator division for the excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians, and support staff who have participated in the construction of this experiment. This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR and FRN, the Dutch Stichting FOM, the Polish KBN under Contract No. 621/E-78/SPUB/CERN/P-03/DZ211, the Grant Agency of the Czech Republic under Contract No. 202/95/0217, the DAE, DST, CSIR, and UGC of the Government of India, the Indo-FRG Exchange Program, the PPE division of CERN, the Swiss National Fund, the INTAS under Contract No. INTAS-97-0158, ORISE, the University of Tsukuba Special Research Projects, and the JSPS. (Received 10 April 2000)

Three-particle correlations have been measured for identified π^- from central 158A GeV Pb + Pb collisions by the WA98 experiment at CERN. A substantial contribution of the genuine three-body correlation has been found as expected for a mainly chaotic and symmetric source.

In nuclear and particle physics, the study of Bose-Einstein correlations between identical particles is widely used. It is an essential tool to obtain information on the size and time evolution of expanding systems created in heavy ion collisions [1]. In particular, two-particle Bose-Einstein interferometry has been used for a sophisticated analysis of the dynamical evolution of the freeze-out volume via selection on the transverse momentum and rapidity of the correlated particles.

Three-particle interferometry measurements can provide additional information on the space-time emission which is not accessible by two-particle interferometry [2–5]. In particular, if the emission is fully chaotic, the three-particle interference study gives access to the phase of the source function's Fourier transform, which is affected by the emission asymmetry. These asymmetries may be induced by source geometry, flow, or resonance decays. If the source is not completely chaotic, as is likely to be the case, the interpretation is more difficult. Nevertheless, a comparison of the three-particle to the two-particle result allows one to extract the relative strength of the true three-body correlation and can in principle remove obscuring effects, such as background from misidentified tracks or long-lived decay products, and therefore provide information more directly about the degree of coherence of the emission source [4]. In this Letter we present first results from three-particle interferometry in central ^{208}Pb + ^{208}Pb collisions at the CERN SPS.

The fixed target experiment WA98 [6] combined large acceptance photon detectors with a two arm charged particle tracking spectrometer. The incident 158A GeV Pb beam impinged on a Pb target near the entrance of a large dipole magnet. The results presented here have been obtained from an analysis of the 1995 data set. These data were taken with the most central triggers corresponding to about 10% of the minimum bias cross section of 6190 mb. The π^- measurements were obtained with data from the negative particle tracking arm of the spectrometer. This tracking arm consisted of six multistep avalanche chambers with optical readout [7]. A time of flight detector with a time resolution better than 120 ps allowed for particle identification. The rapidity acceptance ranged from $y = 2.1$ to 3.1 with an average at 2.7, close to midrapidity which was 2.9. The momentum resolution of the spectrometer was $\Delta p/p = 0.005$ at $p = 1.5$ GeV/c. Severe track quality cuts were applied, resulting in a final sample of 4.2×10^6 π^-, providing 7.2×10^6 pairs and 8.2×10^6 triplets. The $\pi^-\pi^-$ correlation analysis has been reported elsewhere [8].

The most common use of hadron interferometry concerns the study of pairs of identical particles. The two-particle correlation function can be defined as

$$C_2(\mathbf{p}_1, \mathbf{p}_2) = \frac{d^2N(\mathbf{p}_1, \mathbf{p}_2)/d\mathbf{p}_1 d\mathbf{p}_2}{dN(\mathbf{p}_1)/d\mathbf{p}_1 \cdot dN(\mathbf{p}_2)/d\mathbf{p}_2},$$

where $\mathbf{p}_1$ and $\mathbf{p}_2$ are the three-momenta of the correlated particles. The product of single particle distributions in the denominator is usually obtained experimentally by a mixed event technique, whereas the pair distribution in the numerator is constructed from all pair combinations of identical particles found in each event. C_2 is normalized to unity far away from the interference region. In the plane wave approximation for chaotic sources of identical particles C_2 can be written as [9]

$$C_2(\mathbf{p}_1, \mathbf{p}_2) = 1 \pm |F_{12}|^2 \tag{1}$$

with the + (−) sign for bosons (fermions). F_{12} is the Fourier transform of the space-time source function $S(x, k_{12})$

$$|F_{12}|^2 = \frac{|\int d^4x\, S(x, k_{12}) \exp[iq_{12}x]|^2}{|\int d^4x\, S(x, k_{12})|^2} \tag{2}$$

with $q_{12} = p_1 - p_2$, the four-momentum difference of the two particles, and $k_{12} = (p_1 + p_2)/2$. F_{12} is unity as $q_{12} \to 0$. Thus the production of identical bosons is enhanced for pairs created close together in phase space with a small momentum difference $Q_{12} \equiv \sqrt{-q_{12}^2}$.

Typically $\pi\pi$ correlation data are fit with a Gaussian form for $|F_{12}|^2$,

$$C_2 = 1 + \lambda \exp[-Q_{12}^2 R^2], \tag{3}$$

or an exponential form,

$$C_2 = 1 + \lambda \exp[-2Q_{12}R], \tag{4}$$

where the parameter λ is inserted to take into account the possibility that the source may not be fully chaotic and also that any wrongly reconstructed tracks, or tracks coming from decays of long-lived resonances, will dilute the correlations in the data.

The measurement of C_2 gives access to the radius R of the source, but not to the phase ϕ_{12} contained in $F_{12} \equiv |F_{12}| \exp[i\phi_{12}]$ since C_2 is only a function of the square of the Fourier transform of the source distribution S. By contrast, the three-boson interference produced by a fully chaotic source is sensitive to the phase information of the Fourier transform of the source emission function. Indeed, for a chaotic source the three-body correlation function C_3, which is

$$C_3(\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3) = \frac{d^3N(\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3)/d\mathbf{p}_1 d\mathbf{p}_2 d\mathbf{p}_3}{dN(\mathbf{p}_1)/d\mathbf{p}_1 \cdot dN(\mathbf{p}_2)/d\mathbf{p}_2 \cdot dN(\mathbf{p}_3)/d\mathbf{p}_3},$$

can be written [2–5] as

$$C_3 = 1 + |F_{12}|^2 + |F_{23}|^2 + |F_{31}|^2 + 2\,\mathrm{Re}\{F_{12}F_{23}F_{31}\}, \tag{5}$$

where F_{ij} is the Fourier transform for the pair ij contained in the triplet 123. The genuine three-body correlation in C_3 is the term $2\,\mathrm{Re}\{F_{12}F_{23}F_{31}\}$.

With $F_{ij} \equiv |F_{ij}| \exp[i\phi_{ij}]$ and $W \equiv \cos(\phi_{12} + \phi_{23} + \phi_{31})$ one may rewrite

$$2\,\mathrm{Re}\{F_{12}F_{23}F_{31}\} = 2|F_{12}|\,|F_{23}|\,|F_{31}|W\,. \qquad (6)$$

Having determined $|F_{ij}|$ from the pair correlation function C_2, the measurement of C_3 gives direct access to W, the cosine of the sum of the three phases of the Fourier transforms, and hence provides complementary information on the shape of the source. Indeed, W is related to the odd space-time moments of the source which generate the phases ϕ_{ij} [4]. For example, if the source is fully chaotic and symmetric, F_{ij} are real, $\phi_{12} = \phi_{23} = \phi_{31} = 0$, and W is equal to 1. C_3 is then fully determined by C_2, and the genuine three-particle correlation is maximum. If the source is not fully chaotic, more complicated expressions should be used, mixing the effects of fully chaotic and coherent sources [4]. Nevertheless, Eq. (6) is valid in general with W interpreted as a factor expressing the relative strength of the true three-body correlation compared to that expected for a fully symmetric chaotic source. Consequently, measuring W values less than 1 does not allow one to differentiate between asymmetries or coherence in the source.

Assuming a Gaussian form of the source function, which for two bosons leads to a correlation function described by Eq. (3), one obtains

$$C_3 = 1 + \lambda \sum_{ij=12,23,31} \exp[-Q_{ij}^2 R^2] + 2\lambda^{3/2} \exp[-Q_3^2 R^2/2]W \qquad (7)$$

with $Q_3^2 \equiv Q_{12}^2 + Q_{23}^2 + Q_{31}^2$. If the exponential form of the Fourier transform is assumed instead [Eq. (4)], one obtains

$$C_3 = 1 + \lambda \sum_{ij=12,23,31} \exp[-2Q_{ij}R] + 2\lambda^{3/2} \exp[-(Q_{12} + Q_{23} + Q_{31})R]W\,. \qquad (8)$$

Inserting the values of λ and R obtained from the two-particle analysis into Eqs. (7) or (8), one can extract the three-particle strength information W.

The one-dimensional correlation function C_2, analyzed in terms of Q_{12}, is shown in Fig. 1. The two-track resolution of the spectrometer (2 cm) is dealt with by application of a proximity cut to each track pair. The data are corrected for the Coulomb and strong final state interactions in an iterative way [10], taking into account the source size obtained in the fit. The Gamow correction was abandoned as we found that it overcorrects the data for Q_{12} in the range of 0.1 to 0.3 GeV/c.

The effect of the experimental resolution, which is estimated by a full Monte Carlo, can be approximated in the interference region by a Gaussian of constant σ of 7 MeV/c both for Q_{12} and Q_3. It is taken into account

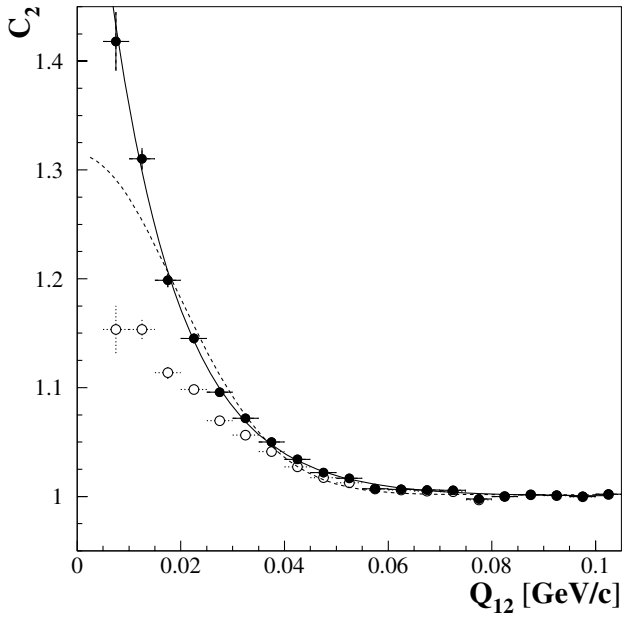

FIG. 1. The measured $\pi^-\pi^-$ correlation function C_2 (full symbols) fit with an exponential (solid curve) or Gaussian form (dashed curve) corrected for resolution. The empty symbols show the data before Coulomb and resolution corrections. Only statistical errors are shown.

by replacing the function $C_2(Q_{12})$ used to fit the noncorrected data by

$$C_2^{rc}(Q_{12}) = \int r(Q_{12}, Q'_{12}) C_2(Q'_{12})\, dQ'_{12}\,,$$

which is the convolution of $C_2(Q_{12})$ with the resolution function $r(Q_{12}, Q'_{12})$ of the spectrometer. For display purposes, Fig. 1 is obtained by multiplying each data point by $C_2^{rc}(Q_{12})/C_2(Q_{12})$. Fitting the corrected data with C_2 gives the same results as fitting the noncorrected data with C_2^{rc}. The correlation function C_2 is seen to be non-Gaussian. Instead, it is better represented by an exponential form [8]. For the C_3 analysis, an accurate description of the shape of C_2 is essential since the estimate of the W factor extracted from C_3 depends on it. The exponential fit [Eq. (4)] yielding $R = 7.29 \pm 0.11$ fm and $\lambda = 0.753 \pm 0.013$ is shown in Fig. 1.

Figure 2 shows the three-pion correlation as a function of Q_3, after correction for resolution. A very strong $\pi^-\pi^-\pi^-$ correlation is observed, which is robust under all tracking criteria. The result shown is obtained for the same sample and the same cuts applied on the three pair combinations contained in each triplet as used for the two-pion interference analysis. For the C_3 result, the Coulomb correction applied to a particular triplet is the product of the Coulomb corrections used for the three pair combinations contained in that triplet. The resolution is taken into account using the same procedure as in the two-pion analysis. The resolution has a tiny effect compared to the Coulomb correction, and it has been checked that the results are not affected by the order in which these corrections are applied to the data. The dashed line is a fit to a double exponential

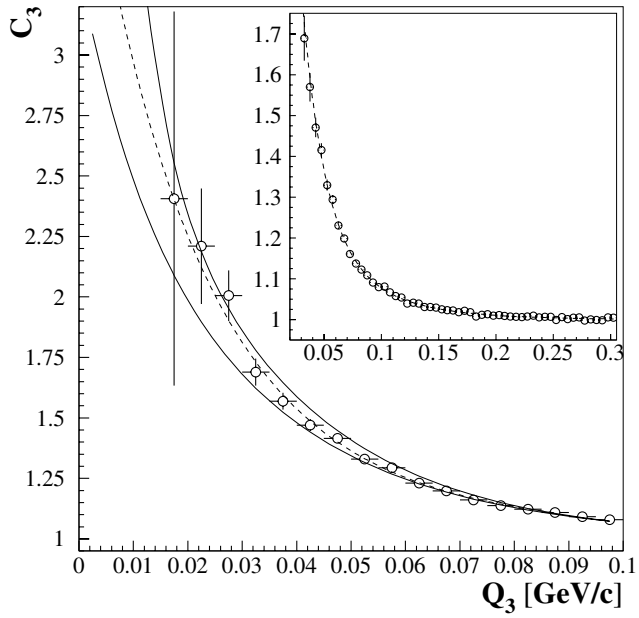

FIG. 2. The three-pion correlation function C_3 as a function of Q_3 with a fit to a double exponential form (dashed line—see text). The result is also compared to an estimate of C_3 with $W = 1$ (upper solid line) and $W = 0$ (lower solid line). The inset shows C_3 over a larger Q_3 range.

function

$$C_3 = 1 + \lambda_1 \exp[-2Q_3R_1] + \lambda_2 \exp[-2Q_3R_2] \quad (9)$$

with fitted parameters $R_1 = 5.01 \pm 0.38$ fm, $\lambda_1 = 2.79 \pm 0.32$, $R_2 = 1.72 \pm 0.12$ fm, $\lambda_2 = 0.343 \pm 0.072$, and a χ^2 per degree of freedom of 0.88. The three-pion correlation data cannot be well fitted by a Gaussian or a single exponential as a function of Q_3. Such non-Gaussian behavior has been predicted by a final-state rescattering model [11].

In Fig. 2, the three-pion correlation data are compared to an estimate using Eq. (8) with $W = 1$ (upper line) and $W = 0$ (lower line). This estimate is made using triplets from mixed events with the λ and R parameters extracted from the two-pion interferometry analysis. Although the calculated contribution to C_3 from the genuine three-pion correlation is rather small and becomes insignificant for $Q_3 > 60$–80 MeV/c, the experimental results clearly indicate a W factor which lies between 0 and 1.

As proposed in Refs. [4,12], a method to extract the experimental value of W as a function of Q_3 is to invert Eqs. (5) and (6) and rewrite $|F_{ij}|$ in terms of C_2 using Eq. (1) to obtain

$$W = \frac{\{C_3(Q_3) - 1\} - \{C_2(Q_{12}) - 1\} - \{C_2(Q_{23}) - 1\} - \{C_2(Q_{31}) - 1\}}{2\sqrt{\{C_2(Q_{12}) - 1\}\{C_2(Q_{23}) - 1\}\{C_2(Q_{31}) - 1\}}}. \quad (10)$$

In this method, the analysis must be performed in two steps. First, the λ and R parameters are determined for both the two-pion and the three-pion correlations with a fit to the data of Eqs. (4) and (9) as previously explained. Then the data are analyzed again, and, for each triplet found, characterized by the value Q_3, W is determined using Eqs. (4), (9), and (10) with the values Q_{12}, Q_{23}, and Q_{31} corresponding to the three pair combinations contained in the triplet.

For each bin in Q_3 containing N triplets, the statistical error on the mean value $\langle W \rangle$ is $\sigma/\sqrt{N}$, where σ^2 is the variance of the W distribution in this particular bin. The estimate of systematic errors is done by varying the different analysis cuts in the two- and three-pion interference studies. It includes, in particular, the cuts used to identify the pions with the time of flight system. The systematic error on the Coulomb correction due to the error on the determination of the R parameter in the two-pion fit, as well as a possible 10% systematic error on the evaluation of the Q_{12} and Q_3 resolution, is also taken into account. The effects on W of the statistical errors in the determination of C_2 and C_3 are treated as systematic errors by changing C_2 and C_3, respectively, by $\pm\sigma_{C_2}$ and $\pm\sigma_{C_3}$. All of these variations are then added in quadrature.

Figure 3 shows the W values obtained for five bins of 10 MeV/c in Q_3. The error bars are the sum of statistical and systematic errors. The statistical errors (not shown separately in Fig. 3) are nearly negligible. The slight Q_3

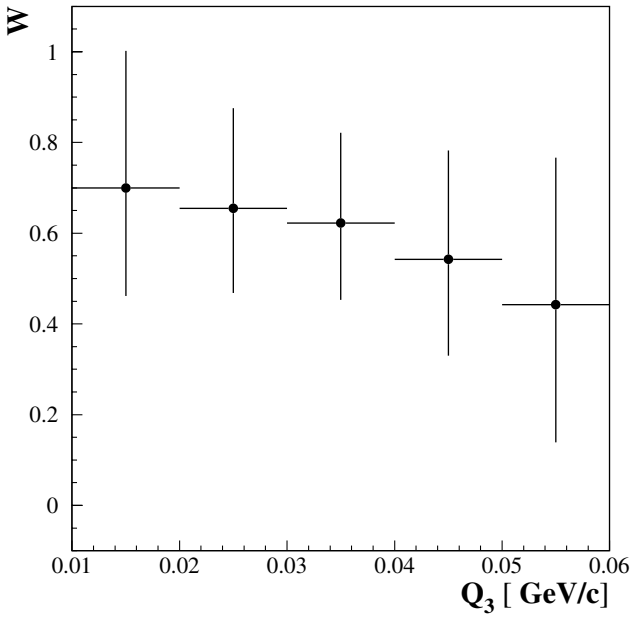

FIG. 3. The factor W as a function of Q_3. The error bars include statistical and systematic errors. The statistical errors alone (not shown) are contained within the size of the symbols except for the first bin where it amounts to twice the size of the symbol. The horizontal bars indicate the bin width.

dependence observed is not significant in view of the errors. The genuine three-body correlation is substantial with a weighted mean $\langle W \rangle = 0.606 \pm 0.005 \pm 0.179$ for $Q_3 < 60$ MeV/c. (The weighted systematic error is obtained by calculating the weighted average over the five Q_3 bins separately for each kind of systematic error. These errors are then added in quadrature. On the contrary, adding quadratically the systematic errors of the five Q_3 bins as done for weighted statistical errors, or as done in [12], would give ± 0.097 instead of ± 0.179 for the systematic uncertainty.) This result should be compared to the lower $\pi^+\pi^+\pi^+$ result of $\langle W \rangle = 0.20 \pm 0.02 \pm 0.19$ observed by the NA44 Collaboration [12] in S + Pb minimum bias collisions at 200 GeV per nucleon.

In conclusion, we have studied the $\pi^-\pi^-\pi^-$ interference of pions produced in central Pb + Pb collisions at 158 GeV per nucleon. Although its contribution is small, the genuine three-pion correlation, the portion of the correlation not trivially due to the two-pion interference, has been extracted and found to be substantial. The genuine three-pion correlation is greater than reported for S + Pb minimum bias collisions [12], but not as large as expected for a fully chaotic and symmetric source.

We thank the CERN-SPS accelerator crew for providing an excellent Pb beam. This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR, the Dutch Stichting FOM, the Swiss National Fund, the Humboldt Foundation, the Stiftung für deutsch-polnische Zusammenarbeit, the Department of Atomic Energy, the Department of Science and Technology and the University Grants Commission of the Government of India, the Indo-FRG Exchange Programme, the PPE division of CERN, the INTAS under Contract No. INTAS-97-0158, the Polish KBN under Grant No. 2P03B16815, the Grant-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science, Sports and Culture, JSPS Research Fellowships for Young Scientists, the University of Tsukuba Special Research Projects, and ORISE. ORNL is managed by UT-Battelle, LLC, for the U.S. Department of Energy under Contract No. DE-AC05-00OR22725.

Abstract. Transverse energy, charged particle pseudorapidity distributions and photon transverse momentum spectra have been studied as a function of the number of participants (N_{part}) and the number of binary nucleon-nucleon collisions (N_{coll}) in 158·A GeV Pb+Pb collisions over a wide impact parameter range. A scaling of the transverse energy pseudorapidity density at midrapidity as $\sim N_{part}^{1.08\pm0.06}$ and $\sim N_{coll}^{0.83\pm0.05}$ is observed. For the charged particle pseudorapidity density at midrapidity we find a scaling as $\sim N_{part}^{1.07\pm0.04}$ and $\sim N_{coll}^{0.82\pm0.03}$. This faster than linear scaling with N_{part} indicates a violation of the naive Wounded Nucleon Model.

1 Introduction

Heavy-ion collisions at ultrarelativistic energies probe nuclear matter at high temperatures and densities. A major goal of these studies is the search for a deconfined phase of nuclear matter. A necessary condition to reach such a phase transition is local equilibration as might be achievable through rescattering of the produced particles. Since the amount of rescattering should increase with the size of the reaction system, it is of interest to study these reactions over a wide range of centralities.

For hard processes, where cross sections are small, the naive expectation is a scaling of the particle yields with the number of binary collisions. Experimentally, the scaling of cross sections with target mass in p+A collisions was studied and the scaling was observed to be even stronger than this expectation [1]. This was later attributed to multiple parton scattering in the initial state [2,3]. From the same experiment it was also seen that particle production at intermediate p_T shows a much weaker increase with target mass.

The gross features of particle production in nucleon-nucleus collisions and reactions of light nuclei are well described in the framework of the Wounded Nucleon Model [4]. In this model the transverse energy and particle production in p+A and A+A reactions is calculated by assuming a constant contribution from each participating nucleon. This kind of scaling has also been observed by the WA80 collaboration in reactions of ^{16}O and ^{32}S projectiles with various targets where $dE_T/d\eta|_{max}$ was found to depend approximately linearly on the average total number of participants [5].

While a scaling with the number of collisions arises naturally in a picture of a superposition of nucleon-nucleon collisions, with a possible modification by initial state effects, the Wounded Nucleon Model or participant scaling is more naturally related to a system with strong final state rescattering, where the incoming particles lose their memory and every participant contributes a similar amount of energy to particle production. The scaling behavior of particle production may therefore carry important information on the reaction dynamics. Various experimental signatures in heavy ion reactions require a comparison of observables for different system sizes. Therefore it is important to have a good understanding of these basic scaling properties. The scaling behavior can also be used as a valuable test for models of particle production in heavy ion reactions (see e.g. [6]).

Furthermore, several observables in heavy ion reactions seem to show qualitative changes once a certain system size is reached. Strangeness production is enhanced in S+S reactions compared to p+p, but seems to saturate for even larger nuclei (see e.g. [7]). Recent results from the WA98 experiment [8] show a significant change of the shape of the π^0 p_T spectrum in peripheral Pb+Pb collisions compared to p+p data. The shape, however, remains unchanged in the range of semi-central Pb+Pb collisions with about 50 participating nucleons up to central reactions.

The NA50 collaboration has observed an anomalously suppressed J/ψ yield in central Pb+Pb collisions in contrast to peripheral reactions [10] where the suppression of the J/ψ yield can be explained by absorption in nuclear matter. This anomalous J/ψ suppression provides an additional incentive to study the scaling behavior of particle production with the number of participants. Most models based on J/ψ absorption by hadronic comovers assume the comover density to scale linearly with the number of participants and are then not able to fit the anomalous suppression [11,12]. Only if the hadronic comover density scales substantially faster than linearly with the number of participants it is possible to obtain reasonable fits to the anomalous suppression. It is therefore of interest to study in detail the centrality dependence of particle production and investigate its scaling properties with respect to the number of participants or collisions.

2 Experiment and data analysis

The CERN experiment WA98 is a general-purpose apparatus which consists of large acceptance photon and hadron spectrometers together with several other large acceptance devices which allow to measure various global variables on an event-by-event basis. The experiment took data with the 158·A GeV ^{208}Pb beams from the CERN SPS in 1994, 1995, and 1996. The layout of the WA98 experiment as it existed during the final WA98 run period in 1996 is shown in Fig. 1. The data presented here were taken during the 1996 lead beamtime. The transverse energy and charged particle distributions shown in this paper were measured with the magnetic field of the Goliath magnet turned off. The minimum bias cross section for this configuration was $\sigma_{mb} = (6260 \pm 280)$ mb. The error of the minimum bias cross section relates to the uncertainty of the target thickness and the uncertainty in the subtraction of the contribution from interactions outside the target. The contribution of these interactions was determined in special target-out runs. A 20% uncertainty of this contribution was assumed in the calculation of the uncertainty of the minimum bias cross section. The WA98 experiment took most of the data with the Goliath

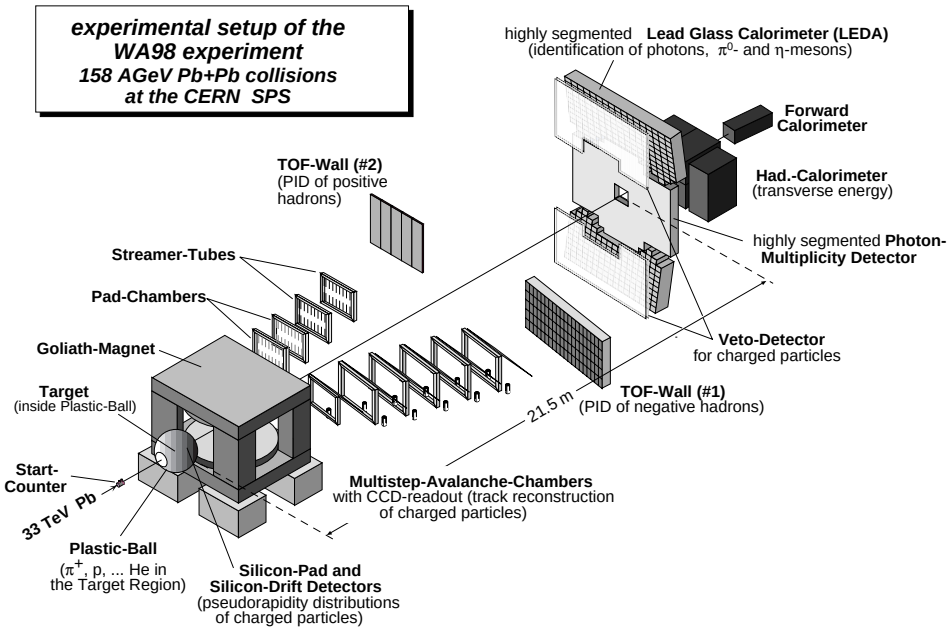

Fig. 1. The WA98 experimental setup

magnet turned on. Since the analysis of the photon and neutral pion scaling requires high statistics the respective spectra used here were measured in a field-on configuration. The minimum bias cross section for this data set was $\sigma_{mb} = (6440 \pm 300)$ mb.

The Zero Degree Calorimeter is located 30 m downstream of the target and measures the total energy of all particles within an angle $\Theta < 0.3°$ relative to the beam axis in the laboratory system. The MIRAC calorimeter is placed 24 m downstream of the target [13]. It consists of a hadronic and an electromagnetic section and covers the pseudorapidity interval $3.5 < \eta < 5.5$. MIRAC plays the central role in the WA98 minimum bias trigger where the measured E_T is required to be above a minimum threshold. The systematic errors of $dE_T/d\eta$ at midrapidity are dominated by the correction for the differences in the response of the MIRAC to hadronic and electromagnetic showers and to the extrapolation of the distribution of $dE_T/d\eta$ to midrapidity. These combine to give an overall systematic uncertainty of $\approx 20\%$ in the absolute result for $dE_T/d\eta|_{max}$. The centrality dependent part of this uncertainty is much smaller and estimated to be approximately 5% only. The correction of $dE_T/d\eta$ due to interactions outside the target for peripheral Pb+Pb reactions is less than 2%.

The charged particle multiplicity is measured with a circular Silicon Pad Multiplicity Detector (SPMD) located 32.8 cm downstream of the target [14]. It consists of four quadrants each produced from a 300 μm thick silicon wafer. This detector provides full azimuthal coverage of the pseudorapidity region $2.35 < \eta < 3.75$ with 180 Φ-bins and 22 η-bins. The pad size increases radially to provide an approximately uniform pseudorapidity coverage. In central Pb+Pb collisions the probability that a pad is hit by two or more particles is not negligible. Therefore the multiplicity in an η-ring is determined from the sum of the measured energy losses of the charged particles traversing the η-ring divided by the average energy loss per charged particle. The charged particle pseudorapidity distribution is corrected for δ-electrons produced by lead ions traversing the 213 μm thick ^{208}Pb target foil. On average these electrons give rise to roughly 11 additional hits in the SPMD. This contribution has been determined from beam triggers where no inelastic interaction took place. The systematic error of $dN_{ch}/d\eta$ relates to the uncertainty in the determination of the total energy loss of the charged particles in the SPMD and to the correction for δ-electrons. The uncertainty in the energy loss measurement is estimated to result in a 3% centrality independent systematic error. The correction for δ-electrons at midrapidity ($dN_\delta/d\eta|_{mid} \approx 9$) is assumed to be known with an accuracy of 10% and contributes significantly to the total uncertainty only for peripheral reactions. However, the $dN_{ch}/d\eta$ distributions as shown in Fig. 6 exhibit a slight asymmetry around midrapidity. We can force the $dN_{ch}/d\eta$ distribution to be symmetric by arbitrarily increasing the subtracted δ-electron contribution. For central events the δ-electron yield has to be increased by roughly 80%. This factor decreases when going to semi-central and peripheral events. It's difficult to imagine a physical reason for a much larger δ-electron production than what was measured for beam triggers. However, by making these extreme assumptions we estimate the centrality dependent error of $dN_{ch}/d\eta$ by comparing the $dN_{ch}/d\eta$ distributions with δ-electrons subtracted as measured in beam events with the $dN_{ch}/d\eta$ distributions that were forced to be symmetric. For peripheral and semi-central events this uncertainty typically is of the order of $3-4\%$ and decreases to 2% in central events. The correction of $dN_{ch}/d\eta$ measured with the SPMD in peripheral events due to interactions outside the target is typically of the order of 15%. The uncertainty of $dN_{ch}/d\eta$ due to this correction is estimated to be around 3%.

The photon distributions used in this analysis were measured with the LEDA spectrometer in the rapidity interval $2.3 < \eta < 3.0$. This detector is located 21.5 m from the target and consists of 10080 leadglass modules each read out by a photomultiplier. A streamer tube array placed directly in front of LEDA was used as a charged particle veto detector to correct for the charged hadron contamination in the leadglass. The remaining correction for neutrons and anti-neutrons has been made based on simulation results using the GEANT package [15]. The detection efficiency of photons in LEDA is based on GEANT simulations and experimental data in order to take into account the effects of overlapping showers which can result in a shift in the measured transverse momentum. These corrections require high statistics and therefore only 8 centrality classes have been used for the photon analysis here. These are the same 8 centrality classes used in the analysis of the scaling of neutral pion production presented in [8]. The systematic error on the photon and neutral pion multiplicities is estimated to be $\approx 10\%$ mainly originating from corrections for efficiency and contamination.

3 Model calculations

In the present analysis, the photon and charged particle scaling has been investigated with the centrality of the Pb+Pb collision determined from the transverse energy, E_T, measured with the MIRAC calorimeter. However, in the E_T scaling analysis, the forward energy E_F of projectile spectators measured with the Zero Degree Calorimeter has been used for the centrality selection, in order to avoid auto-correlations. Twenty-one centrality classes have been defined based on the measured E_T. Each class corresponds to 5% of the minimum bias cross section, with an additional very central class corresponding to the 1% most central events. The ZDC cannot resolve the centrality of very peripheral collisions as well as the MIRAC calorimeter and therefore the E_T scaling analysis is limited to centrality classes which correspond to more than approximately 40 participants.

The number of participants N_{part} and collisions N_{coll} for a given centrality class have been determined from a simulation based on the event generator VENUS 4.12 [16]. Control calculations were made with the FRITIOF event generator [29]. The definition of N_{part} and N_{coll} in these models is based on a geometrical picture (Glauber model) where nucleons travel on straight-line trajectories and the nucleon-nucleon cross section is independent of the number of collisions a nucleon has undergone before. The approach of using event generators allowed to take into account the energy resolution of the ZDC and MIRAC calorimeters. Furthermore, the minimum bias trigger efficiency has been included in the simulation. Figure 2 shows a comparison of the measured E_T and E_F distributions to the VENUS simulations. The overall agreement in the E_T distribution between the data and the model is good. However, the VENUS prediction extends to slightly higher transverse energy for the most central reactions. In the forward energy distribution, the strong peak for peripheral reactions is not precisely reproduced, while the general shape is quite similar. Also the event-by-event anti-correlation of E_T and E_F observed in the experimental data is in good agreement with the model calculations (see Fig. 3).

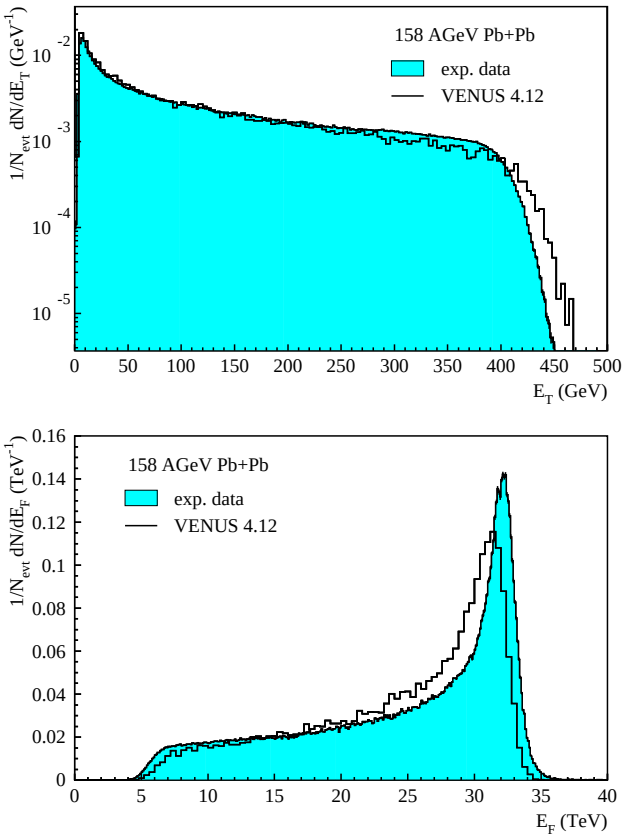

Fig. 2. Distributions of the transverse energy E_T as measured in MIRAC (upper graph) and the forward energy E_F as measured with the ZDC (lower graph) in 158·A GeV Pb+Pb collisions. Predictions of the event generator VENUS 4.12 are included

To obtain a robust estimate of N_{part} and N_{coll}, which is less sensitive to discrepancies in the energy distributions, the centrality classes in the model have been chosen to represent the same absolute cross section as the data. The effect of the centrality cuts on the distributions of the number of participants can be seen from Fig. 4, where distributions of N_{part} for centrality classes corresponding to fractions of the minimum bias cross section of 0-1%, 1-5%, 5-10%, 10-20%, 20-40%, 40-60%, 60-80% and 80-100% are shown. One can see that the limited acceptance, the detector resolution, and the fluctuations in particle production as implemented in the model lead to an overlap of the distributions of adjacent centrality classes. Nevertheless, it is observed that even a strong cut on the 1% most central reactions yields a significantly different selection than e.g. the 5% most central reactions.

Figure 5 shows a summary of the RMS-values versus the average values of the distributions of N_{part} for the centrality selections as used in the later analysis in this

paper. While the classes selected with E_F have a slightly smaller width for very central reactions, for peripheral reactions the resolution of the selection is much better using E_T.

The precise number of participants or number of collisions may, however, depend on the specific model assumptions. We have therefore performed a detailed study of the influence of these assumptions and other sources of systematic errors for the analysis presented here. A summary of these studies is given in Appendix A.

4 Results

The pseudorapidity distributions for the transverse energy, the charged particle multiplicity, and the photon multiplicity are shown in Fig. 6 for five centrality classes. All distributions have been corrected for possible contributions of reactions upstream and downstream of the target and in the target frame by subtracting the respective yield determined in target-out runs, see [19] for further details. To obtain $dE_T/d\eta|_{max}$ the measured data points have been reflected at midrapidity ($\eta_{cm} = 2.91$) and fitted with a Gaussian.

A first impression of the centrality dependence of E_T and charged particle production can be obtained by normalizing the yields to the number of participants. This is shown in Fig. 7. Both for E_T and the charged multiplicity the yield per participant increases when going from peripheral to more central reactions. As described in the

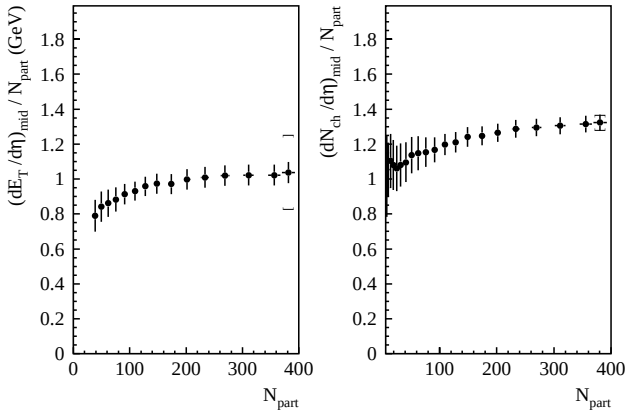

Fig. 7. Transverse energy and charged particle yields in 158·A GeV Pb+Pb reactions normalized to the number of participants as a function of the number of participants. For the number of participants an uncertainty as indicated in Fig. 16 was assumed. Furthermore, all centrality dependent errors of $dE_T/d\eta$ and $dN_{ch}/d\eta$ as described in Sect. 2 were taken into account in the calculation of the error bars. The brackets indicate the centrality independent uncertainty of the overall $dE_T/d\eta$ and $dN_{ch}/d\eta$ scale

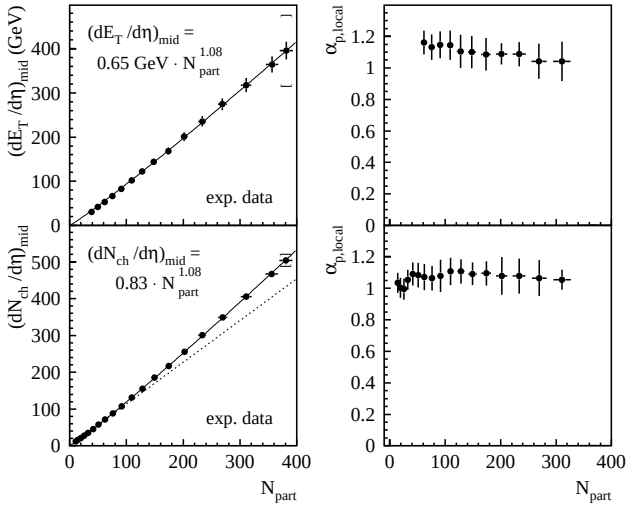

Fig. 8. Pseudorapidity density of E_T and N_{ch} at midrapidity as a function of the number of participants. The participant numbers shown here were calculated in a VENUS simulation (denoted as calculation A in the appendix). Both for E_T and N_{ch} the fit results obtained from a fit of all data points are shown. In order to demonstrate the stronger than linear increase of the data points a linear extrapolation of the charged particle multiplicity in peripheral Pb+Pb reactions ($N_{part} \approx 50$) is shown as a dotted line in the lower left plot. The scaling behavior can be verified in more detail on the right panel where the local scaling exponents are shown. The local scaling exponents have been obtained from a fit of 5 neighboring E_T and N_{ch} data points

appendix we have also used the FRITIOF model instead of VENUS to calculate the number of participants and the number of nucleon-nucleon collisions. The results of these two calculations for the number of participants are compared in the appendix (Fig. 16) and used to obtain the estimated uncertainty of the number of participants which was used in the calculation of the error bars in Fig. 7.

The scaling behavior is studied in more detail in Fig. 8 which shows the dependence of the E_T and N_{ch} pseudorapidity densities at midrapidity on the number of participants. The scaling behavior of these observables was parameterized as

$$\left.\frac{dX}{d\eta}\right|_{mid} \sim N_{part}^{\alpha_p},\ N_{coll}^{\alpha_c}, \quad X = E_T,\ N_{ch}\,. \qquad (1)$$

This functional dependence gives a reasonable description of the data for the entire centrality range. Taking the number of participants from the VENUS calculation (denoted as calculation A in the appendix) the charged particle scaling can be described by a scaling exponent $\alpha_p = 1.08$. The calculations of the number of participants using VENUS, or VENUS with an experimentally determined nucleon density distribution, or FRITIOF (denoted as calculations A, B, and F in the appendix) are all based on reasonable assumptions. These three calculations give slightly different participant numbers. We quote the average of the corresponding three scaling exponents α_p as the final result. As described in the appendix the estimated uncertainty of α_p due to the uncertainty of the number of participants is 0.036. In the fit from which we obtain the value of α_p we only take the statistical error of the data points into account. Since the statistical errors are small the fit error is negligible. In order to estimate the influence of the centrality dependent errors of $dN_{ch}/d\eta$ on α_p we systematically move the data points within the error bars and repeat the fit. From this procedure we estimate an uncertainty of 0.02 for α_p due to the centrality dependent errors of $dN_{ch}/d\eta$. Adding all errors in quadrature we finally obtain $\alpha_p = 1.07 \pm 0.04$ for the charged particle scaling.

For the E_T scaling we perform a similar error analysis. An additional uncertainty comes from the assumed centroid of the $dE_T/d\eta$ distribution. Primarily due to massive particles like protons and neutrons, the difference between pseudorapidity and rapidity could lead to an increase of the centroid relative to midrapidity ($y_{mid} = 2.91$). By varying the assumed $dE_T/d\eta$ centroid position in the η-range 2.91 ± 0.3 a corresponding error of 0.02 was estimated for the E_T scaling exponent α_p. Adding all errors in quadrature we obtain $\alpha_p = 1.08 \pm 0.06$.

In more detail, the relative scaling for different centralities can be judged from the *local scaling exponent* α_{local} shown on the right hand side of Fig. 8. These have been obtained from a fit of 5 neighboring E_T and N_{ch} data points. For the charged particles it can be seen that the scaling remains approximately constant over the whole centrality range. For E_T the local scaling exponent appears to be almost constant in the range $N_{part} > 100$. However, below $N_{part} \approx 100$ the local scaling exponent seems to increase slightly.

Considering the scaling with the number of binary nucleon-nucleon collisions and averaging the results determined with calculations A, B, and F we obtain a similarly

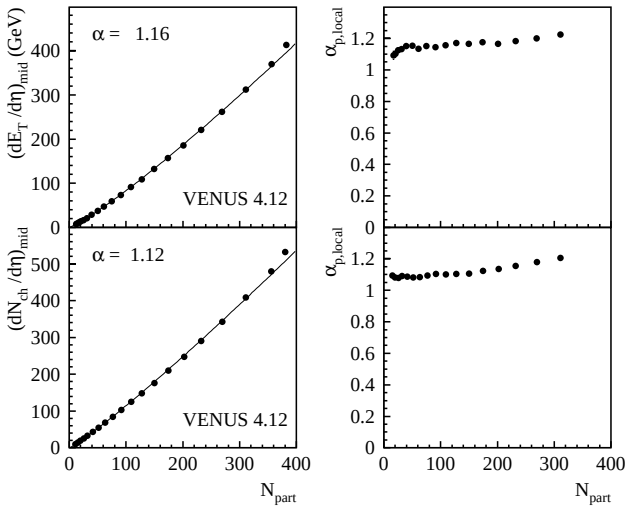

Fig. 9. Pseudorapidity density of E_T and N_{ch} at midrapidity as a function of the number of participants as in Fig. 8 from VENUS 4.12 simulations

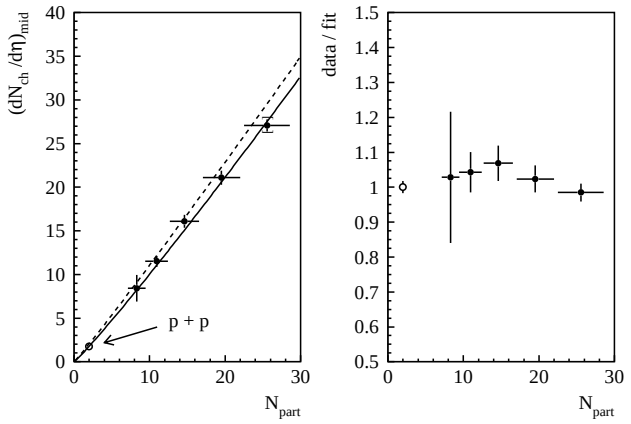

Fig. 10. Pseudorapidity density of N_{ch} at midrapidity as a function of the number of participants for p+p [22] and Pb+Pb collisions. The number of participants shown here were calculated using VENUS (calculation A in the appendix). The fit function plotted as a solid line is the same as obtained in Fig. 8. The dashed function is the fit result using the participant values from the FRITIOF calculation (calculation F). On the right hand side the ratio of the data (using participants from VENUS) to the fit function is shown

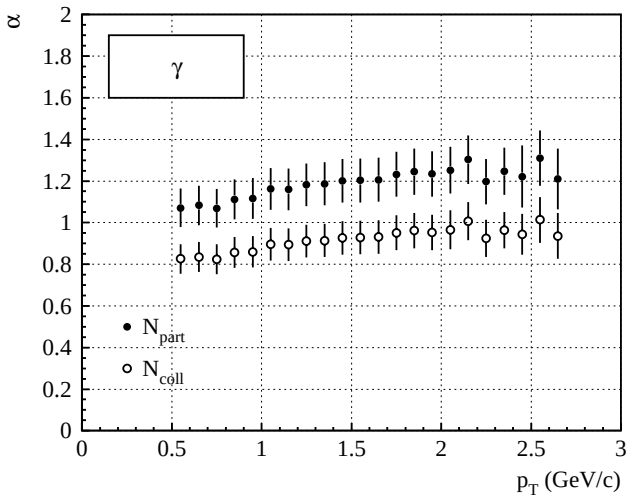

Fig. 11. Exponents for a scaling with the number of participants and nucleon-nucleon collisions for photons measured in LEDA as a function of the transverse momentum. Only reactions with $N_{part} \geq 30$ have been used. The data points shown were obtained using the number of participants from VENUS. The error bars reflect the uncertainty of the photon measurement, the uncertainty in the calculation of N_{part}/N_{coll} and the fit error

good description with $\alpha_c = 0.82 \pm 0.03$ for the charged particle scaling. For the E_T scaling we obtain $\alpha_c = 0.83 \pm 0.05$. These results are not surprising since for symmetric systems one naively expects a scaling relation to hold between the number of collisions and the number of participants:

$$N_{coll} \propto N_{part}^{\alpha_{cp}} \text{ with } \alpha_{cp} = \frac{4}{3}. \qquad (2)$$

Fits of the parameters extracted from VENUS simulations indeed yield a value of $\alpha_{cp} = 1.28$ which is close to the above value. For a scaling with $N_{part}^{1.08}$ this would lead to a behavior as $N_{coll}^{0.84}$.

A similar analysis can be performed on the data obtained from the VENUS simulation itself. The results of such an analysis are displayed in Fig. 9. It is observed that the scaling exponents are higher in the simulation, and that both for E_T and N_{ch} the exponent α shows a tendency to increase with centrality. We note here that the extraction of the number of participants and the number of binary nucleon-nucleon collisions is almost completely independent of the scaling exponent present in the underlying event generator. As described in Sect. 3 this is due to the fact that the centrality classes defined in the model calculations correspond to the same absolute cross section as the experimental centrality classes.

It is interesting to extrapolate this scaling towards smaller system sizes and compare to the expectation from pp collisions [22]. This has been done in Fig. 10. It can be seen that the scaling obtained from charged particle production in Pb+Pb collisions extrapolates nicely to pp collisions. In particular, there is no threshold effect visible in the charged particle multiplicity when going to central Pb+Pb collisions.

In a recent publication [18] we have discussed the systematics of inclusive photon production as measured with the WA98 Photon Multiplicity Detector. There it was found that the pseudorapidity density of photons at midrapidity scales with the number of participants as $N_{part}^{1.12 \pm 0.03}$. This is slightly larger, but consistent with the exponent from the present analysis of E_T and N_{ch}. Photon production can be investigated in further detail with the photon spectrometer LEDA. It can very naturally be studied as a function of the transverse momentum. The corresponding scaling exponents α extracted are shown in Fig. 11. The photon measurement in LEDA suffers from larger systematic uncertainties at low momenta, so only photons for $p_T > 500$ MeV/c have been considered. At

a transverse momentum of $p_T \approx 500$ MeV/c the inclusive photon yield shows a scaling behavior similar to that observed for E_T and N_{ch}. However, the extracted scaling exponents tend to rise with increasing p_T and at $p_T \approx 2$ GeV/c the scaling can be described as $\sim N_{part}^{1.2}$ and $\sim N_{coll}^{0.9}$.

Since a large fraction of the inclusive photons originates from the decay of neutral pions it is of interest to compare the scaling of photons to that of neutral pions which have already been discussed in [8]. These data have been reanalyzed [9] and the results of the scaling exponents with respect to the number of participants are shown in Fig. 12. The values are nearly constant at $\alpha \approx 1.1$ with a tendency to decrease towards higher transverse momenta. It should be noted that the extracted exponents are smaller compared to the values given in [8]. This is mostly due to a more sophisticated calculation of the number of participants used here.

We have recently published results on the production of direct photons in 158·A GeV Pb+Pb collisions [20,21]. A significant yield of direct photons at $p_T > 1.5$ GeV/c is observed in central collisions, while in peripheral collisions the photon production is consistent with the yield expected from the decays of neutral pions, η mesons, and other hadrons. At $p_T \approx 2$ GeV/c the direct photon yield in central collisions amounts to roughly 20% of the photons from hadronic decays. The scaling of the neutral pion yield presented in Fig. 12 appears to be consistent with the scaling of charged particles and the transverse energy, while the photon yield at higher transverse momenta seems to increase more strongly with the number of participants. We assume that for a relatively small yield of direct photons in central collisions, the centrality dependence of the inclusive photons can still be described with a scaling law as in (1). It's then obvious that the production of direct photons in central Pb+Pb collisions necessarily increases the scaling exponent α of the inclusive photons at high transverse momenta. In this respect the behavior of the extracted scaling exponents for inclusive photon and neutral pion production are consistent with the direct photon excess observed in central Pb+Pb collisions. However, due to the uncertainties of the scaling exponents for photons and neutral pions it is not possible to draw quantitative conclusions about direct photon production from Figs. 11 and 12.

In simple multiple collision models a heavy ion reaction is regarded as a sequence of independent nucleon-nucleon collisions which can be described as in free space [23,24]. After a projectile nucleon suffers an inelastic collision the assumption of local baryon number conservation assures that a baryon-like object is still present. This baryon-like object is assumed to contribute to the particle production in subsequent collisions with the same cross section as the initial nucleon. In this picture the contribution of each nucleon-nucleon collision is added incoherently which leads to a linear scaling of E_T and particle production with the number of binary collisions. If the energy degradation in each nucleon-nucleon reaction is taken into account a reasonable description of E_T and particle production can

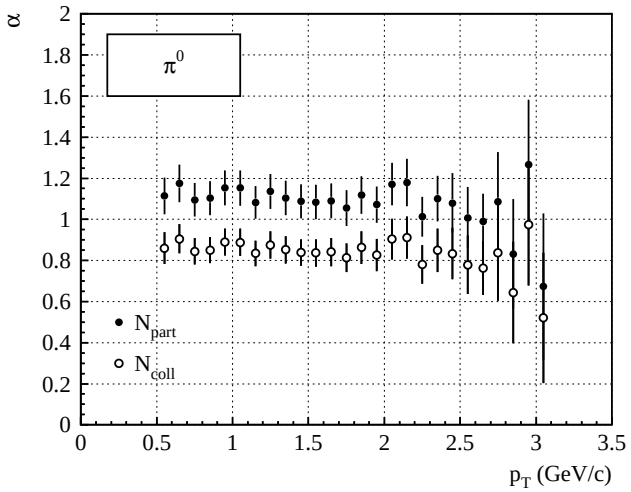

Fig. 12. Exponents for a scaling with the number of participants and nucleon-nucleon collisions for neutral pions measured in LEDA as a function of the transverse momentum. Only reactions with $N_{part} \geq 30$ have been used. The data points shown were obtained using the number of participants from VENUS. The error bars reflect the uncertainty of the π^0 measurement, the uncertainty in the calculation of N_{part}/N_{coll} and the fit error

be obtained. The approximate scaling as $N_{coll}^{0.83}$ for the transverse energy and charged particles may be used to obtain information on the average energy degradation in a nucleon-nucleon collision.

A simple way of investigating this hypothesis is to study the particle production per binary collision as a function of the effective thickness x of the two nuclei, which might be characterized in the following way [23–25]:

$$\frac{dN_{ch}}{d\eta}(AA) = N_{coll} \cdot f(x) \cdot \frac{dN_{ch}}{d\eta}(pp). \qquad (3)$$

Here $f(x)$ should describe the effect of energy degradation on particle production with x being a suitable thickness variable – we have chosen $x \equiv N_{coll}/N_{part}$. Figure 13 shows the pseudorapidity density of N_{ch} at midrapidity in Pb+Pb collisions normalized to the number of collisions and the charged particle density in pp collisions. The data show a continuous decrease of the multiplicity per collision for increasing x, i.e. the more collisions a participant suffers, the smaller is the contribution of each collision to particle production. As an example, this can be illustrated more quantitatively for the centrality classes with $N_{coll}/N_{part} \approx 1$, i.e. for the case that each participating nucleon on the average suffers two nucleon-nucleon collisions. For these reactions the actual charged particle density at midrapidity is 40% lower than one would expect from a linear scaling of the charged particle density in pp reactions with the number of binary nucleon-nucleon collisions. In a simple multiple collision picture this means that on the average the second collisions of each participant contributes only 20% of the yield of the first collision to the charged multiplicity at midrapidity.

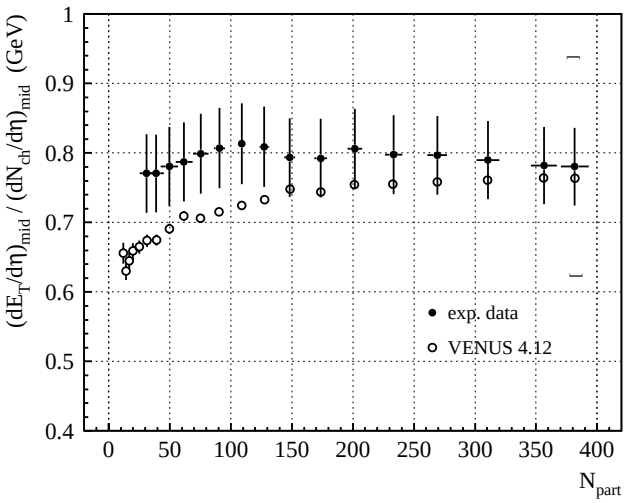

Fig. 14. $\langle E_T\rangle/\langle N_{ch}\rangle|_{mid}$ as a function of the number of participants. For comparison results of VENUS 4.12 calculations are included. The error bars indicate the centrality dependent errors of the experimental result. The overall uncertainty of $\langle E_T\rangle/\langle N_{ch}\rangle|_{mid}$ which is mainly due to the uncertainty in $(dE_T/d\eta)_{mid}$ is indicated by brackets

In proton-nucleus reactions multiplication of the charged particle multiplicity observed in pp reactions by the number of binary nucleon-nucleon collisions overestimates the measured multiplicity by $20-30\%$ [26,27]. In case of proton-nucleus reactions the target participants suffer exactly one nucleon-nucleon collision. This is of course not true in AA collisions. Nevertheless, it is interesting to apply the same recipe to heavy ion reactions. Figure 13 shows that multiplying the pp yield with the number of binary nucleon-nucleon collisions gives as much as 60% too many charged particles in central Pb+Pb reactions.

We have attempted to fit the data in Fig. 13 with the form:

$$f_{fit}\left(\frac{N_{coll}}{N_{part}}\right) = \left[1 + a\left(\frac{N_{coll}}{N_{part}} - 0.5\right)\right]^{-1}. \quad (4)$$

This function basically represents a first order Taylor approximation of the function $1/f$ in (3). A good fit is obtained with $a = 1.19 \pm 0.05$.

In the case of the Wounded Nucleon Model the eventual fragmentation of an excited nucleon after an inelastic collision is not affected by further collisions with other nucleons, no matter how many times it is successively struck. The observation of a stronger than linear increase of E_T and N_{ch} with the number of participants indicates that this model is only approximately correct. It can be clearly seen, regarding the two possible centrality variables investigated here, that the number of participants is better suited, because the scaling exponent is closer to one compared to the number of collisions.

With the present data it is possible to determine the average transverse energy per charged particle at midrapidity

$$\langle E_T\rangle/\langle N_{ch}\rangle|_{mid} \equiv \langle dE_T/d\eta|_{mid}\rangle/\langle dN_{ch}/d\eta|_{mid}\rangle, \quad (5)$$

a quantity that can be seen as a measure of the global mean transverse momentum averaged over all particle species. $\langle E_T\rangle/\langle N_{ch}\rangle|_{mid}$ is plotted in Fig. 14 as a function of centrality, represented by the number of participants. For this figure both $dE_T/d\eta$ and $dN_{ch}/d\eta$ were evaluated in identical centrality classes, defined with the forward energy E_F.

$\langle E_T\rangle/\langle N_{ch}\rangle|_{mid}$ appears to increase up to a system size of $N_{part} \approx 100$ which corresponds to an impact parameter of $b \approx 9$ fm. For more central collisions $\langle E_T\rangle/\langle N_{ch}\rangle|_{mid}$ levels off at a value of 0.80 GeV. This value is slightly higher than the maximum $\langle E_T\rangle/\langle N_{ch}\rangle|_{mid} \approx 0.66$ GeV observed in 200·A GeV S+Au and S+Al reactions [17]. VENUS 4.12 predicts a qualitatively similar behavior for $\langle E_T\rangle/\langle N_{ch}\rangle|_{mid}$, while the absolute value is approximately 100 MeV lower at $N_{part} \approx 100$. One may also note that the VENUS results continue to rise by ≈ 50 MeV when going from $N_{part} \approx 100$ to $N_{part} \approx 400$, while the experimental data appear to be completely flat in this region. A similar saturation with increasing number of participants as observed here has been seen in the (truncated) mean p_T of neutral pions with $p_T > 400$ MeV/c produced in Pb+Pb reactions [8]. A natural explanation of such a behavior would be the assumption that thermalization is reached once the system exceeds a certain minimum size.

5 Conclusions

We have analyzed the dependence of transverse energy and charged particle pseudorapidity distributions and photon transverse momentum spectra in 158·A GeV Pb+Pb collisions on the number of participants and the number of binary nucleon-nucleon collisions. A scaling behavior as $N_{part}^{1.07\pm0.04}$ and $N_{coll}^{0.82\pm0.03}$ describes the

charged particle production over the whole impact parameter range. The E_T production was studied for collisions with more than approximately 40 participants. In this centrality range the E_T production scales as $N_{part}^{1.08\pm0.06}$ and $N_{coll}^{0.83\pm0.05}$.

Photons at $p_T \approx 500$ MeV/c show a scaling behavior similar to the scaling of E_T and N_{ch}. The p_T-dependence of the photon scaling was studied and a rise of the extracted scaling exponents with increasing transverse momentum was found.

We have studied the transverse energy per charged particle as a function of centrality and found an indication of an increase from peripheral to semi-central collisions with approximately 100 participants with a subsequent saturation for larger systems.

While the global variables like E_T and charged particle multiplicity seem to scale closer to the number of participants than to the number of binary collisions, there is a clear participant scaling violation compared to a purely linear dependence. This scaling violation might e.g. have consequences for the suppression of J/ψ production from comovers, since the implied central particle densities are considerably larger than estimated based on a linear scaling.

Acknowledgements. We wish to express our gratitude to the CERN accelerator division for excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians and support staff who have participated in the construction of the experiment. This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR and FRN, the Dutch Stichting FOM, Polish KBN under contract 621/E-78/SPUB/CERN/P-03/DZ211, the Grant Agency of the Czech Republic under contract No. 202/95/0217, the Department of Atomic Energy, the Department of Science and Technology, the Council of Scientific and Industrial Research and the University Grants Commission of the Government of India, the Indo-FRG Exchange Program, the PPE division of CERN, the Swiss National Fund, the INTAS under Contract INTAS-97-0158, ORISE, Research-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science and Culture, the University of Tsukuba Special Research Projects, and the JSPS Research Fellowships for Young Scientists. ORNL is managed by Lockheed Martin Energy Research Corporation under contract DE-AC05-96OR22464 with the U.S. Department of Energy. The MIT and University of Tennessee groups have been supported by the US Dept. of Energy under the cooperative agreements DE-FC02-94ER40818 and DE-FG02-96ER40982, respectively.

Appendix A: Systematic uncertainties in model calculations

In order to obtain an estimate of the systematic uncertainties in the calculation of the number of participants and the number of nucleon-nucleon collisions we have varied several assumptions in the model calculations. The dependence of the particle and transverse energy yield on the number of participants and collisions is described with the scaling exponents α_p and α_c in this paper. In this section we investigate how the extracted scaling exponents α_p and α_c for the charged particle yield (with similar conclusions for the other observables) are affected by the different model assumptions.

In the VENUS 4.12 simulations used to obtain the number of participants and collisions we have varied

- the parameterization of the nucleon density distribution,
- the energy resolution of MIRAC and
- the minimum bias cross section.

As a cross check we have also calculated the number of participants and collisions using the event generator FRITIOF [29].

The nuclear density profile used in VENUS and FRITIOF is an effective parameterization using a Woods-Saxon shape:

$$\rho(r) = \rho_0 \cdot \frac{1}{1+\exp\left(\frac{r-R}{a}\right)}. \tag{6}$$

However, the two models make slightly different assumptions for the nuclear radius R and the diffuseness parameter a. The VENUS parameterization is

$$\begin{aligned} R_{\mathrm{VEN}} &= (1.19A^{1/3} - 1.61A^{-1/3})\ \mathrm{fm} \\ a_{\mathrm{VEN}} &= 0.54\ \mathrm{fm} \end{aligned} \tag{7}$$

which results in $R_{\mathrm{VEN}} \approx 6.78\,\mathrm{fm}$ for a lead nucleus. The radius parameter in FRITIOF for nuclei with $A > 16$ is calculated as

$$\begin{aligned} R_{\mathrm{FRI}} &= r_0 \cdot A^{1/3} \quad \text{with} \\ r_0 &= 1.16 \cdot (1 - 1.16A^{-2/3})\ \mathrm{fm}. \end{aligned} \tag{8}$$

This gives $R_{\mathrm{FRI}} \approx 6.65\,\mathrm{fm}$ for lead nuclei. The diffuseness parameter a is taken to be slightly A-dependent in FRITIOF and lies in the range $0.47\,\mathrm{fm} - 0.55\,\mathrm{fm}$. For lead nuclei FRITIOF uses

$$a_{\mathrm{FRI}} = 0.545\,\mathrm{fm}. \tag{9}$$

Electron scattering experiments have shown, however, that the density distribution has a slightly more complicated structure[1]. For a comparison we will use a parameterization fitted to electron scattering data on ^{208}Pb presented in [28]:

$$\rho_{\mathrm{exp}}(r) = \rho_0 \cdot \frac{c_1 + c_2 r + c_3 r^2}{1+\exp\left(\frac{r-R_{\mathrm{exp}}}{a_{\mathrm{exp}}}\right)} \tag{10}$$

with

$$c_1 = 0.0633,\ c_2 = -0.002045\,\mathrm{fm}^{-1}, c_3 = 0.000566\,\mathrm{fm}^{-2}$$

[1] Strictly this applies only to the charge distribution. The true nucleon distribution, especially in the inner part of the nuclei, is not experimentally accessible

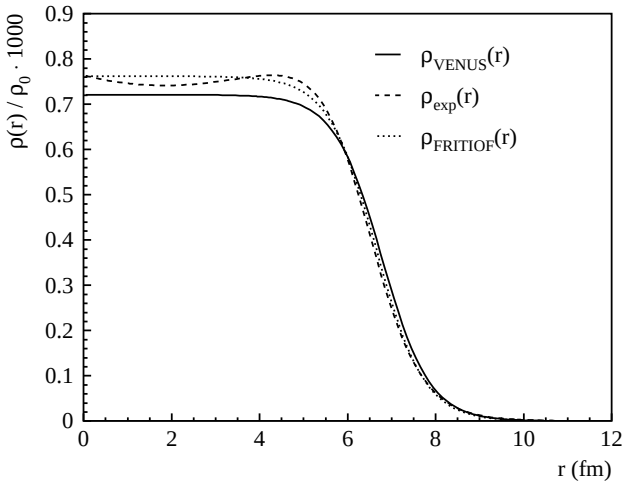

Fig. 15. Different nuclear density distributions used in the calculations of the number of participants and the number of collisions. The solid line shows the distribution implemented in the VENUS 4.12 Monte-Carlo model ((6) with the parameters (7)), the dashed line shows a parameterization of the charge distribution obtained from electron scattering (10) and the dotted line shows the density used in the FRITIOF model ((6) with the parameters (8) and (9))

and

$$R_{\rm exp} = 6.413\,{\rm fm},\ a_{\rm exp} = 0.5831\,{\rm fm}.$$

The three different distributions are shown in Fig. 15. It can be seen that the overall agreement is quite good. The default distribution of VENUS has a slightly larger radius, while the parameterization of the experimental data shows small oscillations compared to the other two distributions.

With respect to the experimental resolution we have varied the energy resolution of the MIRAC calorimeter in the simulations. The measured values of the resolution [13] are for the electromagnetic section:

$$\frac{\sigma_{\rm em}}{E} = \frac{17.9\,\%}{\sqrt{E/{\rm GeV}}} \tag{11}$$

and for the hadronic section:

$$\frac{\sigma_{\rm had}}{E} = \frac{46.1\,\%}{\sqrt{E/{\rm GeV}}}. \tag{12}$$

This has been arbitrarily worsened to

$$\frac{\sigma_{\rm em,had}}{E} = \frac{85\,\%}{\sqrt{E/{\rm GeV}}} \tag{13}$$

for both sections of the calorimeter.

For an accurate determination of the number of participants and the number of nucleon-nucleon collisions it is necessary that the experimental minimum bias threshold is reproduced in the simulation. In Sect. 2 we stated the two sources in the determination of the experimental minimum bias cross-section: the error of the target thickness and the error due to subtraction of interactions outside the target. In our approach of calculating the number of participants and nucleon-nucleon collisions we define centrality classes based on the simulated E_T (in case of the N_{ch} scaling analysis) which correspond to the same absolute cross-sections as the respective classes for the measured E_T. The uncertainty of the minimum bias cross-section due to the error of the target thickness therefore directly leads to an error of the N_{part}-values which affects the entire centrality range. However, the uncertainty in the correction for interactions outside the target affects the experimental $d\sigma/dE_T$ distribution only in the peripheral range. More precisely, since the maximum E_T measured in target-out events is around 75 GeV, according to Table 1 only the range $N_{part} < 50$ is affected.

The measured target thickness is $213 \pm 3\,\mu$m. The uncertainty of the target thickness contributes a relative error of roughly 1.5% to the error of the experimental minimum bias cross section. In order to check the influence on the extracted scaling exponent we arbitrarily increase the minimum bias threshold in the simulation by roughly 2% to $\sigma_{mb}^{sim} = 6386\,$mb. We have furthermore checked the error of α_p due to the uncertainty of the minimum bias cross section that relates to the subtraction of non-target contributions. To do this, we have used an E_T distribution without correction for reactions outside the target to translate the experimental E_T cuts into cross section

Table 1. The number of participants and binary collisions for different centrality classes obtained with the measured transverse energy in Pb+Pb collisions calculated from VENUS and FRITIOF (see text)

% of c.s.	E_T^{min} (GeV)	N_{part} VENUS	N_{coll} VENUS	N_{part} FRITIOF	N_{coll} FRITIOF

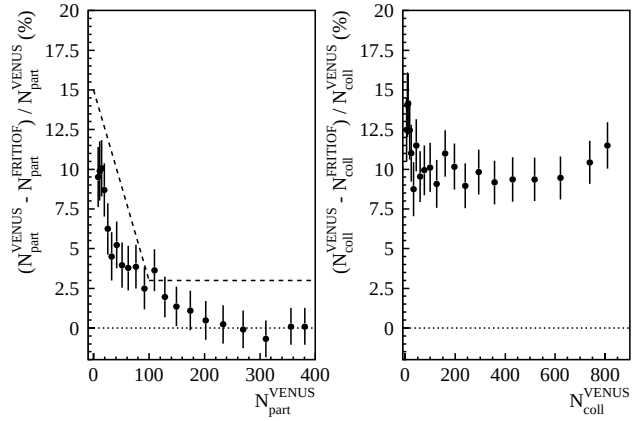

Fig. 16. Relative difference of the number of participants (left) and the number of nucleon-nucleon collisions (right) calculated with VENUS (calculation A) and FRITIOF (calculation F). The dashed line on the left plot indicates the assumed uncertainty of the participant scale that is used in the calculation of the error bars in Fig. 7

cuts. The apparent minimum bias cross section for this E_T distribution was $\sigma_{mb} = 6530$ mb.

The different calculations of the number of participants and collisions are summarized in the following list:

- A VENUS 4.12 calculations using the standard settings for the density distribution, the experimental resolution and the minimum bias cross section.
- B VENUS 4.12 calculations as in case Appendix A: with a modified density distribution according to (10).
- C VENUS 4.12 calculations as in case Appendix A: with a modified MIRAC resolution.
- D VENUS 4.12 calculations as in case Appendix A: with an a minimum bias cross section increased to $\sigma_{mb}^{sim} = 6386$ mb.
- E VENUS 4.12 calculations with cross section cuts derived from an experimental E_T-spectrum that was not corrected for interactions outside the target (apparent minimum bias cross section: $\sigma_{mb} = 6530$ mb).
- F FRITIOF calculations using standard settings as in calculation A.

As an example, the number of participants and collisions from calculation A and F are compared in Fig. 16. In peripheral Pb+Pb reactions VENUS gives up to 10% more participants than FRITIOF whereas in central reactions both simulations yield almost identical results. Almost independent of centrality the number of collisions from VENUS is roughly 10% higher than the FRITIOF result. The results of calculation A and F together with the experimental E_T intervals are given in Table 1.

For the case of the N_{ch} scaling the impact of the different model assumptions on the extracted scaling exponents α is summarized in Table 2. Considering the scaling with the number of participants we take the average of the α_p values from calculations A, B and F as our final result since all three calculations are based on reasonable assumptions. The maximum difference of 0.03 between the α_p values from these calculations is taken as one contribution to the systematic error. By adding the deviations of the results from calculations C, D and E from the mean value 1.07 in quadrature we estimate the total systematic error of α_p related to the uncertainty of the number of participants to be 0.036. The same prescription yields an uncertainty of 0.024 for the exponent α_c that described the scaling with the number of binary nucleon-nucleon collisions.

Table 2. Influence of different model assumptions on the extracted exponents α_p and α_c which describe the scaling of the charged particle yield with N_{part} and N_{coll} according to (1). In addition to the scaling exponents we quote the proportionality constants for the scaling with N_{part} (c_p) and N_{coll} (c_c) for each calculation. The full centrality range was used in the fit of (1) to the measured charged particle yields

Calculation	c_p	α_p	c_c	α_c
A	0.83	1.08	1.94	0.83
B	0.88	1.07	2.15	0.81
C	0.86	1.07	1.99	0.83
D	0.98	1.05	2.13	0.83
E	0.87	1.07	2.01	0.82
F	0.97	1.05	2.13	0.83

(Received 13 June 2000)

A measurement of direct photon production in ^{208}Pb + ^{208}Pb collisions at 158A GeV has been carried out in the CERN WA98 experiment. The invariant yield of direct photons in central collisions is extracted as a function of transverse momentum in the interval $0.5 < p_T < 4$ GeV/c. A significant direct photon signal, compared to statistical and systematical errors, is seen at $p_T > 1.5$ GeV/c. The result constitutes the first observation of direct photons in ultrarelativistic heavy-ion collisions. It could be significant for diagnosis of quark-gluon-plasma formation.

The observation of a new phase of strongly interacting matter, the quark-gluon plasma (QGP), is one of the most important goals of current nuclear physics research. An extensive experimental program has been undertaken at the CERN SPS accelerator with Pb-ion beams of 158*A* GeV to search for and investigate the QGP. Several observations, such as suppression of the J/ψ resonance [1] and the enhancement of strangeness [2], hint at an interesting new behavior of the matter produced in these collisions. While such observations imply a hot and dense initial phase with strong rescattering, consistent with the assumption that a quark-gluon plasma was formed, a direct signature of the plasma and its properties is missing. It is therefore of great interest to search for photons emitted directly from the early hot phase of the relativistic heavy-ion collisions.

Following early estimates of photon emission rates [3–6], Kapusta *et al.* [7] made detailed comparisons of the emissivity of the QGP and a hadron gas as two contrasting scenarios. It was demonstrated that the thermal emission rates of a hadron gas and a QGP were very similar and dependent essentially only on the temperature T. This led the authors to conclude that direct photons are a good thermometer for strongly interacting matter, but would not in themselves allow one to distinguish between the two scenarios.

Recently, it was shown by Aurenche *et al.* [8] that photon production rates in the QGP, when calculated up to two-loop diagrams, are considerably greater than the earlier lowest order estimates. A new higher order process of $q\overline{q}$ annihilation with rescattering was found to dominate the photon emission rate from quark matter at high photon energies. Following this result, Srivastava [9] reinvestigated the predicted photon production in heavy-ion collisions and showed that at sufficiently high initial temperatures the photon yield from quark matter may significantly exceed the contribution from the hadronic matter to provide a direct probe of the quark matter phase.

A large number of measurements of prompt photon production at high transverse momentum ($p_T > 3$ GeV/c) exist for proton-proton, proton-antiproton, and proton-nucleus collisions (see e.g., Ref. [10]). To a great extent, especially at higher $\sqrt{s}$, these data can be successfully described by perturbative quantum chromodynamics calculations and provide an important foundation from which to study photon production in nucleus-nucleus collisions. First attempts to observe direct photon production in ultrarelativistic heavy-ion collisions with oxygen and sulphur beams found no significant excess [11–14]. The WA80 Collaboration [14] provided the most interesting result with a p_T dependent upper limit on the direct photon production in S + Au collisions at 200*A* GeV. This result was subsequently used by several authors to rule out a simple version of the hadron gas scenario [15–18] and has been interpreted to set an upper limit on the initial temperature of $T_i = 250$ MeV [19].

In this paper we report on the first observation of direct photon production in ultrarelativistic heavy-ion collisions. The results are from the CERN experiment WA98 [20] which consists of large acceptance photon and hadron spectrometers. In addition, several other large acceptance devices allow one to measure various global variables on an event-by-event basis for event characterization. Photons are measured with the WA98 lead-glass photon detector, LEDA, which consisted of 10 080 individual modules with photomultiplier readout. The detector was located at a distance of 21.5 m from the target and covered the pseudorapidity interval $2.35 < \eta < 2.95$ ($y_{cm} = 2.9$). The particle identification was supplemented by a charged particle veto detector in front of LEDA.

The results presented here were obtained from an analysis of the data taken with Pb beams in 1995 and 1996. The 20% most peripheral and the 10% most central reactions have been selected from the minimum-bias cross section ($\sigma_{\text{min-bias}} \approx 6300$ mb) using the measured transverse energy E_T. In total, $\approx 6.7 \times 10^6$ central and $\approx 4.3 \times 10^6$ peripheral reactions have been analyzed.

The extraction of direct photons in the high multiplicity environment of heavy-ion collisions must be performed on a statistical basis by comparison of the measured inclusive photon spectra to the background expected from hadronic decays. Individual photons cannot be tagged as isolated direct photons in these reactions due to the high multiplicities. To obtain the direct photon spectrum the following steps are performed (for a detailed description of the detectors and the analysis procedure, see Ref. [21]): The raw photon spectra are accumulated after application of the photon identification criteria (such as transverse shower size) to the showers observed in the LEDA. The raw photon spectra are then corrected for contamination by charged and neutral hadrons, for conversions, for the identification efficiency, and for acceptance. The efficiency includes all effects of the detector response such as distortions by shower overlap, dead and bad modules, and energy resolution. Neutral pions are reconstructed via their $\gamma\gamma$ decay branch. Invariant mass spectra are accumulated for all photon pairs for each pair p_T bin. The photon-pair combinatorial background is estimated by event mixing and then subtracted from the real-pair spectra. The yield in the π^0 mass peak is extracted to obtain the raw neutral pion p_T spectra. These are then corrected for conversions, for the π^0 identification efficiency, and for geometrical acceptance. In addition, η mesons are extracted in a limited transverse momentum range with an analogous procedure.

The final measured inclusive photon spectra are then compared to the calculated background photon spectra to check for a possible photon excess beyond that from long-lived radiative decays. The background calculation is based on the measured π^0 and η spectra. The measured η/π^0 ratio is found to be consistent with m_T scaling [21,22] which is assumed for the spectral shapes of the η and for other unmeasured hadrons having radiative decays.

The unmeasured hadron yields relative to π^0's are taken from the literature [21]. It should be noted that the measured contribution (from π^0 and η) amounts to $\approx$97% of the expected total photon background.

Figure 1 shows the fully corrected inclusive photon spectra for peripheral and central collisions. The spectra cover the p_T range of 0.3–4.0 GeV/c (slightly less for peripheral collisions) and extend over 6 orders of magnitude. Figure 1 also shows the distributions of neutral pions which extend over a similar momentum range with slightly larger statistical errors. The calculated decay photon background is shown by the solid curves.

The ratio of measured photons to calculated background photons is displayed in Fig. 2 as a function of transverse momentum. The upper plot shows the ratio for peripheral collisions which is seen to be compatible with 1, i.e., no indication of a direct photon excess is observed. The lower plot shows the same ratio for central collisions. It rises from a value of $\approx$1 at low p_T to exhibit an excess of about 20% at high p_T.

A careful study of possible systematical errors is crucial for the direct photon analysis. The various sources of systematical errors have been investigated and are summarized in Table I. The largest contributions are from the γ and π^0 identification efficiencies and the uncertainties related to the η measurement. It should be emphasized that the inclusive photon, π^0, and η yields have been extracted with the same detector for exactly the same data sample. This decreases the sensitivity to many detector related errors and eliminates all errors associated with trigger bias or absolute yield normalization. The estimate of the systematical errors has been checked by performing the entire analysis with various photon selection criteria which change the efficiency and background corrections by factors of 2–3. The final results were verified to be consistent within the systematical errors for the different analysis cuts. Full details on the systematical error estimates are given in [21]. The total p_T dependent systematical errors are shown by the shaded regions in Fig. 2. A significant photon excess is clearly observed in central collisions for $p_T > 1.5$ GeV/c.

The final invariant direct photon yield per central collision is presented in Fig. 3. The statistical and asymmetric systematical errors of Fig. 2 are added in quadrature to obtain the total upper and lower errors shown in Fig. 3. An additional p_T dependent error is included to account for that portion of the uncertainty in the energy scale which cancels in the ratios. In the case that the lower error is less than zero, a downward arrow is shown with the tail of the arrow indicating the 90% confidence level (C.L.) upper limit ($\gamma_{\text{excess}} + 1.28\sigma_{\text{upper}}$).

No published prompt photon results exist for proton-induced reactions at the $\sqrt{s}$ of the present measurement. Instead, prompt photon yields for proton-induced reactions on fixed targets at 200 GeV are shown in Fig. 3 for comparison. Results are shown from FNAL experiment E704 [23] for proton-proton reactions, and from FNAL experiment E629 [24] and CERN SPS experiment NA3 [25] for proton-carbon reactions. These results have been divided by the total pp inelastic cross section ($\sigma_{\text{int}} = 30$ mb)

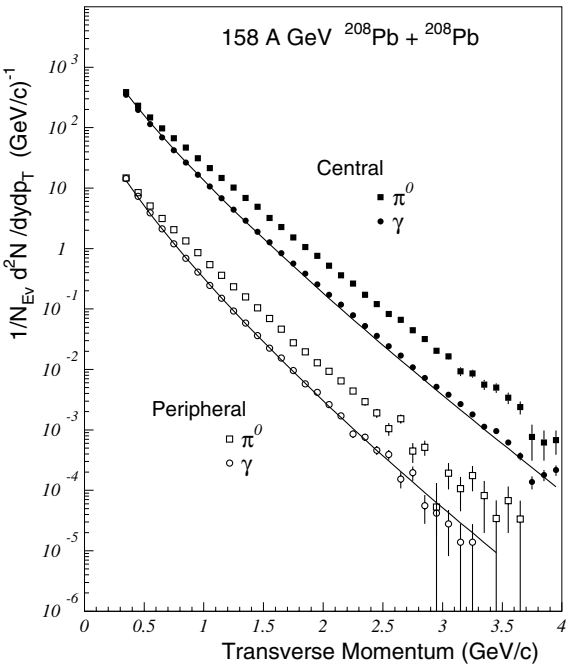

FIG. 1. The inclusive photon (circles) and π^0 (squares) transverse momentum distributions. Only statistical errors are shown.

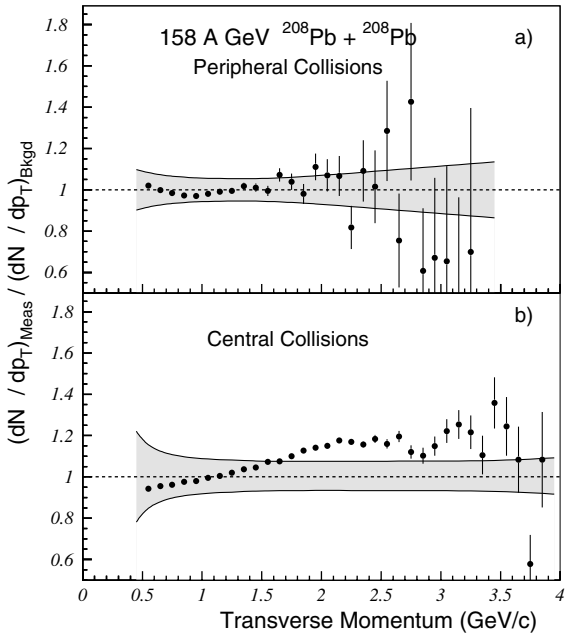

FIG. 2. The ratio of measured-to-calculated background photons as a function of transverse momentum for peripheral [part (a)] and central [part (b)] 158A GeV ^{208}Pb + ^{208}Pb collisions. The errors on the data points indicate the statistical errors only. The p_T dependent systematical errors are indicated by the shaded bands.

TABLE I. Various sources of systematical error in the WA98 158*A* GeV ^{208}Pb + ^{208}Pb direct photon analysis specified as a percentage of $(\gamma/\pi^0)_{\mathrm{meas}}$ (items *a*), $(\gamma/\pi^0)_{\mathrm{bkgd}}$ (items *b*), or $(\pi^0)_{\mathrm{meas}}/(\pi^0)_{\mathrm{bkgd}}$ (item *c*). The systematical errors are quoted at two p_T values to give an indication of the dependence on transverse momentum. See Ref. [21] for full details.

Source of Error	Peripheral Collisions (20% σ_{mb})		Central Collisions (10% σ_{mb})	
	$p_T \approx 1.0$ GeV/c	$p_T \approx 2.5$ GeV/c	$p_T \approx 1.0$ GeV/c	$p_T \approx 2.5$ GeV/c
(*a*) γ yield measurement	2.7	3.2	2.6	3.1
(*a*) π^0 yield measurement	3.1	3.0	6.5	4.2
(*a*) Nontarget background	1.5	<0.1	<0.1	<0.1
(*a*) Energy scale calibration	0.9	1.7	0.8	1.7
(*b*) Detector acceptance	0.5	0.5	0.5	0.5
(*b*) η/π ratio, m_T scaling	2.9	3.2	+3.4 (−4.8)	+3.7 (−5.2)
(*b*) Other radiative decays	1.0	1.0	1.0	1.0
(*c*) π^0 fit	1.6	6.8	2.9	0.4
Total: (quadratic sum)	5.7	8.9	+8.3 (−9.1)	+6.7 (−7.6)

and by the mass number of the target to obtain the invariant direct photon yield per nucleon-nucleon collision. They have then been multiplied by the calculated average number of nucleon-nucleon collisions (660) for the central Pb + Pb event selection for comparison with the present measurements. This scaling is estimated to have an uncertainty of less than 10%. The proton-induced results have also been scaled from $\sqrt{s} = 19.4$ GeV to the lower $\sqrt{s} = 17.3$ GeV of the present measurement under the assumption that $Ed^3\sigma_\gamma/dp^3 = f(x_T)/s^2$, where $x_T = 2p_T/\sqrt{s}$ [26]. The $\sqrt{s}$ scaling effectively reduces the 19.4 GeV proton-induced results by about a factor of 2. This comparison indicates that the observed direct photon production in central ^{208}Pb + ^{208}Pb collisions has a shape similar to that expected for proton-induced reactions at the same $\sqrt{s}$ but a yield which is enhanced.

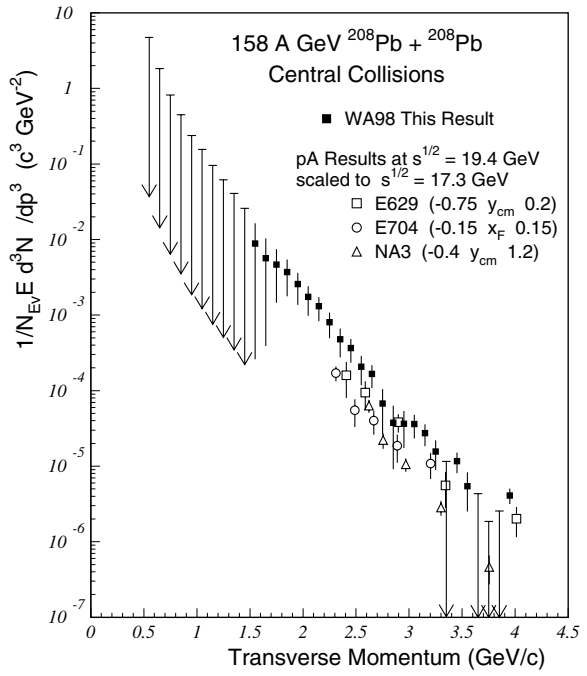

FIG. 3. The invariant direct photon multiplicity for central 158*A* GeV ^{208}Pb + ^{208}Pb collisions. The error bars indicate the combined statistical and systematical errors. Data points with downward arrows indicate unbounded 90% C.L. upper limits. Results of several direct photon measurements for proton-induced reactions have been scaled to central ^{208}Pb + ^{208}Pb collisions for comparison.

In summary, the first observation of direct photons in ultrarelativistic heavy-ion collisions has been presented. While peripheral Pb + Pb collisions exhibit no significant photon excess, the 10% most central reactions show a clear excess of direct photons in the range of p_T greater than about 1.5 GeV/c. The invariant direct photon multiplicity as a function of transverse momentum was presented for central ^{208}Pb + ^{208}Pb collisions and compared to proton-induced results at similar incident energy. The comparison suggests excess direct photon production in central ^{208}Pb + ^{208}Pb collisions beyond that expected from proton-induced reactions. The result suggests modification of the prompt photon production in nucleus-nucleus collisions, or additional contributions from preequilibrium or thermal photon emission. The result should provide a stringent test for different reaction scenarios, including those with quark-gluon-plasma formation, and may provide information on the initial temperature attained in these collisions.

We wish to express our gratitude to the CERN Accelerator Division for the excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians, and support staff who participated in the construction of this experiment. This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR and FRN, the Dutch Stichting FOM, the Polish KBN under Contract No. 621/E-78/SPUB/CERN/P-03/DZ211, the Grant Agency of the Czech Republic under Contract No. 202/95/0217, the Department of Atomic Energy, the Department of Science and Technology, the Council of Scientific and Industrial Research and the University Grants Commission of the Government of India, the Indo-FRG Exchange Program, the PPE division of CERN, the Swiss National Fund, the INTAS under Contract

(February 8, 2008)

A measurement of direct photon production in ^{208}Pb+^{208}Pb collisions at 158 A GeV has been carried out in the CERN WA98 experiment. The invariant yield or upper limit of direct photons as a function of transverse momentum in the interval $0.5 < p_T < 4$ GeV/c is presented. A significant direct photon excess is observed at $p_T > 1.5$ GeV/c in central collisions. The results are compared to proton-induced results and to theoretical predictions. Implications for the dynamics of high-energy heavy-ion collisions are discussed.

I. INTRODUCTION

A major current goal of the field of nuclear physics is the experimental confirmation of the existence of a new phase of strongly interacting matter, the quark gluon plasma (QGP) [1], which is predicted to exist according to lattice calculations of quantum chromodynamics. Enhanced production of strange hadrons, photons, and dileptons, and suppression of J/ψ mesons are some of the proposed consequences of QGP formation. Both J/ψ suppression [2] and strangeness enhancement [3] have been observed in relativistic heavy-ion collisions with strongly enhanced nuclear effects. While these observations naturally lead to the conclusion that the initial phase of the collision consisted of a hot and dense system with strong rescattering, which may be explained by the assumption of QGP formation, the direct experimental detection of QGP through observation of direct emission of real or virtual photons from the quark matter remains to be attained.

Historically, photons and lepton-pairs were the probes first suggested to use to search for evidence of quark-gluon plasma formation in ultrarelativistic heavy ion collisions. During the collision, real photons are produced mainly by scattering amongst the electrically charged objects while virtual (i.e. massive) photons, which later decay into pairs of oppositely charged leptons, or dileptons, are produced mainly by particle-antiparticle annihilations. Once produced, the real and virtual photons will interact with the surrounding hot dense matter through the electromagnetic interaction only. The resulting small interaction cross section implies a long mean free path in the dense matter with the consequence that the photons are likely to escape unscathed once produced. As a result, real and virtual photons carry information about the conditions of the matter from which they were produced throughout the entire history of the heavy ion collision, including especially the initial hot dense phase. Therefore, if the initial phase includes a quark-gluon plasma which radiates real and virtual photons differently than would dense hadronic matter this difference may be apparent in the photon and dilepton spectra observed by the experimentalist. This is in contrast to hadrons which, due to their extremely short mean free path in the hot dense matter, are unlikely to escape until the system has cooled and expanded to the low temperature and low density freezeout stage. As a result, quark-gluon plasma formation during the initial stage of the collision will make its presence evident via hadronic probes only if it alters the macroscopic features of the system, such as its strangeness content or collective flow, in a way which is different from dense hadronic matter *and* if these altered features are preserved until the time of freezeout. Thus the electromagnetic and hadronic probes provide complementary information. Since the real and virtual photon emission rate is greatest in hot dense matter the electromagnetic probes should carry information mostly about the dynamics (or thermodynamics) of the initial phase of the collision, while hadronic probes carry information dominantly about the late stage of the collision.

Originally, Feinberg [4] and Shuryak [5] suggested that thermal emission might be an important process in hadron-induced and even lepton-induced reactions when a large multiplicity of particles are produced in the final state. In particular they pointed out that rescattering amongst the produced particles in local thermal equilibrium during the later stages of the interaction would give rise to real and virtual photon emission. (Bjorken and Weisberg made similar suggestions at that time about the possible importance of rescattering [6]). Such a mechanism could explain the, at that time, puzzling excess dilepton yield observed at intermediate dilepton masses, $M \leq 5$ GeV/c^2 [5]. Feinberg [4] speculated upon the nature of the hot prematter remaining after the interaction and suggested that it may even be gluonic matter with embedded quarks. Shuryak [5] went on to assume formation of such a quark-gluon plasma in order to calculate the emission rates by perturbative QCD methods.

While it remains unknown whether quark-gluon plasma may be produced in hadron-induced reactions, it was suggested shortly afterwards that relativistic collisions of heavy ions provide conditions likely to result in the production of quark-gluon plasma. Initially it was suggested that such a plasma might occur at incident laboratory energies as low as a few GeV per nucleon [7] due to compression of the colliding nuclei and the resulting high baryon density. Another estimate based on extrapolations of known properties of NN and NA collisions at energies of $E_{cm} \geq 30$ GeV suggested that the fragmentation regions of AA collisions were likely to result in quark-gluon plasma formation [8]. Later calculations solving the relativistic hydrodynamic equations indicated that the highest energy densities would instead occur in the mid-rapidity region with energy densities considered sufficient for QGP formation at incident energies of around 400 GeV per nucleon [9].

Almost concurrent with the suggestions to use relativistic heavy ions as a means to produce the QGP in the laboratory were suggestions to use dilepton or photon measurements to diagnose whether QGP has been formed. First estimates considering only the lowest order elementary processes and thermal parton distributions [10,11] concluded that the thermal dilepton emission rate from the QGP should exceed that from a hadronic gas in the mass region below the ρ [10], and that real and virtual photons should provide accurate information on the temperature of the plasma [11]. A simple counting estimate indicated an expected photon enhancement relative to the number of pions in the case of QGP formation [12]. First calculations which performed the space-time integration of the lowest order production rates by solving the relativistic hydrodynamic equations confirmed [13] that the dilepton yield in the mass region

below the ρ was sensitive to the initial temperature of the QGP and to the critical temperature. Alternatively, it was suggested that the ratio of the simultaneously observed photon and dilepton pair yield might provide a signal which was sensitive to QGP formation while being insensitive to the details of the collision dynamics [14].

While these initial estimates indicated that photons and dileptons should be useful probes to diagnose the presence of QGP, the rate estimates themselves were suspect since lowest order perturbative calculations had been applied at energies, or temperatures, similar to Λ_{QCD}, the QCD scale factor. The dilepton and photon rate estimates were put on firmer ground when McLerran and Toimela [15], following the suggestion by Feinberg [4] that the photon and dilepton rates could be determined from the expectation value of the electromagnetic current correlation function, demonstrated that for each order the emission rates had an invariant form with thermal structure functions entering in a manner exactly analogous to the usual structure functions for finding a quark or gluon in a hadron. Also, it was observed that terms which contribute to the dilepton or photon emission which are problematic at the basic diagram level, are regularized in the QGP. For example, dilepton emission from quark-antiquark annihilation is infrared divergent in the limit of zero mass gluons while in the plasma gluons propagate as plasma oscillations with a plasmon mass which provides a cutoff to eliminate the divergences for small gluon momenta [15].

Later, using the resummation techniques of Braaten and Pisarski [16,17], Kapusta et al. [18] demonstrated that the photon emission rates of quark gluon matter and hadronic matter were very similar. As a consequence, it could be concluded that while photon emission was not *per se* a signature of quark gluon matter, detection of the emitted photons could provide a good measurement of the temperature of the hot and dense matter.

Recently, the situation has changed again with the demonstration by Aurenche et al. [19] that the contribution to the photon emission rate from two-loop diagrams are significantly larger than the lowest order contributions of the Compton ($q(\overline{q})g \rightarrow q(\overline{q})\gamma$) and annihilation ($q\overline{q} \rightarrow g\gamma$) processes which were previously thought to dominate the photon emission rate from the quark matter. The two-loop diagrams were shown to give a large bremsstrahlung ($qq(g) \rightarrow qq(g)\gamma$) contribution and a contribution from a previously neglected process of $q\overline{q}$ annihilation accompanied by q(g) rescattering. This annihilation with rescattering process is found to dominate the photon emission rate of the quark matter at large transverse momenta. Inclusion of these rates in hydrodynamic model calculations of heavy-ion collisions has recently shown that photon yield from the quark matter may be significantly larger than the photon yield from the hadronic matter [20]. The direct photons may therefore dominantly carry information about the quark gluon plasma.

A large body of data on prompt photon emission exists for proton-induced reactions on targets of protons, anti-protons, and light nuclei [21–35]. The prompt photon measurements have provided important input on gluon structure functions [36]. It is now possible to perform complete and fully consistent next-to-leading order (NLO) QCD calculations of the prompt photon cross sections. In general, the prompt photon data can be well described from fixed target energies up to Tevatron energies [37] which provides an important foundation for the intrepretation of direct photon production in nucleus-nucleus collisions. In the past, discrepancies with calculation have sometimes been attributed to effects of intrinsic k_T smearing arising from higher order contributions such as soft-gluon emissions [33,36,38]. While the evidence for intrinsic k_T effects remains under debate [39], the observed trend of an underestimated prompt photon yield at low transverse momentum and low incident energy is suggestive of an intrinsic k_T effect [37,39]. A thorough understanding of the source of this discrepancy will be important in the search for thermal direct photons at low transverse momentum in nucleus-nucleus collisions at the presently available low incident energies.

First attempts to observe direct photon production in ultrarelativistic heavy-ion collisions with oxygen and sulphur beams found no significant excess [40–43]. The WA80 collaboration [43] provided the most interesting result with a p_T dependent upper limit on the direct photon production in S+Au collisions at 200AGeV. This result was subsequently used by several authors to rule out a simple version of the hadron gas scenario [44–47] and to establish an upper limit on the initial temperature of $T_i = 250\,\mathrm{MeV}$ [48]. In this paper, the first observation of direct photons from ultrarelativistic heavy-ion collisions is reported for central 158 *A* GeV ^{208}Pb+^{208}Pb collisons. The implications of the result are discussed.

The organization of the paper is as follows: A description of the WA98 experimental setup including the event selection and photon spectrometer are presented in the next section. A general description of the WA98 direct photon analysis method is given in Sec. III. The details of the data analysis including a presentation of the various corrections and their associated errors for extraction of the inclusive photon, π^0, and η yields is given in Sec. IV. The final inclusive photon, π^0, and η distributions are presented in Sec. V. The direct photon result is also presented in Sec. V and the results are compared to calculation and discussed. A summary and conclusion is given in Sec. VI.

II. WA98 EXPERIMENTAL SETUP

The CERN experiment WA98 is a general-purpose apparatus which consists of large acceptance photon and hadron spectrometers together with several other large acceptance devices which allow to measure various global variables on an event-by-event basis. The experiment took data with the 158 A GeV ^{208}Pb beams from the SPS in 1994, 1995, and 1996. The results presented here were obtained from analysis of the 1995 and 1996 data sets. The layout of the WA98 experiment as it existed during the final WA98 run period in 1996 is shown in Fig. 1.

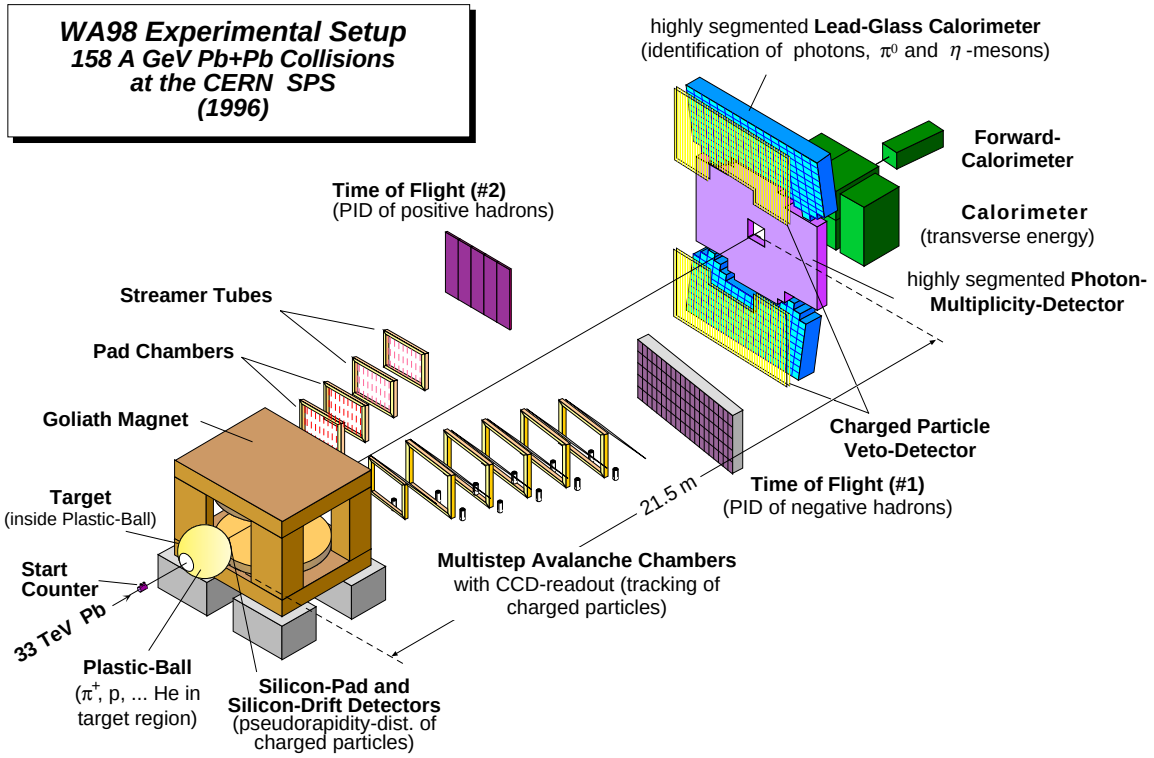

FIG. 1. The WA98 experimental setup.

A. Detector Subsytems

Each 158 A GeV ^{208}Pb beam particle is qualified in a series of trigger counters located upstream of the target. The ^{208}Pb target is mounted in a thin target wheel at the center of a 20 cm diameter spherical thin-walled aluminum vacuum chamber located within the Plastic Ball detector. The target wheel has 5 target positions, one of which was empty for non-target background measurements.

The Plastic Ball detector consists of 655 modules which provide energy measurement and particle identification of charged pions and light particles by $\Delta E - E$ measurement [49]. The Plastic Ball detector provides particle measurement over the interval $-1.7 < \eta < 1.3$. Each module comprises a slow 4 mm thick CaF_2 ΔE scintillator followed by a fast plastic scintillator readout by a common photomultiplier. The signals from the photomultipliers of the two forward-most rings of Plastic Ball modules, subtending the angular region from 30° to 50°, are split and a portion of the signals are analog summed to provide an online energy signal for trigger purposes. This signal is used to suppress interactions downstream of the target.

The target vacuum chamber is extended downstream in a 30° conical vacuum chamber which contains the Silicon Drift Detector (SDD) and the Silicon Pad Multiplicity Detector (SPMD) [50], each consisting of 300 μm thick silicon wafers. The SDD and SPMD are located 12.5 cm and 30 cm downstream from the target, respectively. These detectors

provide charged particle multiplicity measurement over the intervals of $2.5 < \eta < 3.75$ and $2.3 < \eta < 3.75$, respectively.

Charged particle momentum measurement and particle identification is accomplished using two tracking spectrometer arms. The momentum measurement is accomplished by magnetic analysis in a large (1.6 m) aperture dipole magnet called GOLIATH which provides 1.6 Tm bending power. Both tracking spectrometers use straight-line tracking outside the magnetic field. Particle identification is obtained using time-of-flight measured with scintillator slat detectors in each tracking arm. In the normal magnetic field configuration the negative tracks are deflected to the right, looking downstream, into the first tracking arm. The first tracking arm consists of six planes of multi-step avalanche chambers [51]. The active area of the first tracking chamber is 1.2×0.8 m^2 while that of the other five chambers is 1.6×1.2 m^2. The chambers produce UV photons by means of a photoemissive vapor which are then converted to visible light via wavelength shifter plates. On exiting the chamber, the visible light is reflected 45° by thin-foil mirrors to CCD cameras equipped with two-stages of image intensifiers. Each CCD pixel viewed a chamber area of about 3.1×3.1 mm^2.

The second tracking arm measures positive-charged tracks in the normal field condition. It consists of four chambers of 1.6×1.2 m^2 [52]. The first two chambers are multi-step avalanche chambers similar to those of the first tracking arm, but with the avalanche signal collected directly on an anode plane with pad readout. In total about 35000 pads per chamber are read out. The last two tracking chambers consist of streamer tubes read out with 6000 pads each. The second tracking arm was installed and operated for the 1996 run period only.

The Photon Multiplicity Detector (PMD) [53] is located at a distance of 21.5 m downstream from the target. The PMD is a large (21 m^2) preshower detector consisting of 3.3 radiation lengths of lead used to convert and count photons. The lead converter is backed by over 50000 scintillator tiles individually wrapped and readout via wavelength shifter optical fibers coupled in groups to a set of CCD cameras with image intensifiers. The PMD provides a photon multiplicity measurement over the interval $2.8 < \eta < 4.4$.

The WA98 photon spectrometer comprises the LEad-glass photon Detector Array (LEDA), and a charged particle veto detector. The photon spectrometer is divided into two halves placed above and below the beam plane to benefit from the charge-sweeping effect of the GOLIATH magnet, and is located at about the same distance as the PMD. It provides photon energy measurement over the interval $2.4 < \eta < 3.0$. The photon spectrometer is described in more detail below.

Further downstream, at a distance of 24.7 m from the target, the total transverse energy is measured in the MIRAC calorimeter [54]. The MIRAC is a sampling calorimeter with 180 calorimeter towers readout on two sides with wavelength shifter plates coupled to photomultipliers. Each tower is segmented longitudinally to provide separate measurement of the electromagnetic and hadronic energy deposit. A portion of the signal from each photomultiplier of MIRAC is split off and the analog signal is summed with appropriate weight to form a total transverse energy signal for trigger purposes. The MIRAC is deployed in a rectangular wall 3.3 m wide by 2.4 m high centered on the beam axis with a central aperture 61 cm wide by 23 cm high through which the beam passes. A portion of the MIRAC coverage overlaps with the PMD preshower detector. The MIRAC provides total transverse energy measurement with varying azimuthal coverage over the interval $3.2 < \eta < 5.4$.

Finally, the total energy of the uninteracting beam, or of the residual beam fragments and produced particles emitted near to zero degrees, is measured in the Zero Degree Calorimeter (ZDC). The ZDC consists of 35 lead/scintillator sampling calorimeter modules of 15×15 cm^2 cross sectional area each. For each module the scintillator is read out from the side with a fast wavelength shifter plate coupled to a photomultiplier with an active base. This allowed stable operation with intensities up to 1 MHz of the full 33 TeV ^{208}Pb beam. The ZDC modules were stacked in an array 7 modules wide by 5 modules high. Since it serves as the WA98 beam stop the ZDC is located in a shielded cave (not shown in Fig. 1) for radiological protection reasons. The cave is located just behind MIRAC with an entrance aperture the same size as the aperture through MIRAC.

In order to minimize backgrounds, WA98 has been designed with attention to minimize the amount of material in the beamline and in the flight paths of the detected particles. Thus, except for trigger detectors in the beamline and a small air gap in the GOLIATH magnet, the beam is transported in an evacuated beampipe (not shown in Fig. 1) from the point of extraction from the SPS through the entire experiment until just before being stopped in the ZDC. A trapezoidal chamber extends the vacuum beyond the silicon detectors to the entrance of the GOLIATH magnet. It ends with a $1.4 \times 1.$ m^2 exit window of 125 μm thick mylar suspended by a kevlar mesh of 240 μm average thickness. For the 1995 run period a 2.5 mm thick aluminum ring of 15 mm diameter with a 11 mm diameter hole was attached to the exit window at the location of the beam exit. The thick mylar and kevlar mesh was removed from the ring aperature and replaced by a thin mylar foil. While the purpose of the thin foil had been to reduce downstream interactions, the ring caused significant interactions from the beam halo and so the exit window was replaced with a homogeneous mesh and mylar foil for the 1996 run period. After a 75 cm air gap, the vacuum continues with a series of 0.5 mm thick carbon fiber beam tubes. The first beam tube is of 5 cm diameter and 1.44 m length followed by a second tube of

10 cm diameter and 4.5 m length. A third beam tube continues through the experiment with a 20 cm diameter to the front of the MIRAC calorimeter where it attaches to a rectangular vacuum pipe which defines the aperture in MIRAC and terminates the vacuum at the rear of MIRAC just before the entrance to the ZDC.

The PMD, SDD, and tracking spectrometers are not used in the present analysis and will not be discussed further. Additional details on event selection and on the photon spectrometer are given next.

B. Event Selection

The WA98 trigger detectors comprise a nitrogen gas Čerenkov counter [55] to provide a fast start signal ($\leq$ 30 ps time resolution), beam-halo veto counters, and the MIRAC calorimeter. A clean beam trigger is defined as a signal in the start counter, located 3.5 m upstream of the target, with no coincident signal in the veto scintillator counter (which had a 3 mm diameter circular hole and was located 2.7 m upstream of the target), or in beam halo scintillator counters which covered the region from the veto counter to 25 cm transverse to the beam axis. Beam fragments from upstream interactions are rejected by use of a high threshold on the start counter signal, set just below the ^{208}Pb signal. Short timescale pileup events are vetoed by an anti-coincidence requirement with a higher threshold start signal, set just above the ^{208}Pb signal. Additional background event rejection is performed offline using the amplitude and timing information from the trigger detectors. For purposes of background rejection each of the trigger logic signals is copied multiple times and recorded on TDCs with various delayed starts or delayed stops which allow to inspect the time period immediately preceeding or following the trigger event. This set of TDCs allows to reject pileup beam particles or interactions over preceeding or following time ranges of 100 ns, 500 ns, or 10 μs in the offline analysis.

The MIRAC calorimeter provides an analog total transverse energy sum for centrality selection for online trigger purposes. The WA98 minimum bias trigger requires a clean beam trigger with a MIRAC transverse energy signal which exceeds a low threshold. Two additional trigger signals are derived from the MIRAC transverse energy signal using thresholds set somewhat above and far above the minimum bias threshold. These three MIRAC thresholds define three non-overlapping event classes which are used to define the WA98 physics triggers. The thresholds were adjusted such that the so-called peripheral event class, between the lowest and next-to-lowest thresholds, corresponded to about 20% of the minimum bias event rate and the central event class, above the highest threshold, corresponded to about 10% of the minimum bias event rate. The remaining $\approx 70\%$ of the minimum bias cross section between central and peripheral event classes is referred to as the not-so-central event class. Taken together the three event classes were equivalent to the minimum bias event class. In normal run operation the central event class triggers were taken without prescale factor while the peripheral event triggers were typically downscaled by a factor of two and the not-so-central triggers were usually prescaled by a factor of 32 (after deadtime suppression) for the 1995 run period. For the 1996 run period the peripheral and not-so-central event classes were typically downscaled by a factor of 4 and 16, respectively. Downscaled beam triggers and in-spill pedestal triggers were also taken at a low rate as well as various out-of-spill calibration triggers for monitoring and calibration purposes for the various detectors. In order to obtain absolute cross section information, all trigger logic signals were counted with scalers before and after deadtime suppression, and after application of downscale factors. The scalers were recorded between spills.

In order to obtain the maximum data rate for the direct photon measurement, WA98 was operated with three different event types. The event types were distinguished by different groups of detectors with different readout deadtimes, varying up to about 5ms, 10 ms, or 15 ms for event types one, two, or three, respectively. Event type one included the trigger detectors, MIRAC, ZDC, Plastic Ball, and the photon spectrometer. Event type two also included the PMD, SPMD, and SDD. Event type three further included the tracking spectrometers. Zero-suppressed data volumes of about 50 kbyte/event were produced for central collisions. The experiment operated with a typical beam intensity of ≈ 0.5 MHz ^{208}Pb delivered to target over an effective SPS spill of about 2.5 s during the 14.4 s machine cycle. About 250 events were recorded per spill with a typical deadtime of about 80%.

C. Photon Spectrometer

The WA98 photon spectrometer consists of a large area lead-glass detector array, LEDA, supplemented with a charged particle veto (CPV) detector placed immediately in front of it (see Fig. 1). The spectrometer has an unobstructed view of the target through the vacuum chamber exit window at the entrance to the GOLIATH magnet. The photon spectrometer is separated into two nearly symmetric halves above and below the beam plane in the two regions of reduced charged particle density which result from the sweeping action of the GOLIATH magnet. The two detector halves are inclined by an angle of 8° such that photons near the center of the detector impinge with normal incidence. The maximum deviation from normal incidence to the detector surface is less than 9° at the detector corners. The

perpendicular distance to the front surface of the lead-glass is 22.1 m. This distance was chosen to allow the photon measurement near mid-rapidity while maintaining a maximum local particle hit occupancy below 3%, which is necessary to insure that overlapping shower effects remain manageable.

The acceptance of the photon spectrometer for π^0 and η detection, in rapidity and transverse momentum of the π^0 or η, is shown in Fig. 2. The acceptance is calculated for a 750 MeV photon energy threshold. The acceptance in part a) is shown for detection of a single photon from the decaying π^0. It indicates the phase space region over which π^0's contribute photons into the acceptance of the spectrometer. The acceptance for simultaneous detection of both photons from the π^0 and η two-photon decay branch is shown in parts b) and c), respectively. The acceptance covers the region $2.4 < y < 3.0$, near mid-rapidity ($y_{cm} = 2.9$).

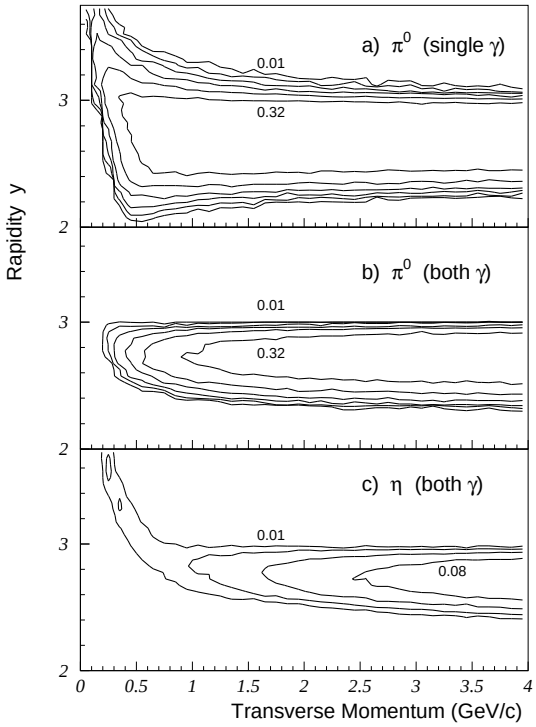

FIG. 2. The acceptance of the WA98 photon spectrometer in parent particle rapidity versus transverse momentum for a) single photons from π^0 decay and for photon-pairs from b) π^0 decay or c) η decay with a 750 MeV photon energy threshold. The contours show the fraction of full phi acceptance in steps of factors of two.

1. Lead-Glass Detector

The lead-glass detector comprises 10,080 individual lead-glass modules. Each module is a $4 \times 4 \times 40$ cm^3 (14.3 radiation lengths) TF1 lead-glass block with photomultiplier readout. The sides of each block are wrapped in an aluminized mylar reflective foil and sealed in a PVC plastic shrink tube of 0.15 mm wall thickness. Twenty-four lead-glass modules are epoxied together in an array 6 modules wide by 4 modules high to form a super-module. Each super-module has its own calibration and gain monitoring system based on a set of 3 LEDs mounted inside a sealed reflecting front cover dome [56]. Each lead-glass module views the reflected LED light through an aperture on the front surface, while the LED light is simultaneously monitored by a PIN-photodiode.

All 10,080 lead-glass modules were calibrated with 10 GeV electrons in the X1 beamline in the west area of the CERN SPS during the period of fall 1993 to spring 1994. The calibration beam was used to determine the GeV equivalent of the photodiode-normalized LED light viewed by each lead-glass module. The LED system allowed the calibration to be maintained after the lead-glass was installed in the WA98 experimental area with a new readout system. The energy and position resolution, and the non-linearity of the lead-glass detector were measured in the same test beam using electrons of incident energies from 3 GeV to 20 GeV. The measured energy resolution could be parameterized as [56]

$$\sigma/E = (5.5 \pm 0.6)\%/\sqrt{E} + (0.8 \pm 0.2)\% \tag{2.1}$$

and the measured position resolution could be parameterized as

$$\sigma_x = (8.35 \pm 0.25)\ \mathrm{mm}/\sqrt{E} + (0.15 \pm 0.07)\ \mathrm{mm} \tag{2.2}$$

with energy measured in GeV.

Each lead-glass module is read out by an FEU-84 photomultiplier with individually controlled high voltage. The high voltage is generated on-base with custom developed [57] Cockcroft-Walton voltage-multiplier type bases. The bases are controlled using a VME based processor and controllers. The photomultiplier signals are digitized with a custom-built ADC system [58] which was installed in the fall of 1994. The system features a fast shaping amplifier with dual gain ranges separated by a factor of 8 in gain. Each gain range is digitized with 10-bits resolution for 13-bits of effective dynamic range. The ADC system includes an analog memory in which the integrated signal is sampled and stored at 20 MHz in a ring buffer 16 cells deep. The analog memory provides the latency needed (≈ 400 ns) for the WA98 trigger decision without the need for cable delay of the photomultiplier signals. The readout system also includes a constant fraction discriminator with TAC for time-of-flight measurement, and overlapping module current sums for possible trigger purposes, neither of which are used for the present analysis.

After calibration and installation in WA98 with the new readout system, the high voltage of each module was adjusted to set the full-scale ADC value at 40 GeV, based on the GeV-equivalent of the calibrated LED light. During the period of datataking, the LED system was pulsed and all lead-glass modules and photodiodes were read out and recorded between spills at a frequency of a few Hz. These calibration events were used offline to provide time-dependent gain correction factors for each module. The gain correction factors were stored in a database and applied on a run-by-run basis in the offline analysis. The overall stability of the lead-glass system is indicated in Fig. 3 where the time-dependent gain correction, averaged over all lead-glass modules, is plotted as a function of time during the 1995 run period. The rms of the distribution of module gains at a given time is indicated by the vertical bars. The smallness of the rms values throughout the run period demonstrates the stability of the high voltage and readout systems while the diurnal variation of the average gain factors suggests a sensitivity of the photomultiplier gains to the temperature in the experimental hall. Fig. 3 gives a good indication of the magnitude and importance of the time-dependent gain corrections which have been applied.

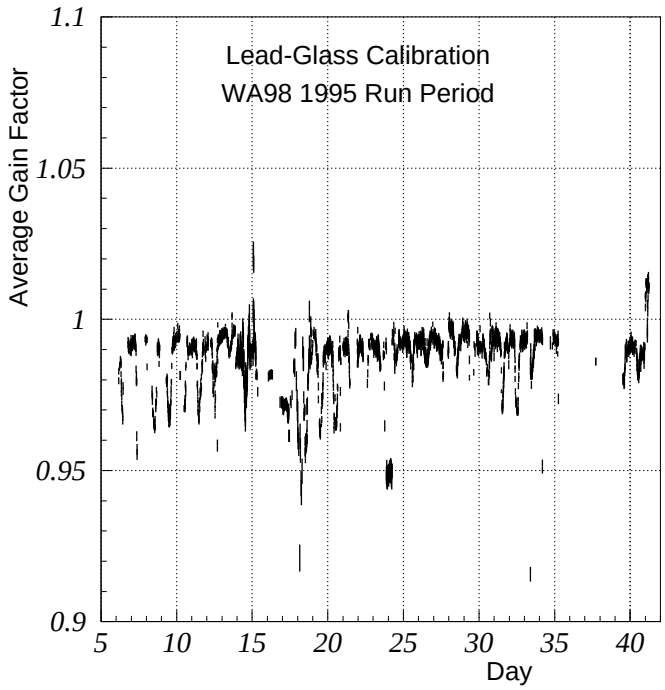

FIG. 3. The stability of the lead-glass calibration as determined with the LED monitoring system. The time-dependent gain factor, averaged over all modules, is shown as a function of time for the entire 1995 run period. The vertical size of the points indicates the rms of the distribution of time-dependent gains of all modules.

2. Charged Particle Veto Detector

In order to tag and thereby directly deduce the fraction of showers observed in the lead-glass originating from charged hadron, the photon spectrometer is supplemented by a Charged Particle Veto (CPV) detector which covers the lead-glass region of acceptance [59]. The two sections of the CPV each consist of 86 Iarocci-type plastic streamer tubes in a single layer. Each tube is tilted by 30° to avoid normal particle incidence which would result in a 7% geometrical inefficiency due to the streamer tube walls. The streamer tubes are operated with a gas mixture of 10% argon, 30% isobutane, and 60% carbon dioxide at atmospheric pressure. A streamer discharge induces a charge signal on externally mounted pads which have a size of 42 mm $\times$ 7 mm. Groups of 16 pads are connected to a charge sensitive chip which converts a charge signal into a 6 bit ADC value. In total 49120 pads and 3070 chips are necessary to read out the 19 m^2 active area of the CPV. The CPV detector is nearly transparent to high energy photons with only 2.0% of incident photons converting and producing detectable signals inside the streamer tubes. The CPV was under construction at the time of the 1995 ^{208}Pb run and was fully operational only for the 1996 run period. As a result, the CPV has been used in the analysis of the 1996 data set only.

By employing magnetic field off data, with straight-line trajectories from the target, the silicon pad multiplicity detector can be used together with the lead-glass detector to determine the average CPV efficiency *in situ*. The SPMD consists of four quadrants each divided into 1012 pads with 46 azimuthal divisions and 22 radial divisions. Each pad has roughly equal size in $\Delta\eta \times \Delta\phi$ of about $0.065 \times 2^\circ$. The efficiency for detecting a charged particle in the SPMD was measured in a test beam to be better than 99%.

III. DATA ANALYSIS METHOD

In this section we discuss the WA98 direct photon analysis method. An overview of the method is presented followed by a discussion of the details of the photon identification criteria and the photon and π^0 efficiency determination. These are the main sources of systematical error in the present direct photon analysis. Next, the method to determine the charged particle contamination in the photon yield is discussed. Then the calculation of the photon background expected from radiative decays of long-lived resonances is described. Finally, the extraction of the direct photon excess is discussed.

A. Direct Photon Analysis Overview

Due to the high photon multiplicity in central Pb+Pb collisions, and the limited photon spectrometer acceptance, it is not feasible to identify isolated single direct photons on an event-by-event basis. Instead, in the direct photon analysis presented here, the transverse momentum distribution of direct photons is determined on a statistical basis. In brief, the direct photon excess is extracted from the difference between the measured inclusive photon yield and the photon yield predicted from a calculation of the radiative decays of long-lived resonances. Among such decay photons, the π^0 and η comprise the largest source, contributing roughly 97% of the photon yield according to the expected relative abundances of produced particles (see Fig. 28). Therefore, in order to maximize the sensitivity of the measurement to a direct photon excess, it is imperative to accurately determine the π^0 and η yield.

In the WA98 measurement, the π^0 and η yield are determined via their two-photon decay branch for exactly the same event sample for which the inclusive photon yield is measured. This eliminates all systematical error sources related to absolute cross section normalization or centrality selection. In fact, this analysis method allows to determine the decay background correctly even if data sets with very different centralities or run conditions were combined arbitrarily since the averaged decay photon distribution would follow directly from the averaged π^0 and η distributions. Thus, for example, contributions from background sources such as a secondary target will not produce an apparent photon excess in this analysis, as long as their contribution to the π^0 and η yield can be extracted from the two-photon invariant mass peaks. Such background sources would distort the extracted π^0 and η transverse momentum distributions, but this distortion would also be reflected in the inclusive photon distribution. Similarly, a distortion of the photon momentum distribution due to a calibration error or non-linearity of the detector response would be reflected in the momentum (and mass) distribution of the reconstructed π^0's and η's. This means that the sensitivity of the direct photon search to detector calibration or non-linearity errors is reduced in this analysis. Furthermore, the momentum dependence of the π^0 invariant mass peak provides an *in situ* means to verify and quantify the accuracy of the detector calibration.

A major source of systematical error in the present analysis is the determination of the photon detection efficiency. Roughly speaking, since the photon detection efficiency enters quadratically in the efficiency correction of the π^0 yield extracted via its two-photon decay, but only linearly in the photon yield correction, an error in the photon

detection efficiency directly modifies the apparent photon excess. Thus a major emphasis of the present analysis is to demonstrate an accurate determination of the identification efficiencies and associated systematical errors. This is accomplished by applying different photon identification criteria having very different efficiencies and sensitivities to backgrounds, and verifying that the final corrected results are consistent in all cases.

Another source of error may be due to mis-identified non-photon backgrounds. Since the number of charged hadrons exceeds the number of photons by about a factor of three at large transverse momenta, they pose a large potential background of apparent excess photons if mis-identified as photons. Fortunately, high energy hadrons deposit only a small fraction of their incident energy in the lead-glass detector (its 40 cm length is about one interaction length). As a result, showers with large energy deposit, or large apparent transverse momentum, are predominantly photons with a hadron contamination of only about 10%. Since hadronic showers typically have large transverse dimension the hadron shower contamination can be further reduced by a factor of 2-3 by excluding showers with large width. Since the magnetic field alters the distribution and apparent transverse momenta of the charged hadrons while leaving the neutral particle distributions unchanged, a comparison of the extracted neutral shower result for magnetic field on and field off provides a consistency check of the charged hadron rejection. The Charged Particle Veto detector is used to determine the charged hadron contribution to the photon spectrum.

Another source of apparent photons is neutrons and anti-neutrons. This contribution is estimated by simulation only. Its contribution can similarly be reduced by excluding showers with large width. Consistency in the final result with different shower identification criteria and run conditions provides confirmation that the background contributions are properly eliminated.

B. Particle Identification and Yield Determination

The most critical requirement of the direct photon search is an accurate determination of the inclusive photon and π^0 yields. In general, the accuracy of the yield determination is verified by using different identification criteria with large differences in efficiency and background sensitivity, and demonstrating consistent final results. The π^0 yield is largely insensitive to background particles since the π^0's are self-identified by their mass peak in the two-photon invariant mass spectrum. The effect of background particles is mainly to increase the combinatorial background in the invariant mass spectrum which makes the problem of extraction of the peak content more difficult. On the other hand, charged hadrons and neutrons are significant backgrounds to the photon yield determination. In the present analysis, the Charged Particle Veto detector is used to identify charged hadron showers and remove the charged hadron contribution from the photon spectrum. At the same time, care must be taken not to remove converted photons from the photon or π^0 data.

The photon yield extraction involves the following steps:

Γ-1. The photon identification criteria are applied to the reconstructed showers and a photon candidate p_T spectrum is accumulated.

Γ-2. The normalized target-out background photon candidate p_T spectrum is subtracted, if necessary.

Γ-3. The CPV detector is used to determine the charged hadron contamination included in the photon candidate spectrum. The charged shower contribution is subtracted from the photon candidate distribution to produce the uncorrected neutral shower p_T spectrum.

Γ-4. The neutral shower spectrum is corrected for photon conversions and for the reconstruction efficiency.

Γ-5. The neutron and anti-neutron contamination, based on simulation, is removed to produce the raw photon p_T spectrum, within the lead-glass detector acceptance.

Γ-6. The raw photon spectrum is corrected for the geometrical acceptance to produce the final photon p_T spectrum.

The π^0 (or η) yield extraction involves the following steps:

Π-1. The photon identification criteria are applied to the reconstructed showers to produce a list of photon candidates for each event.

Π-2. The invariant mass of each photon pair within an event is calculated and sorted into invariant mass histograms according to the p_T of the photon pair. An invariant mass histogram is accumulated for each p_T bin to be used in the final π^0 p_T spectrum.

II-3. The photons are simultaneously used to construct artificial mixed events of similar multiplicity for each centrality class. The mixed events are analyzed in exactly the same manner as the real events to produce background invariant mass spectra as a function of p_T.

II-4. The final mixed event invariant mass spectra are normalized and subtracted from the the final real event invariant mass spectra to remove the combinatorial background from the real event spectra.

II-5. The normalized target-out final invariant mass spectra are subtracted from the final invariant mass spectra, if necessary.

II-6. The final invariant mass spectra are analyzed to extract the content in the π^0 (or η) peak at each p_T. The result is the uncorrected π^0 p_T spectrum.

II-7. The π^0 p_T spectrum is corrected for the π^0 reconstruction efficiency and losses due to photon conversions to produce the raw π^0 p_T spectrum within the lead-glass detector acceptance.

II-8. The raw π^0 spectrum is corrected for the geometrical acceptance and photon energy threshold to produce the final π^0 p_T spectrum.

For both the photon and π^0 analysis, the shower reconstruction itself involves the following steps [60]: First, all lead-glass detector modules with energy deposit are analyzed and contiguous modules are associated together as a cluster. The list of clusters is then analyzed to determine the number of local maxima in each cluster. Clusters with a single maximum are treated as single showers. Clusters with multiple maxima are assumed to result from overlapping showers, with one shower per maximum. The energy deposit in each module in the cluster is partitioned to the overlapping showers according to the distance of the module from the shower maxima, assuming all showers to have electromagnetic radial shower profiles. The individual showers are then analyzed to calculate the total shower energy, position, and spatial dispersion (width) [60]. The shower positions are calculated with a logarithmic weighting of the energy deposit [61] and are projected to the front surface of the lead-glass detector, correcting for the shower depth and the non-projective geometry. The distance from the shower position to the nearest hit in the CPV is also extracted. All of this information is recorded on Data Summary Tapes (DSTs) as an intermediate analysis step.

After application of the minimum energy threshold of 750 MeV used in the analysis and acceptance calculations, the showers are subject to various sets of further identification criteria. The different criteria result in varying non-photon background contaminations and photon (π^0) identification efficiencies, which must then be determined. In order to avoid shower distortions near the detector edges, or around "dead" detector modules, an edge cut is applied to require that the reconstructed shower position lies beyond a specified distance from the detector edges or dead modules. A distance cut of two module widths from the detector edge and 1.5 modules widths from the center of a dead module was used.

In the present analysis, the photon selection has been made with the following shower identification criteria:

S1. Use all reconstructed showers.

S2. Use only narrow showers which have a dispersion (width) which is less than a specified value.

S3. Use only showers which have no associated CPV hit.

S4. Use narrow showers satisfying the dispersion cut with no CPV hit.

The first condition will have the highest photon identification efficiency but largest non-photon background contribution, while the last condition will have the lowest efficiency but lowest background contributions. For the extraction of the photon yield, the criteria S1 and S2 are not entirely independent from the criteria S3 and S4 since the CPV detector is used in the first case also to determine the charged hadron contamination. The distinction is mainly in the manner in which the data is processed and in how the corrections are applied. In particular, with criteria S3 and S4 the neutral shower distribution is acquired directly, but must be corrected for photons which were rejected due to random associated hits in the CPV, or due to photon conversions, while for criteria S1 and S2 the charged shower distributions are extracted using the CPV and corrected for random associated hits and conversions and then the corrected charged shower contribution is removed from the total shower distribution to obtain the neutral shower distribution. For the π^0 yield extraction the CPV is not used at all when criteria S1 or S2 are used with the result that no corrections for random CPV hits are needed and smaller conversion corrections are required. Criteria S2 and S4 make use of the fact that the transverse size of hadronic showers, with large energy deposit, is significantly greater than that of electromagnetic showers in the lead-glass calorimeter. The cut on the shower dispersion is chosen to accept more than 99% of

the isolated photon showers while rejecting hadron showers by a factor of 2-3. However, the shower dispersion cut is more likely to lose electromagnetic showers in the case of shower overlap.

For additional consistency checks, the data has also been analyzed with the shower energy threshold increased from 750 MeV to 1.5 GeV, with the outer edge module cut increased to three module widths, and with a photon energy asymmetry cut applied in the π^0 analysis.

C. Particle Reconstruction Efficiency

The large particle multiplicities in central Pb+Pb collisions result in module occupancies in the WA98 lead-glass detector of up to 20%, which poses a special problem for the direct photon search. These large occupancies result in overlapping showers in which photons may be lost, mis-identified, or significantly altered in position or energy. This results in a significant dependence of the photon and π^0 identification efficiency on the centrality of the collision. Furthermore, the position and energy resolution, and even the energy scale, will be centrality dependent due to the effect of shower overlap. For an accurate direct photon search it is imperative to accurately determine and account for these effects. For the present analysis this has been accomplished by the method of randomly inserting test showers into real events and studying how they are altered and the efficiency with which they are recovered. This procedure has been used to determine the γ, π^0, and η reconstruction efficiency.

For this reconstruction procedure the WA98 experiment geometry was implemented in GEANT [62] with the GEANT tracking parameters for LEDA adjusted to reproduce test beam measurements of the LEDA response to electrons. The generation and transport of Čerenkov photons in GEANT was parameterized and this parameterized Čerenkov response was used in the full WA98 GEANT simulation due to the prohibitive CPU-time consumption of the full Čerenkov tracking in GEANT. Single π^0's (η's) were simulated with a uniform distribution in transverse momentum and pseudo-rapidity over the LEDA acceptance and the decay photons were tracked through GEANT. The simulated LEDA response was recorded to create a library of photon test showers in the form of digitized LEDA signals. Only simulated π^0's with both decay photons in the nominal LEDA acceptance were recorded. The reconstruction efficiency was then extracted with the procedure illustrated in Fig. 4. First the raw data were calibrated and the event was characterized by the trigger detectors and other detectors of WA98. Then three passes were made through the LEDA event analysis software. In the first pass, the calibrated LEDA data was analyzed to perform the clustering and shower characterization as described above. The position, energy, shower dispersion, and distance to nearest hit in the CPV were saved for all identified showers together with the calibrated information from the other WA98 detectors. Next, a π^0 event was read from the shower library and inserted into an empty LEDA raw event. Simulated signals in dead modules were eliminated and the event was then analyzed as a real event. The shower information reconstructed from the simulated showers in the empty LEDA was recorded together with the primary π^0 and photon information prior to the GEANT response. Finally, the real LEDA event was overlaid with the simulated LEDA event and the signals were summed. Then the superimposed event was analyzed. In this step the position, energy, shower dispersion, and distance to nearest hit in the CPV were saved only for all new showers which were not in the list of showers found in the original raw event. Also, all showers of the original event found to be missing from the reanalyzed overlap event were marked as lost. All of this information was stored for each event in a single pass through the WA98 raw data and recoded on the Data Summary Tapes. Thereafter the data analysis was performed from the DSTs since they could easily be analyzed multiple times, or simultaneously, with different shower selection criteria.

In order to determine the photon reconstruction efficiency it is necessary to determine which shower in the overlap event corresponds to the simulated photon incident on the LEDA. In the first step, the empty LEDA GEANT shower information is analyzed to determine the reconstructed position of the highest energy shower in the vicinity of the incident GEANT photon. The overlap event is then analyzed to find the shower nearest to that position. If that shower has less than twice the energy[1] of the shower in the empty LEDA event it is taken as the reconstructed photon. Otherwise the photon is considered to be lost. After the associated shower is identified, it is tested to determine whether it passes the photon energy threshold requirement and whether it passes the detector edge cut. Also, if its position falls on the location of a so-called "bad" module with questionable gain, as described below, it is eliminated. Finally, it is tested against the various shower identification criteria S1-S4 described above.

[1]The factor of two change in energy criterion determines who "eats" whom when showers overlap and is necessary to avoid double counting.

The efficiency corrections are made as a function of the measured transverse momenta. The photon reconstruction efficiency can be constructed as a two-dimensional response matrix which transforms the transverse momentum of the incident photon into the transverse momentum of the reconstructed test shower, if it passes all identification criteria (the reconstructed transverse momentum is set to zero if the criteria are not satisfied). This two-dimensional efficiency matrix must then be inverted and applied to the measured transverse momentum distribution to obtain the final efficiency corrected result [63]. Alternatively, the efficiency can be applied as an iterative one-dimensional correction. In this case, one-dimensional histograms are accumulated of the incident transverse momentum and reconstructed transverse momentum with each entry weighted according to the final transverse momentum spectrum and rapidity distribution. The reconstruction efficiency is given as the ratio of reconstructed to input distributions. This one-dimensional efficiency determination must be iterated until the weighted input distribution matches the final measured distribution.

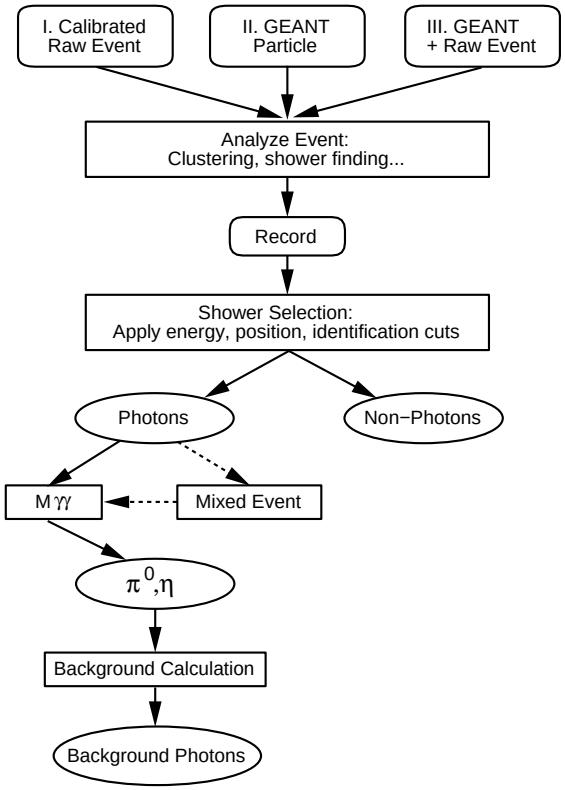

FIG. 4. An outline of the analysis procedure using the method of GEANT shower overlap used for the photon and π^0 efficiency determination. The intermediate results are recorded to DSTs after the event analysis step. The shower selection and further analysis is performed on the DSTs.

The π^0 reconstruction efficiency is similarly obtained by requiring that the showers from both of the decay photons simultaneously pass the photon identification criteria. The π^0 mass and transverse momentum is then calculated from the momenta of the two reconstructed photon showers. It is then required that the reconstructed mass fall within the π^0 peak mass integration region, and it may be additionally required that the photons pass an asymmetry ($\alpha = |E_1 - E_2|/|E_1 + E_2|$) cut on their reconstructed energies. The π^0 reconstruction efficiency is applied as a one-dimensional function of the transverse momentum. As in the photon case, the correction is determined from the ratio of reconstructed to input transverse momentum distributions. The input π^0 transverse momentum and rapidity weights must be adjusted by iteration until the assumed input transverse momentum distribution is the same as the final corrected distribution.

It should be noted that while these correction factors have been referred to as efficiency corrections, they might more properly be termed response corrections. They include essentially all detector effects other than the nominal detector acceptance. Specifically, they include the effects of detector edge cuts, dead and bad modules, energy resolution, and

distortions or loss due to shower overlap, as well as the efficiency to satisfy the specified identification criteria. In particular, the correction for smearing due to overlap and energy resolution can result in efficiency correction factors which exceed unity.

D. Background Calculation and Direct Photon Excess

As described above, the direct photon excess is obtained from the difference between the measured inclusive photon yield and the background photon yield expected from radiative decays of long-lived final state hadrons. The background photon yield in the WA98 LEDA acceptance is calculated by a Monte Carlo simulation of radiative decays of hadrons. The most important input to this calculation is the measured WA98 π^0 yield, which is extracted from the same data sample used to obtain the inclusive photon yield (see Fig. 4). Photons from π^0 decay account for about $80-90\%$ of the total expected background from radiative decays. It is important to note that the background photon yield attributed to π^0 decay includes both directly produced π^0's, as well as those from hadronic decays with π^0's in their final state. Thus, photons resulting from the $3\pi^0$ decay branch of the η are taken into account via the measured π^0 yield. On the other hand, the lifetime of the K_L^0 is sufficiently long that few of the $3\pi^0$ weak decays occur in front of the LEDA detector and therefore there is little contribution to the π^0 yield, and hence little contribution to the background photon yield. However, the weak decay of the K_S^0 to $2\pi^0$ is a special case. The K_S^0 lifetime is such that a substantial fraction of the decays are distributed over the distance between the target and the LEDA detector. As with the K_L^0 contribution, those decays which occur beyond the LEDA distance do not contribute to the π^0 or background photon yield. On the other hand, photons from a π^0 produced in a K_S^0 decay will have correctly measured energies but will be assumed to be produced at the target location and therefore will have an incorrect opening angle. This will result in a reconstructed π^0 invariant mass which is incorrect. While K_S^0 decays which occur close to the target will have a reconstructed π^0 mass which falls into the π^0 identification window, and so its decay photon contribution will be included via the measured π^0 yield, some fraction of the K_S^0 decays will occur sufficiently far from the target that their π^0 decays will not be properly identified. Only this portion of the K_S^0 decay photon contribution must be included in the calculated photon background.

The 2γ decay of the η is the second most important contribution to the photon decay background after the π^0 contribution. Together the π^0 and η photon decays constitute approximately 97% of the expected radiative decay background (see Fig. 28). Compared to the π^0 yield measurement the η measurement is more difficult due to the smaller production rate, the smaller 2γ decay branching ratio, and the resulting smaller signal to combinatorial background ratio in the 2γ invariant mass distribution. In the present analysis, the η yield is measured with modest statistical accuracy over a limited transverse momentum range due to these difficulties. In order to extrapolate the measured η transverse momentum distribution into unmeasured regions it is assumed that the η yield obeys m_T-scaling. This is the phenomenological observation [64] that the differential invariant cross sections, plotted as a function of the transverse mass $m_T = \sqrt{m_0^2 + p_T^2}$, for the various hadrons, h, have the same form, $f(m_T)$, with a normalization factor, C_h, which can vary but is found to be the same for many species:

$$E\frac{d^3\sigma_h}{dp^3} = C_h \cdot f(m_T). \tag{3.1}$$

Quite different theoretical explanations [65–67] can account for this observation. For various proton and pion-induced reactions at similar incident energies [68–75] it is observed that the η yield obeys m_T-scaling to good accuracy [76]. A scaling factor relative to π^0 production of $R_{\eta/\pi^0} = C_\eta/C_{\pi^0} = 0.55$ is obtained for the case of proton-induced reactions [76,77]. Similarly, the η yield is found to be consistent with m_T-scaling in minimum bias sulphur-induced reactions [77] at 200 *A* GeV incident energy.

Collective transverse flow will affect the spectrum of produced particles according to their mass with the result that m_T-scaling might be violated in collisions of very heavy ions. Evidence for collective transverse flow has been observed at the SPS for central ^{208}Pb+^{208}Pb collisions with estimated average transverse flow velocities as large as $\beta_T \approx 0.5$ [78–80]. For a particle of mass m and transverse momentum p_T the effective m_T inverse slope, or temperature T_{eff}, will be modified as [81]

$$T_{eff} = \frac{\sqrt{1-\beta_T^2}}{1-\beta_T\sqrt{1+m^2/p_T^2}}T \tag{3.2}$$

where β_T is the average transverse flow velocity and T is the thermal temperature. While the modification of the transverse mass spectrum is seen to decrease with increasing p_T, the effect can be significant. As an example, a

transverse flow of $\beta_T = 0.5$ would increase T_{eff} for the η by about 4% at $p_T = 2$ GeV/c which would result in an increase of about 50% in the η yield at $p_T = 2$ GeV/c.

It has been suggested that if chiral symmetry restoration occurs in the hot dense system formed in relativistic heavy ion collisions, then the masses of the η and η' mesons might decrease with an associated increase in their production rates [82,83]. These initial estimates suggested that the η and η' yields might be increased by as much as a factor of 3 and 10, respectively. Once produced, the η and η' are expected to interact relatively little in the dense matter with the result that they would survive to the final state to decay with their vacuum masses and contribute significantly to the decay background to produce excess photons and dileptons [82]. On the other hand, more recent calculations within the context of the non-linear sigma model suggest that the temperature dependence of the η and η' masses and mixing are negligible [84]. In view of these significant uncertainties in the extrapolation of the η yield from proton-induced reactions to central ^{208}Pb+^{208}Pb collisions it is important to measure the η yield directly for central collisions to provide experimental constraints on its possible contribution to the background photon yield.

Besides the π^0 and η, other hadrons with radiative decays which may contribute to the background photon yield are listed in Table I [85]. The production rates of these other hadrons are not measured in this experiment. As for the η, their production has been assumed to follow m_T-scaling with the same m_T spectrum as the measured π^0 spectrum and with relative normalizations R_{X/π^0} (equivalent to the asymptotic ratio as $p_T \rightarrow \infty$) given in Table I. Within experimental errors the ratio $R_{X/\pi^0}(p_T \rightarrow \infty) \approx 1$ independent of incident energy for the ρ and ω [64,73,75,86] and for the η' [86]. For the K^0_S a ratio of $R_{K^0_S/\pi^0} \approx 0.4$ [87–89] is observed for proton-induced reactions with indications for an increased ratio for nucleus-induced reactions [89,90].

Of the other radiative decays listed in Table I only the η' and ω are expected to contribute more than one percent of the background photons (see Fig. 28). The η' is notable in that it might be significantly enhanced due to the mechanism discussed above. While the η' production rate is not determined in the present measurement, it can be constrained by the η measurement due to its 65.5% branching ratio to $\pi\pi\eta$.

To summarize, the background photon yield in the acceptance of the WA98 lead-glass detector is calculated by a Monte Carlo simulation of radiative decays of all hadrons listed in Table I. The various hadrons are assumed to have the same transverse mass spectrum as the measured WA98 π^0 transverse mass spectrum for each event class. The yields of the other hadrons relative to the π^0 yield are given by the m_T-scaling factors listed in Table I. The one exception is the η scaling factor for central ^{208}Pb+^{208}Pb collisions where the measured η m_T-scaling factor is used. The Monte Carlo program uses the JETSET 7.3 routines [91] to implement the hadron decays with proper branching ratios and decay distributions. The hadrons are assumed to have a Gaussian rapidity distribution centered on mid-rapidity $y = 2.9$ with a width of $\sigma_y = 1.3$ according to measurements for ^{208}Pb+^{208}Pb collisions [92].

TABLE I. Dominant radiative decays which contribute to the inclusive photon background. $R_{X/\pi^0}(p_T \rightarrow \infty)$ is the assumed asymptotic ratio of yield of hadron X relative to π^0's, or equivalently the m_T-scaling factor. $\sigma(X)/\sigma(\pi^0)$ is the ratio of integrated yields which would be obtained for an exponential spectrum in m_T with a slope of 200 MeV/c^2 and the assumed R_{X/π^0} values. It is only an indication of the ratio of integrated yields since the actual value will depend on the measured π^0 m_T spectrum. The listed decays and branching ratios are taken from Ref. [85].

State	Mass	$R_{X/\pi^0}(p_T \rightarrow \infty)$	$\sigma(X)/\sigma(\pi^0)$	Decay Branch	Branching Ratio

IV. DATA ANALYSIS DETAILS

In this section, detailed results are presented for the extraction of the γ, π^0, and η yield and their error estimates, as required for the direct photon analysis. First, a description of the data sample selection is presented. This is followed by a discussion of the analysis involving the Charged Particle Veto detector. The CPV is used to determine the charged particle contamination in the photon shower sample. Next follows a description of the details of the extraction of the inclusive photon transverse momentum distributions, including a discussion of the background contributions from charged particles and neutrons, and losses due to photon conversions. The photon identification efficiency for the various methods is discussed together with a summary of the estimated systematical error on the inclusive photon measurement. Next, the π^0 yield extraction is described. This includes a discussion of the yield extraction method, efficiencies, backgrounds, and systematical error. Finally, the η yield extraction is described. The final results and the extraction of the direct photon excess are described in the following section.

A. Data Selection

The present analysis has been performed using the event samples summarized in Table II. The data have been taken over six week run periods in 1995 and in 1996 with the 158 *A* GeV ^{208}Pb beam of the SPS on ^{208}Pb targets of 495 and 239 mg/cm^2, respectively. During both run periods most data were taken with the GOLIATH magnet on, as required for the WA98 tracking spectrometer measurements. The minimum bias cross sections for the various data sets, after subtraction of the target out backgrounds, are given in Table II. Because of the change in the apparent transverse momenta of the charged particles due to the deflection in the magnetic field, the apparent transverse energy measured in MIRAC is increased with magnet on compared to the actual transverse energy. With the fixed low transverse energy trigger threshold, this resulted in larger minimum bias cross sections for the magnet on data sets. During the 1995 datataking period the vacuum exit window at the entrance to the GOLIATH magnet produced a significant background of downstream interactions which satisfied the minimum bias transverse energy threshold. These downstream interactions were eliminated by requiring an interaction at the target location by the requirement of a hit in the Plastic Ball in the angular region from 30° to 50° using the Plastic Ball trigger (described in Sec. II A) in coincidence with the minimum bias trigger. For the 1996 run period, the vacuum exit window was changed resulting in fewer downstream interactions. As a result, the Plastic Ball trigger was not required in the online trigger which resulted in less biased minimum bias cross sections. The rms variations of the minimum bias cross sections determined on a run-by-run basis are also given in Table II. The measured variation gives an indication of the uncertainty in the measured absolute cross sections due to normalization and background corrections. The background corrections were obtained from special empty target runs with no target in the target location. Due to the lower event rates, and resulting low deadtime and lack of need to be downscaled, the empty target data was taken with similar number of integrated beam triggers as obtained for the Pb data. Specifically, the 1995 and 1996 empty target data corresponded to a factor of 2.3 and 1.4 fewer beam triggers than the 1995 and 1996 Pb target data, respectively.

TABLE II. Summary of the event selection used for the present analysis. The table shows the WA98 158 *A* GeV ^{208}Pb+^{208}Pb minimum bias cross sections for the 1995 and 1996 run periods under conditions of magnetic field on and field off. The rms of the minimum bias cross section extracted run by run is indicated in parenthesis. The central event class is defined by those events falling above a high cut on the measured transverse energy where the cut is chosen to give a cross section of 635 mb above the cut. Similarly, the peripheral event class is defined by those events falling below a low transverse energy cut where the cut is chosen to give a total cross section of 4910 mb above the cut. The number of peripheral and central events used under each condition for the present analysis are listed.

Run Period	^{208}Pb Target Thickness (mg/cm^2)	Minimum Bias $\sigma_{minbias}$ (mb)	Peripheral Collisions N_{Events}	Central Collisions N_{Events}
1995 Field On	495.	6192. (56.)	2694528	2879652
1995 Field Off	495.	5971. (30.)	159291	213170
1996 Field On	239.	6451. (53.)	1203407	2937565
1996 Field Off	239.	6202. (58.)	222917	650521

The direct photon analysis has been performed for event selections corresponding approximately to the 20% most peripheral and 10% most central portions of the minimum bias cross sections. These event classes are defined by cuts on the total transverse energy, measured in MIRAC, as calculated in the offline analysis. The selections correspond closely to the online trigger event classes described in Sec. II B. More precisely, the transverse energy cut which defines the central event sample was chosen to correspond to a most central cross section of 635 mb, or impact parameters less than about 4.5 fm, for all data sets. Similarly, the transverse energy cut which defines the peripheral event sample was chosen to correspond to a cross section of 4910 mb above the transverse energy cut, or to a peripheral event sample with impact parameters greater than about 12.5 fm. Due to the variation of the minimum bias cross section for the different data sets analyzed (see Table II), the meaning of the peripheral event class (for example, as reflected in the particle multiplicity) depended on the data sample. These event class definitions are shown in Fig. 5 for the 1995 magnet on data set where the multiplicity of showers in the lead-glass fiducial region with energy above 750 MeV is plotted versus the total transverse energy. The projections onto each axis are also shown. Similar transverse energy cuts are used for the event class definitions for both the 1995 and 1996 data sets. However, quite different cuts are used for the magnet on and magnet off data sets due to the change in the apparent transverse energy scale noted above.

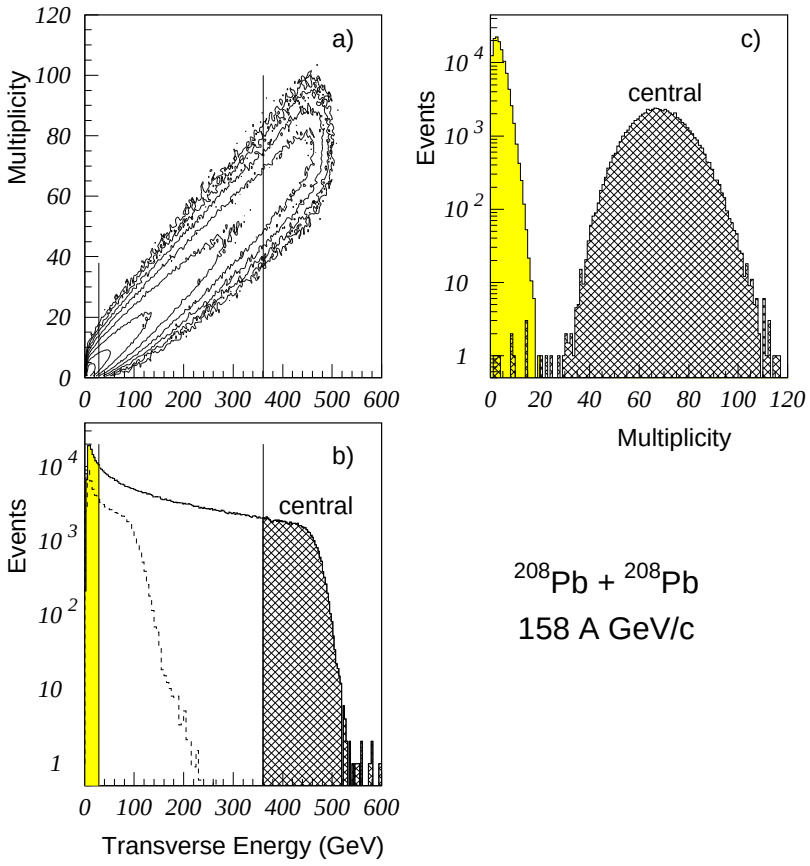

FIG. 5. The correlation between the number of showers observed in the lead-glass detector and the measured transverse energy for 158 *A* GeV ^{208}Pb+^{208}Pb collisions for a sample of the 1995 magnet on data. Part b) shows the projection onto the transverse energy axis with the shaded regions indicating the peripheral and central event class selections used for the present analysis. The distribution is uncorrected for the empty target contribution which is shown by the dashed histogram with arbitrary relative normalization. Part c) shows the projection onto the lead-glass multiplicity axis for the selected events.

We note that while the central event samples in the four data sets should be very similar in terms of the impact parameter range selection and particle multiplicity, the peripheral event samples of the different data sets are likely to be more variable. This is due to the rapid variation of the overlap geometry in the peripheral region and the variations in the minimum bias cross section and background corrections for the four data sets noted above.

In the offline analysis the various trigger signals are checked to remove events with inconsistent trigger information and to remove events with another beam particle within 100 ns or another interaction within about 300 ns of the

triggered event. These trigger cuts discard about 10% of the events. For the 1996 data set the Plastic Ball trigger was not required in the online trigger or used in the offline analysis for the final data sample. However, events which did not satisfy the Plastic Ball trigger requirement were used in the offline analysis to investigate the downstream interaction contributions in more detail. Since the downstream interactions are on light materials, such as air, mylar, and aluminum ($A < 30$) and have underestimated emission angles, they produce small measured transverse energies with the result that their contamination is almost entirely in the peripheral event sample (see Fig. 5). The peripheral data sample for the 1996 data set was smaller than that for the 1995 data set due to the factor of two larger prescale factor used in the 1996 peripheral trigger.

In addition to a selection of the data sample based on trigger cleanup cuts, the lead-glass shower data was analyzed in a preliminary scan of the data and modules with questionable gain were eliminated for the subsequent analysis. This selection was made by accumulating the shower energy spectrum for each individual module where the shower centroid was within that module. The results were compared to the average dependence across the detector surface. Modules whose spectrum deviated from the average behavior, with rather strict criteria, were flagged as bad. In the actual data analysis, showers with positions within a module which was flagged as bad were eliminated. As a result of the rejected bad modules and the modules eliminated around the edges of the detector and dead modules, the effective LEDA acceptance was reduced by about 40%.

B. Charged Particle Veto

The Charged Particle Veto detector provides essential information for the photon analysis. It allows charged showers in LEDA to be identified and associated with charged hadrons or photon conversions (see step G3 of Sec. III B). When the photon selection is made without invoking the CPV directly in the shower identification criteria (criteria S1 and S2 of Sec. III B) then the CPV is used to accumulate the transverse momentum spectrum of charged LEDA showers. This spectrum is corrected for the p_T-independent CPV efficiency and then subtracted from the total LEDA shower transverse momentum spectrum to obtain the neutral shower transverse momentum spectrum. The charge/neutral ratio is extracted and fitted as a function of the transverse momentum and used to calculate a correction factor applied to the total shower spectrum to obtain the neutral shower spectrum. The neutral shower spectrum is then corrected for neutrons and anti-neutrons, and for conversions to obtain the raw photon spectrum.

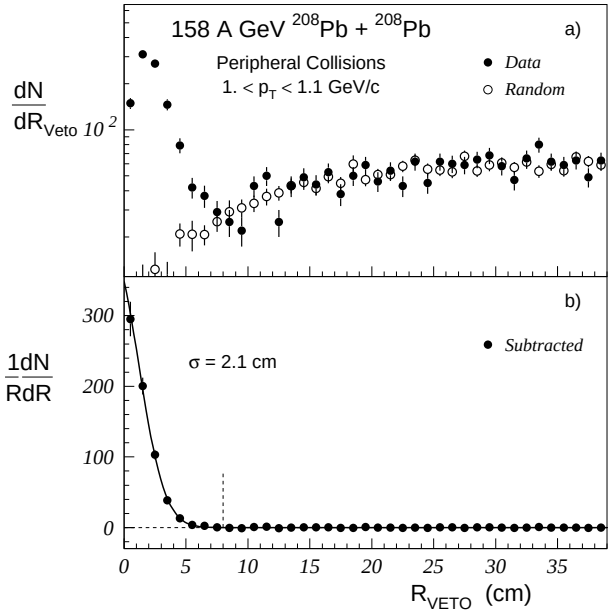

FIG. 6. The distribution of distances, R_{Veto}, to the nearest CPV hit from a shower particle in the lead-glass for peripheral events. In part a) the distribution for real events is shown by the solid circles. The distribution for randomly vetoed hits is shown by the open circles. The random veto distribution is obtained using test GEANT showers inserted into real events. The true veto radius distribution after subtraction of the random veto distribution is shown in part b).

Alternatively, the CPV can be used directly in the shower selection criteria to choose non-charged photon candidates (criteria S3 and S4 of Sec. III B). However, because the CPV detector was fully installed and operated for the 1996 run period only, it was not possible to perform the analysis with the CPV in this way for the 1995 data sample. Instead it was necessary to extract the charge/neutral correction from the 1996 data sample and apply this correction to the 1995 data. Therefore it was important to verify the consistency of the two methods in which the CPV information was used.

In the shower analysis procedure described in Sec. III C, each shower in the list of individual localized showers in LEDA is compared with the list of hits in the CPV and the distance between the LEDA shower position and the nearest CPV hit position is recorded. An example of this distance distribution is shown in Fig. 6a) for showers in peripheral collisions with transverse momenta $1 < p_T < 1.1$ GeV/c. The distribution shows a clear peak at small veto distance with a long tail extending to large veto radii. The long tail results from random associations between showers in LEDA and hits in the CPV. The veto radius distribution of these random associations is also shown in Fig. 6a). This distribution is extracted from the veto distance distribution obtained for the GEANT test photons introduced into the LEDA event, as described in Sec. III C. Since these test showers have no correlated hit in the CPV their veto distance distribution is strictly random. The random hit distribution is normalized to the distribution for real LEDA showers at large veto distance and subtracted from the distribution for real showers to obtain the distance distribution of real charged showers shown in Fig. 6b). While the random veto contribution is quite small for peripheral collisions, the detector occupancies are much greater in central collisions with the result that there is a much higher probability for a CPV hit to be randomly associated with a shower in LEDA. This is shown in Fig. 7 where the same veto distance distributions are shown for central collisions. In this case the correction for the random CPV hits is essential.

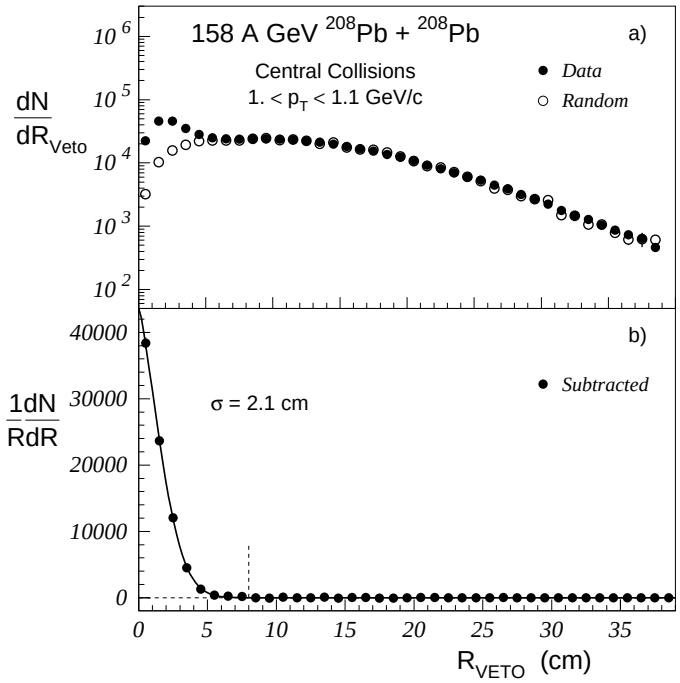

FIG. 7. The distribution of distances, R_{Veto}, to the nearest CPV hit from a shower particle in the lead-glass for central events. In part a) the distribution for real events is shown by the solid circles. The distribution for randomly vetoed hits is shown by the open circles. The random veto distribution is obtained using test GEANT showers inserted into real events. The true veto radius distribution after subtraction of the random veto distribution is shown in part b).

Based on these distributions, showers with a CPV hit within a distance cut of 8 cm are tagged as charged showers. For the analysis methods S1 and S2, in which the CPV is used to extract a charged/neutral correction factor, the charged shower yield is extracted for each p_T bin as the random subtracted yield in the veto peak within the 8 cm distance cut. The result is the charged shower p_T distribution which is then used to obtain the charged/neutral shower correction factor as a function of p_T. The charged/neutral shower ratio as a function of the shower energy is shown in Fig. 8 for peripheral collisions using a 8 cm distance cut. The peak in the spectrum at about 550 MeV is due to non-showering hadrons which pass through the lead-glass and deposit similar energy by dE/dx only. A minimum shower energy

threshold of 750 MeV has been applied in the present analysis to eliminate this minimum-ionizing particle, or MIP, peak from the photon candidates. It is seen that the charged hadron background differs for the magnet on and magnet off run conditions.

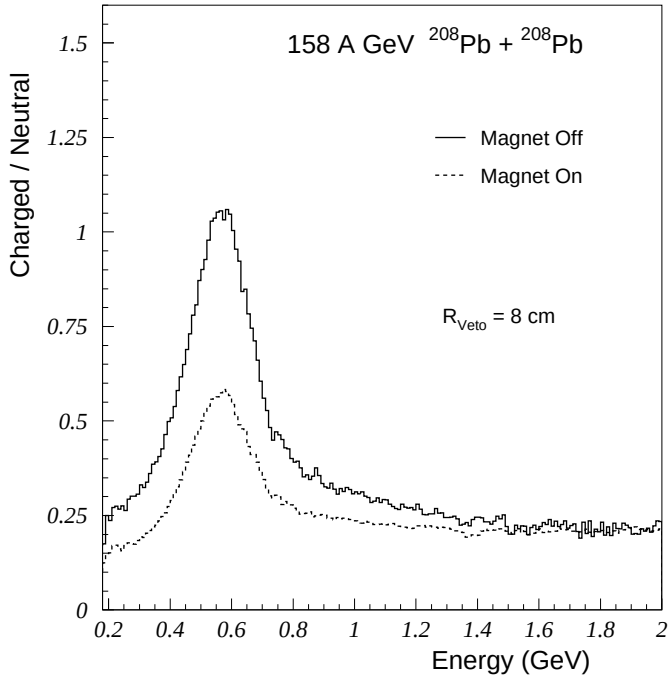

FIG. 8. The ratio of charged to neutral clusters identified in the lead-glass detector for peripheral collisions with magnet on or magnet off run conditions as a function of the total energy of the cluster in the low transverse momentum region. The solid curve shows the ratio for clusters identified as charged hits by a coincident hit in the CPV within a distance of $R_{Veto} = 8$ cm of the cluster. The peak at 550 MeV from non-showering minimum ionizing particles is clearly seen in the distributions. A minimum energy threshold of 750 MeV is used in the present analysis.

For the analysis methods S3 and S4 charged hadrons are rejected directly from photon candidate showers by an associated CPV hit within the 8 cm distance cut. In this case there is no charged/neutral correction necessary to the photon candidate spectrum. On the other hand, the loss of photon showers due to random vetos and conversions is treated as an efficiency loss which is then taken into account at a later step in the efficiency correction (see Sec. IV C 3).

The charged shower identification must be corrected for the efficiency of the Charged Particle Veto. As mentioned in Sec. II C 2, the CPV efficiency has been determined *in situ* using LEDA and the Silicon Pad Multiplicity Detector. The analysis is performed using magnet off data to allow straight line tracking between the SPMD and LEDA. Peripheral collisions are used to keep the detector occupancies low in order to minimize random hit associations. Hits in the SPMD are projected to the LEDA detector surface and associated with a hit in LEDA if they fall within the SPMD projected pad area. If a hit is found within LEDA the distance from the LEDA shower to the nearest hit in the CPV is extracted. The raw CPV efficiency, ϵ^0_{CPV}, obtained as the ratio of the number of CPV hits found to the number of SPMD-LEDA coincidence tracks, is shown in Fig. 9 as a function of the distance between the LEDA shower and the CPV hit. It is seen to increase rapidly up to a veto distance of about 15 cm and then increase very slowly for larger distances. This slow rise at large distances is due to random coincidences with hits in the CPV which artificially increase the apparent efficiency. The random CPV hit efficiency, ϵ^R_{CPV}, also shown in Fig. 9, is extracted by an event mixing technique in which the CPV data are taken from a different peripheral event than the one used for the SPMD-LEDA track. The CPV efficiency is corrected for such random CPV associations as $\epsilon_{CPV} = (\epsilon^0_{CPV} - \epsilon^R_{CPV})/(1 - \epsilon^R_{CPV})$. In addition, due to the SPMD inefficiency or interactions, there can be random coincidences between the SPMD and LEDA, for which a hit in the CPV would not be expected, which decrease the

apparent CPV efficiency. The shape of the SPMD-LEDA random coincidence distribution is also shown in Fig. 9. A small additional correction is applied to ϵ_{CPV} to account for this effect.

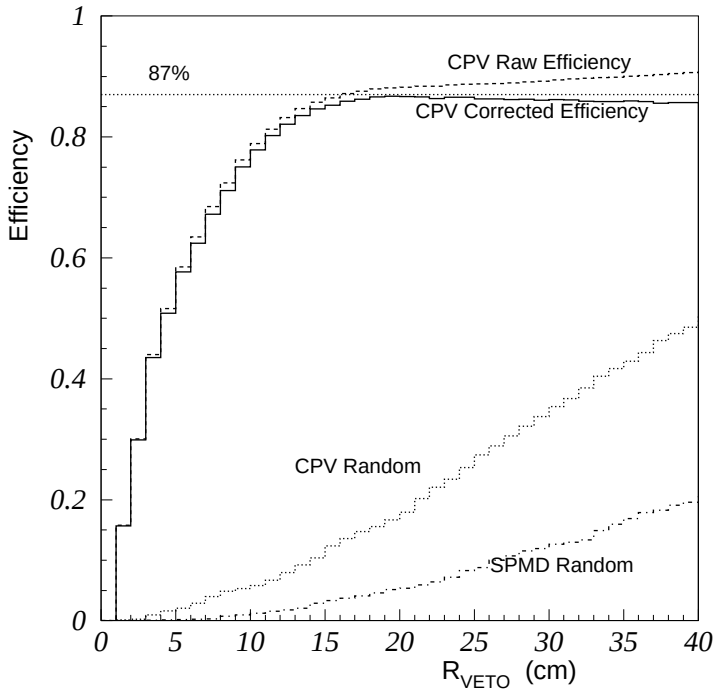

FIG. 9. The efficiency of the charged particle veto as a function of veto radius. The results are obtained from magnetic field off peripheral data. The dashed curve shows the probability that a hit in the CPV is found within a distance R_{Veto} of a charged hit in the lead-glass. The lead-glass hit has been tagged as charged by a coincident hit in the SPMD within distance R_{Veto}. The distance R_{Veto} is measured in the plane projected onto the lead-glass surface. The dashed curve includes random vetoes which artificially increase the apparent efficiency with increasing radius. The dotted curve shows the random veto efficiency of the CPV. The dot-dashed curve shows the random veto efficiency of the SPMD. The solid curve shows the final CPV efficiency result.

As shown in Fig. 9, an asymptotic corrected CPV efficiency of $\epsilon_{CPV} = 87\%$ is obtained for veto distance cuts greater than about 17 cm. It will be noted that this distance is considerably larger than indicated by the width of the veto distance distributions shown in Figs. 6 and 7. This difference is due to the fact that the CPV efficiency analysis uses all charged hits in the SPMD. Therefore it is dominated by charged hadrons which deposit very little energy in LEDA either due to poorly developed hadronic showers, or due to energy deposit by dE/dx only. These low energy showers have very poor position determination in LEDA. This effect is also evident by the observation that the width of the LEDA-CPV correlation (see Figs. 6 and 7) increases at very low transverse momentum. As a result the R_{Veto} distance cut is increased for low transverse momenta to insure that the asymptotic CPV efficiency is attained. The CPV efficiency is assumed to be 87% independent of transverse momentum.

During datataking, CPV readout errors occurred with apparently random frequency which resulted in loss of portions of the CPV data in the event. These errors were not excluded in the present analysis and account for most of the extracted CPV inefficiency. Since the readout errors resulted in loss of trailer information in the CPV data packets it was possible to identify such readout errors and determine the CPV efficiency for a data sample without readout errors. An intrinsic detector efficiency of better than 98% was obtained [59]. It was also possible to verify that the readout error rate did not vary with detector occupancy or with time during the run period. The readout errors occurred relatively frequently but affected only a small portion of the CPV data of an event when they did occur. Therefore rejection of all events in which a CPV readout error occurred would have resulted in an unacceptable reduction of the data sample.

C. Photon Analysis

The method to extract the inclusive photon transverse momentum spectra are described in Sec. III B. In summary, the procedure is to remove the charged hadron contamination from the photon candidates or candidate spectrum, remove the neutron and anti-neutron contamination, correct for photon conversions, then correct for the photon identification efficiency, and finally to correct for the detector acceptance. The details of this procedure are described in this section.

1. Charged Particle Contamination and Conversions

The CPV detector is used to select charged showers. The charged shower transverse momentum distribution is constructed from the random corrected yield in the veto peak for each p_T bin, as discussed in Sec. IV B (see Figs. 6 and 7). The random corrected charged shower p_T distribution is then corrected for the CPV efficiency to obtain the total charged shower distribution. This corrected charged shower distribution includes both charged hadrons and photon conversions. Next, the corrected charged shower p_T distribution is subtracted from the total shower distribution to obtain the raw neutral shower p_T spectrum. The neutral shower spectrum is depleted uniformly as a result of photon conversions and must be corrected by a factor $1/(1-P_C)$ where P_C is the photon conversion probability. The amount of conversion material between LEDA and the target was the same for both the 1995 and 1996 run periods. The air plus vacuum exit window contributed 5.4% to the conversion probability and the CPV material before the active volume of the CPV contributed an additional 2.0% to the conversion probability. Finally, the 1995 and 1996 target (half) thicknesses contributed an additional 3.0% and 1.45%, respectively. Thus the total photon conversion probability for the 1996 run period during which the CPV was in operation was $P_C = 8.6\%$.

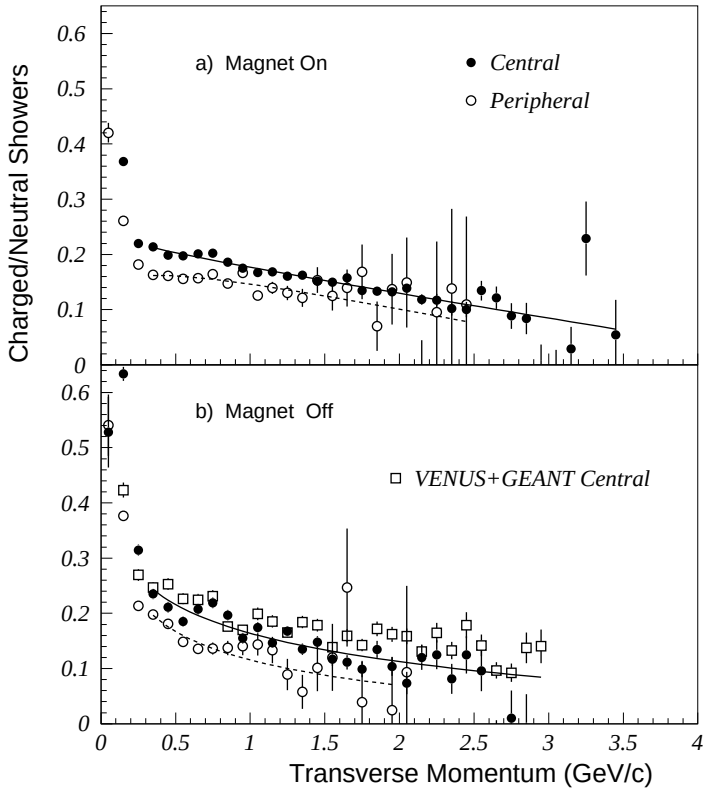

FIG. 10. The measured ratio of charged to neutral showers in the lead-glass detector for peripheral (open circles) and central (solid circles) 158 *A* GeV ^{208}Pb+^{208}Pb collisions as a function of the transverse momentum of the cluster. The results are shown for all clusters for a) magnet on and b) magnet off. The data have been corrected for photon conversions and the CPV efficiency. The lines are fitted curves.

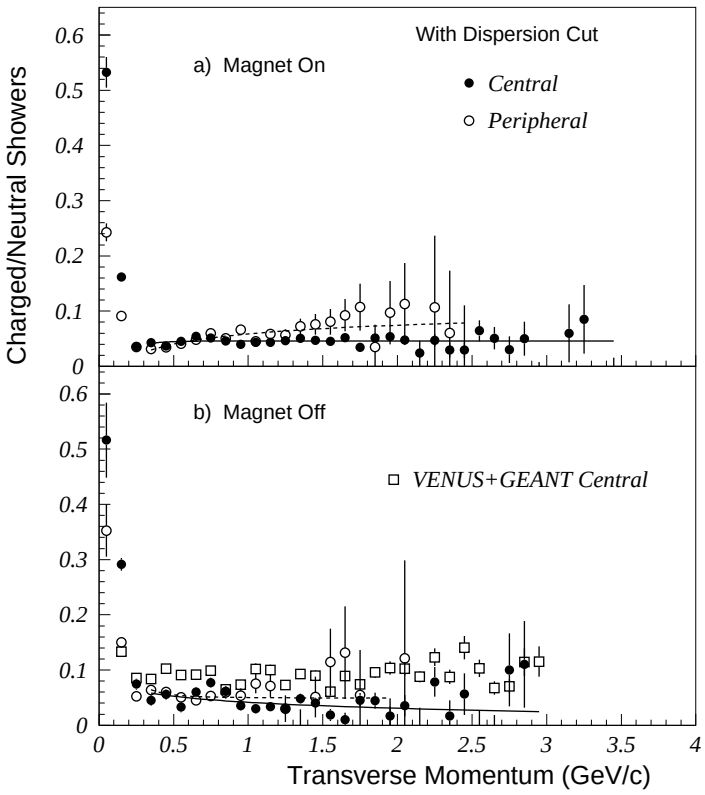

FIG. 11. The measured ratio of charged to neutral showers in the lead-glass detector for peripheral (open circles) and central (solid circles) 158 *A* GeV ^{208}Pb+^{208}Pb collisions as a function of the transverse momentum of the cluster. The results are shown for clusters which pass a photon-like dispersion cut for a) magnet on and b) magnet off. The data have been corrected for photon conversions and the CPV efficiency. The lines are fitted curves.

The neutral shower spectrum, after correction for conversions, is subtracted from the total shower spectrum to obtain the final charged hadron shower spectrum. By this procedure the amount of contamination of the selected showers due to charged hadrons is determined for each shower identification criterion and for the magnet on and magnet off run conditions. The extracted ratio of charged/neutral showers under the condition to use all showers (S1) is shown in Fig. 10 for central and peripheral collisions and for magnet on and magnet off. The charged hadrons are seen to constitute about 20% of all showers at low p_T decreasing to about 5% at the highest p_T. When the shower dispersion cut is applied in the shower selection criterion (S2) the hadron contamination is reduced to about 5% nearly independent of p_T as seen in Fig. 11. For comparison, simulation results are also shown for the case of magnet off. The simulation was performed using full VENUS 4.12 [93] events calculated for central ^{208}Pb+^{208}Pb collisions. All particles incident on LEDA were tracked with GEANT [62] with full tracking of the produced Čerenkov photons, which is the dominant component of the shower observed in the lead-glass. The results shown were obtained using the GCALOR hadronic shower package for hadrons [94]. Reasonably good agreement with measurement is observed. In addition, the GEANT calculations were performed using the GHEISHA and FLUKA hadronic shower packages. The GHEISHA results were in better agreement with measurement while the FLUKA results overpredicted the observed charged/neutral ratio with the GCALOR result intermediate between the other two results. The proper description of hadronic showers in the lead-glass is an especially severe test of the hadronic shower packages. Since only that component of the shower which produces Čerenkov light which reaches the photomultiplier contributes to the observed signal, the lead-glass response to hadrons is sensitive to details of the hadronic shower composition. For the charged/neutral corrections the measured results have been used. In contrast, the corrections for neutrons and anti-neutrons discussed below are, by necessity, based solely on the contributions calculated using GEANT.

The measured charged/neutral ratio spectra, (c/n), are fitted (as seen in Figs. 10 and 11) to remove statistical fluctuations and to extrapolate to high p_T. The lowest p_T bins are not used in the present analysis due to the sharply

increasing rise in the hadron contamination.[2] The fitted result provides the neutral/total shower ratio $1/(1+c/n)$ which is then used as a multiplicative factor to extract the neutral shower spectrum from the total shower spectrum. This charged hadron correction procedure was necessary for the analysis of the 1995 data set since there was no CPV measurement to extract the charged hadron contamination information. It also allowed to use the full 1996 data sample including periods when the CPV was not fully operational. It should be noted that the 1995 and 1996 run conditions and analysis procedures were the same, and so the amount of charged hadron contamination extracted from the 1996 data sample should be the same for the 1995 data sample. A minor difference between the two data samples is the thicker target used for the 1995 run period which resulted in an additional 1.55% conversion probability. For the magnet off data sample this is expected to have no effect since essentially all converted photons are identified as single showers, which means that the total shower spectrum is unchanged. Therefore the charged/neutral shower correction factor is the same nearly independent of the amount of conversions. For the magnet on run conditions the e^+e^- pair produced at the target will separate in the magnetic field and the total shower spectrum will depend on the amount of photon conversions. Therefore a small correction ($\approx 1\%$) for this effect has been applied to the charge/neutral ratio when used for the 1995 magnet on data. Based on the results shown in these figures, a conservative 30% uncertainty has been assumed for the charged/neutral ratio for the photon analysis.

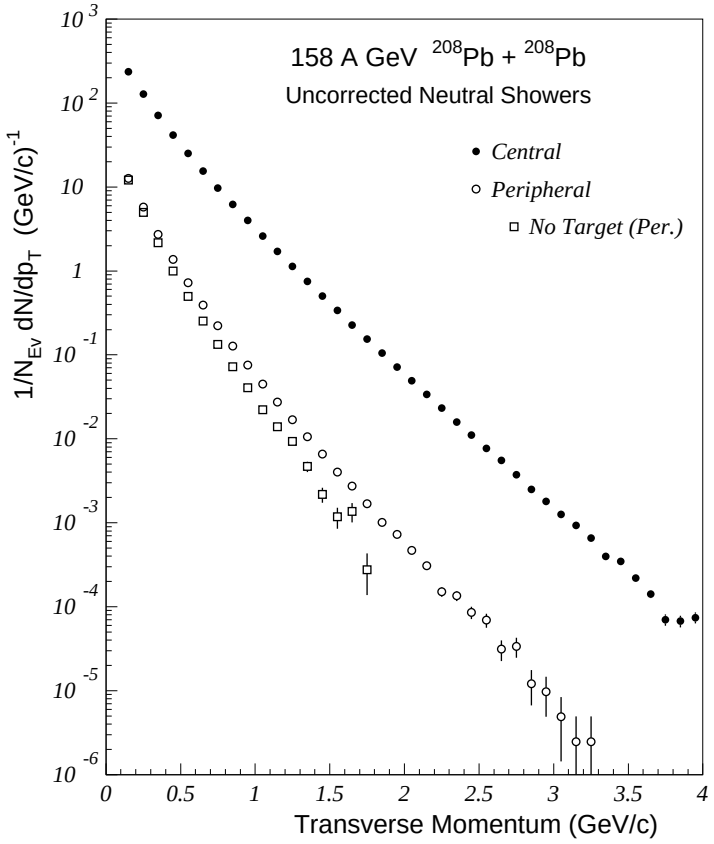

FIG. 12. The multiplicity of all neutral showers as a function of transverse momentum for peripheral (open circles) and central (solid circles) 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The results are the sum of 1995 and 1996 magnet on data sets. Results are also shown (open squares) for peripheral event selection for runs with no target. The spectra have not been corrected for efficiency or acceptance. They are used as the first iteration in the iterative efficiency correction.

[2]Note that while results will be shown to low p_T for various intermediate analysis steps, the final results will be presented only for the region $p_T > 0.5$ GeV/c due to various systematical error sources which increase at low p_T.

The raw neutral shower multiplicity per event as a function of transverse momentum, uncorrected for neutrons, efficiency, or acceptance, are shown in Fig. 12. The results are shown for central and peripheral collisions for the sum of 1995 and 1996 data samples. The measured distributions extend over more than 6 orders of magnitude and extend to about 3 and 4 GeV/c for peripheral and central collisions, respectively. A flattening of the distribution is observed in going from peripheral to central collisions. Also shown is the distribution obtained for events satisfying the peripheral trigger condition for runs with no target. No events from empty target runs satisfy the central event trigger condition (see Fig. 5). The empty target data is seen to have a neutral shower multiplicity which is similar to the peripheral ^{208}Pb+^{208}Pb case but to fall more steeply with transverse momentum. The similarity is not surprising since the trigger selection on the transverse energy for peripheral Pb collisions will select events with a similar number of nucleon-nucleon collisions as for an empty target interaction. The no-target interactions most likely occur on light materials of the target wheel and vacuum system (aluminum or carbon). The steeper falling empty target spectrum results from the fact that many of those interactions occur on downstream materials and therefore have underestimated angles and correspondingly smaller apparent transverse momenta. Since the spectral shapes differ, the peripheral spectrum should be corrected for the effect of the empty target contribution. The true peripheral spectrum, S_{Per}^{True}, should be obtained from the raw peripheral spectrum, S_{Per}, and empty target spectrum S_{Empty} as

$$S_{Per}^{True} = S_{Per} + f \cdot (S_{Per} - S_{Empty}), \tag{4.1}$$

where f is the fraction of empty target events to true Pb target events in the peripheral data sample. Based on the live-beam scalers, downscale factors, and number of peripheral triggers a value of $f = 0.098$ is obtained for the results shown in Fig. 12 where the empty target results are obtained with the same trigger cleanup cuts as used for the Pb data. On the other hand, as will be discussed in regard to the π^0 result in Sec. IV D below, there are reasons to believe that the target out contribution to the peripheral data may be larger than indicated by the properly normalized empty target data. With the requirement of a coincident hit in the forward region of the Plastic Ball detector (see Sec. IV A) as for the 1995 data sample, the properly normalized fraction of empty target events in the peripheral data sample is only $f = 0.01$.

2. Neutron and Anti-neutron Corrections

The neutral shower spectra must be corrected for neutron and anti-neutron contributions to obtain the raw photon spectrum. For this correction it is necessary to rely entirely on results from simulation. The incident neutron and anti-neutron flux into the LEDA acceptance has been estimated using VENUS. In Fig. 13a) the VENUS predictions of the number of particles per decay photon are shown as a function of their incident transverse momentum for neutrons, anti-neutrons, and π^+. In the region of greatest interest at high p_T, the neutron flux is seen to exceed the π^+ flux by roughly an order of magnitude. Even the incident anti-neutron flux is similar to the π^+ flux at large p_T. Fortunately, as for the charged hadrons, the neutrons and anti-neutrons deposit only a small portion of their incident energy in the lead-glass detector which results in a much reduced apparent transverse momentum.

The response of the lead-glass detector to the neutrons and anti-neutrons, and to photons was simulated with GEANT with full tracking of the produced Čerenkov photons. The resulting ratio of neutron+anti-neutron $(n + \overline{n})$ to total neutral $(n + \overline{n} + \gamma)$ showers as a function of their apparent transverse momentum is shown in Fig. 13b). The $(n + \overline{n})$ contamination is seen to be significantly reduced in comparison to the incident flux due to the small energy deposit. The contamination is dominated by the neutron contribution. Results are shown with and without application of the shower dispersion cut. It is seen that the requirement of a narrow photon-like dispersion significantly reduces the $(n + \overline{n})$ contamination from about 5% to 1-2%.

The results shown have been calculated using the GCALOR hadronic shower package [94] of GEANT. Calculations were also performed using the GHEISHA and FLUKA hadronic shower packages. GHEISHA predicted $(n + \overline{n})$/neutral ratios which were nearly a factor of two lower than the FLUKA predictions while the GCALOR result was about 1-2% in value below the FLUKA result for the case of all showers. With the narrow shower condition applied GCALOR and FLUKA gave consistent results. While no hadronic shower package has been clearly demonstrated to be superior [95], we have chosen to use the GCALOR results, since GCALOR, as well as FLUKA, is considered to be more reliable for neutron transport.

The proton spectrum predicted by VENUS for central ^{208}Pb+^{208}Pb is considerably flatter than the measured spectrum reported by NA49 [96]. This would suggest that VENUS also overpredicts the neutron and anti-neutron yield at high transverse momentum, which would suggest a smaller contamination. On the other hand, VENUS also overpredicts the π^0 and hence inclusive photon yield at high p_T [97]. The open points in Fig. 13a) show an experimental estimate of the neutron/γ ratio based on the NA49 proton measurement and the present WA98 photon measurement.

The NA49 proton transverse mass distribution (measured over the interval $0. < m_T - m_p < 0.3$ GeV/c^2 [96]) has been fitted to an exponential with the integral yield normalized to the predicted VENUS neutron multiplicity. It is seen that the neutron/γ ratio estimated from the experimental results is quite similar to that predicted by VENUS, even in the region extrapolated beyond the NA49 measurement. Moreover, after GEANT response the final $(n + \overline{n})$/neutral ratio is very similar to the VENUS result over the entire p_T region. In view of the uncertainties inherent in comparing different experimental results with different event selections, especially for peripheral collisions, the VENUS predictions have been used for the neutron and anti-neutron corrections. Due to these uncertainties, and especially those uncertainties associated with the simulation of the neutron response, a 50% uncertainty has been assumed for the $n + \overline{n}$ contribution to the photon result.

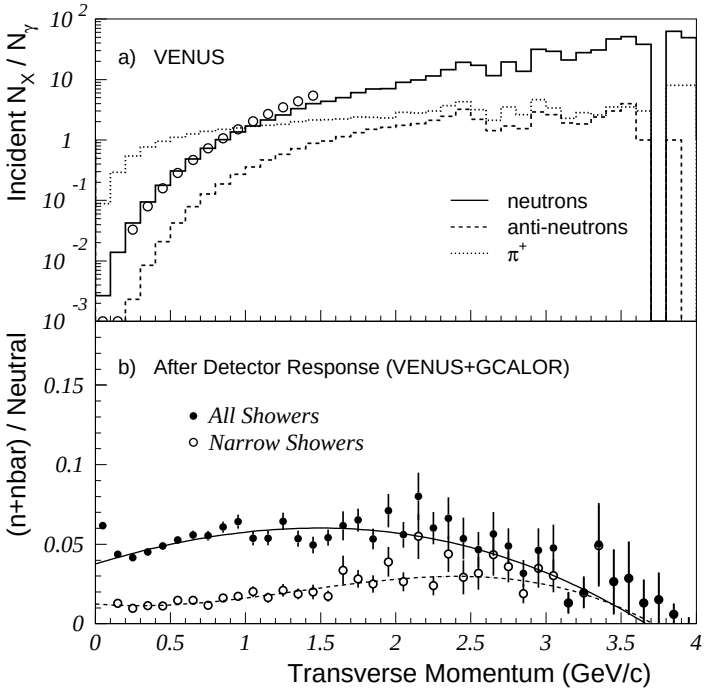

FIG. 13. In part a) the ratio of neutrons (solid line), anti-neutrons (dashed line), and π^+ (dotted line) to photons into the LEDA acceptance is shown as a function of the transverse momentum. The results are predictions of the VENUS 4.12 event generator for central 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The open points are described in the text. In part b) the ratio of neutrons plus anti-neutrons to neutral $(n + \overline{n} + \gamma)$ is shown after the effects of the lead-glass detector response calculated with GEANT. Results are shown after application of shower identification criteria of using all showers (solid circles) or narrow showers (open circles). The curves are fit results.

The $(n + \overline{n})$/neutral ratio is fitted (as shown in Fig. 13b)) and the uncorrected neutral spectra (see Fig. 12) are then corrected by the factor γ/neutral$= 1 - (n + \overline{n})/(n + \overline{n} + \gamma))$ to obtain the raw photon spectrum. The anti-neutrons comprise about one third of the total neutral correction. The result is the raw inclusive photon spectra which must then be corrected for the photon reconstruction efficiency and acceptance.

3. Reconstruction Efficiency

As described in Sec. III C, the photon reconstruction efficiency is extracted by the method of inserting GEANT photon test showers into real events and determining how the test showers are modified or lost. The efficiency is extracted as the ratio of the transverse momentum spectrum of found photons divided by the transverse spectrum of input photons. The input photon and its associated found photon are weighted such that the input distribution reproduces the measured transverse momentum distribution for each event class. The input weights are taken according to the raw photon distribution (see Fig. 12) for the initial efficiency result and the weights and resulting efficiency are iterated until the input distribution agrees with the final result.

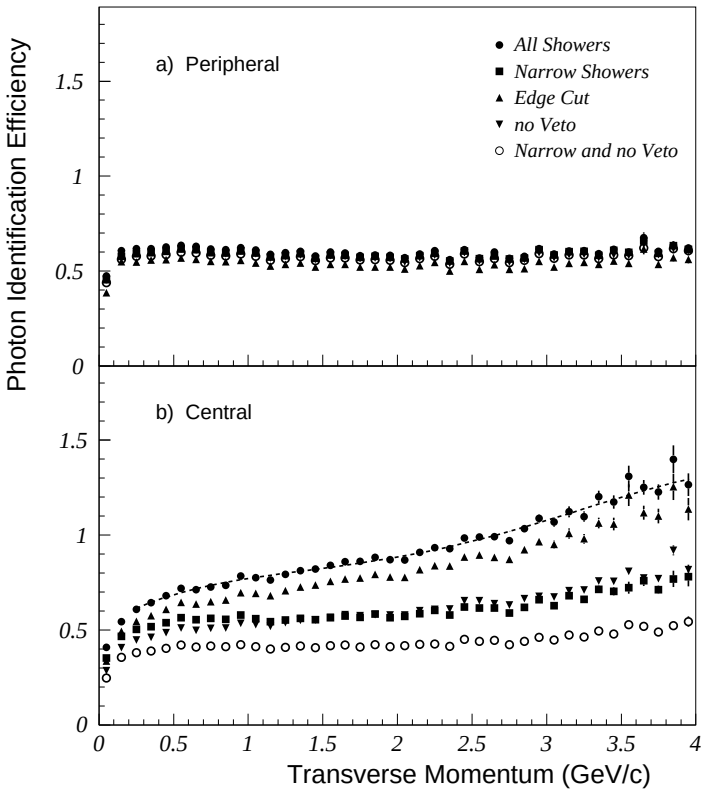

FIG. 14. The photon identification efficiency including effects of resolution, shower overlap, and excluded lead-glass modules as a function of transverse momentum for a) peripheral and b) central 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The efficiencies are shown for several shower identification methods using the 1996 magnetic field on data. The efficiency is shown for the following criteria: all showers (solid circles), showers satisfying a dispersion cut (solid squares), all showers within a further restricted acceptance (solid triangles), all showers with no associated hit in the CPV (inverted solid triangles), and all showers satisfying a dispersion cut with no associated hit in the CPV (open circles). An example of the fitted parameterization of the efficiency is shown by the dashed curve in part b) for the criterion of using all showers.

The final photon identification efficiency results are shown in Fig. 14 for peripheral and central collisions in parts a) and b), respectively. The results are shown for the various photon idenification criteria (see Sec. III B): All showers (S1); Narrow showers surviving a shower dispersion cut (S2); All showers within an increased edge cut (detector edge dead region increased from 2 modules to 3 modules); All showers with no associated CPV hit (S3); and Narrow showers with no associated CPV hit (S4). As previously discussed, what is called identification efficiency should more properly be called a response correction. It includes acceptance losses resulting from the fiducial cuts to define the useable detector region as well as dead or bad modules eliminated from the analysis. The acceptance is calculated for the full geometrical area of the lead-glass detector while the identification efficiency corrects for modules removed from the acceptance in the analysis. The efficiency correction also includes resolution corrections which can increase the apparent efficiency to values greater than one.

For peripheral reactions it is seen that the photon identification efficiency is only about 60% independent of transverse momentum. This reflects the loss of acceptance due to such eliminated modules. The efficiency is seen to be slightly smaller with the increased edge cut reflecting the decreased fiducial region. Otherwise, the photon efficiency is nearly independent of the identification method for peripheral collisions. This indicates that few photons are lost by these identification criteria or by shower overlap effects.

In contrast, for central collisions a large difference in photon identification efficiency is obtained for the different identification criteria. For the case of using all recovered showers the efficiency is seen to rise strongly with transverse momentum. This is understood as a result of the increase in the shower energy, and hence its transverse momentum,

as a result of absorbing the energy of underlying showers which have been overlapped. Due to the steeply exponential transverse momentum distribution of the photons (see Fig. 12) there is a large feeddown of showers from low p_T to high p_T when the shower energy is increased due to overlap. When the shower dispersion cut is applied this rise in the efficiency is dramatically reduced, indicating that many overlapping showers are eliminated because they are found to be too broad to be single photons (recall that the clustering algorithm separates obvious shower overlap clusters with multiple maxima into multiple clusters with single maxima). The photon identification efficiency is reduced further when it is required that there be no associated hit in the CPV detector. This reduction is due to the elimination of photon showers which overlap with charged hadrons which would otherwise appear as a single photon shower. As discussed previously (see Secs. III B and IV B), all photon identification methods use the CPV information to eliminate the charged hadron contamination. The difference between methods S1, S2 and methods S3, S4 is mostly a matter of procedure. In methods S3 and S4 in which the CPV is used directly to reject charged showers no charged hadron correction of the photon candidate spectrum is necessary. On the other hand, as seen in Fig. 14 the photon losses due to random overlap with charged hits are greater, resulting in a reduced photon identification efficiency.

The photon identification efficiencies are fitted (see Fig. 14) to remove fluctuations[3] and the fitted efficiency corrections are applied to the raw photon spectra to obtain the final photon transverse momentum distributions which need only be corrected for the LEDA acceptance. The identification efficiencies obtained by iteration were compared to efficiencies obtained by the two-dimensional unfolding method III C . The systematical error on the photon identification efficiency is estimated to be 2%.

4. Systematical error

The systematical errors relevant for the direct photon analysis which contribute solely to the extraction of the inclusive photon yield are listed in Table III at two representative transverse momenta. The errors are estimated for the case of photons identified with the narrow shower criterion (S2). The 30% uncertainty in the charged/neutral measurement discussed in regard to Figs. 10 and 11 leads to the listed p_T dependent uncertainty in the photon yield due to the charged particle background correction. Based on a comparison of the magnetic field on and field off results, and a comparison with and without the CPV requirement, a 0.5% uncertainty on the photon conversion probability has been assumed. The assumed 50% uncertainty on the neutron and anti-neutron contribution discussed in regard to Fig. 13 results in the listed p_T dependent uncertainty in the photon yield. Finally a 2.0% uncertainty in the photon identification efficiency has been assumed. The systematical errors are added in quadrature to give the total systematical error on the photon yield measurement listed in Table III. Other sources of systematical error, such as the energy calibration and non-target backgrounds, which also affect the π^0 yield extraction will be discussed in Sec V D.

The total systematical error on the photon yield measurement can be investigated by comparison of the inclusive photon results obtained with the different photon identification criteria. In particular, it was shown above that the charged and neutron backgrounds are reduced by about a factor of two when the shower dispersion cut is applied. Also, the photon identification efficiencies are observed to vary by a factor of 2-3 for central collisions depending on the identification criterion (see Fig. 14). The results of such a comparison are shown in Fig. 15 for peripheral and central collisions where the photon transverse momentum spectra obtained with the various photon identification criteria are divided by the photon spectrum obtained using the criterion of all showers. Since the corrections are largest for the condition of using all showers, it is the method expected to have the largest systematical error, with errors which should be larger than those which have been estimated for the narrow shower condition. The p_T dependent upper and lower systematical errors on the photon yield measurement are indicated by the horizontal lines. In general, to the extent allowed by the statistical uncertainties, one may conclude that the various results are consistent within the systematical error estimates.

[3]Note: The fluctuations for different identification methods are correlated since the efficiencies are extracted from the same simulated shower sample for all methods

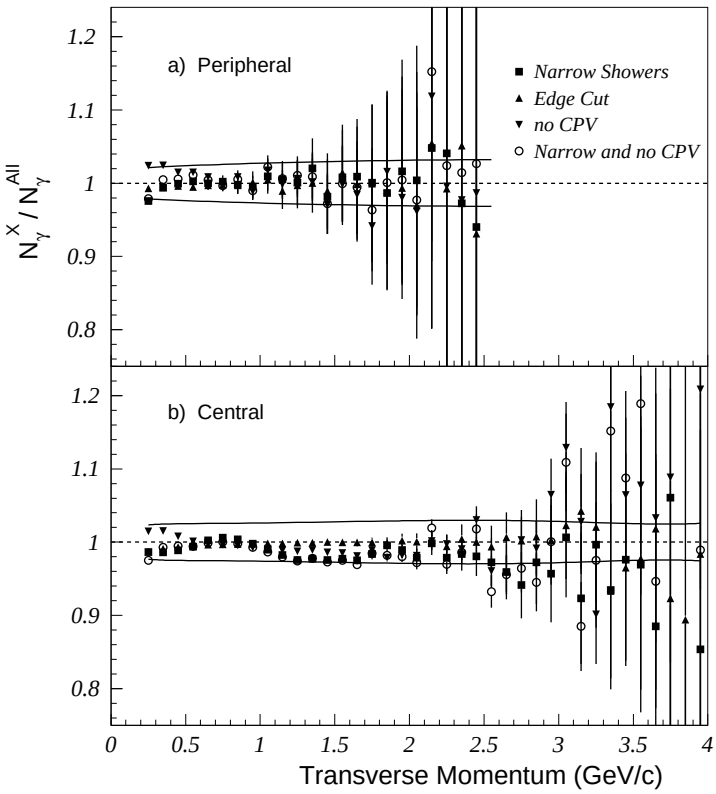

FIG. 15. The ratio of the efficiency-corrected inclusive photon yield for various methods compared to the method of using all showers (N_γ^{All}) is shown as a function of transverse momentum. The results are shown for a) peripheral and b) central 158 *A* GeV ^{208}Pb+^{208}Pb collisions for the 1996 magnet on data set. The error bars indicate statistical errors only. The deviation from unity, beyond statistical error, is indicative of the systematical error attributed to the photon identification method. The horizontal lines indicate the estimated systematical error on the photon yield determination.

D. π^0 Analysis

The method to extract the π^0 transverse momentum spectra is described in Sec. III B. In summary, the procedure is to calculate the two-gamma invariant mass spectrum for each p_T bin and extract the yield in the π^0 peak. This is done using the various photon identification criteria and run conditions and the final results are checked for consistency. While charged hadron and neutron contamination in the selected photon showers will not directly contribute to the π^0 peak and yield, they will contribute excess photon pairs in the combinatorial background which must be subtracted to obtain the yield in the peak. The large combinatorial background in the $m_{\gamma\gamma}$ invariant mass distribution, especially for central collisions, poses a special difficulty for the π^0 analysis. After the raw π^0 yield is extracted it is corrected for the π^0 identification efficiency, and finally for the lead-glass detector acceptance. The details of this procedure are described in this section.

1. π^0 Yield Extraction

The two-photon invariant mass distributions for peripheral ^{208}Pb+^{208}Pb collisions are shown in part a) of Figs. 16 and 17 for photon pair transverse momenta in the range of $0.5 < p_T < 0.6$ GeV/c and $1.5 < p_T < 1.6$ GeV/c, respectively. The distributions are obtained using all showers which pass the 750 MeV energy threshold. While it is evident that the π^0 peak content can easily be extracted at high p_T, it is seen that the peak sits on top of a rather large and broad background with a complicated shape for the case of low pair p_T. This combinatorial background arises

as a result of "random" combinations of photons within the detector acceptance where the pair of photons did not originate from the same radiative decay (e.g. different π^0's) and hence the two photons have little or no correlation. Although correlations between the photon pairs could exist, such as from a residual $\pi^0\pi^0$ Bose-Einstein correlation, or from a multi-π^0 decay final state, or from collective flow, it is expected that the shape of the photon pair combinatorial background depends mainly on the photon spectrum and on the detector acceptance. To accurately determine its shape without resort to a complicated fit procedure, an event-mixing technique has been used in which all photons of an event are paired with all photons of the next analyzed event within the same centrality selection. This procedure removes all resonance pair correlations but leaves some of the higher order correlations which might also exist in the real-pair background distribution. No attempt was made to impose cuts on the mixed event shower pairs to implement the effect of merging showers. This has the result that the mixed events are not expected to accurately reproduce the very low mass region of the real event mass spectra.

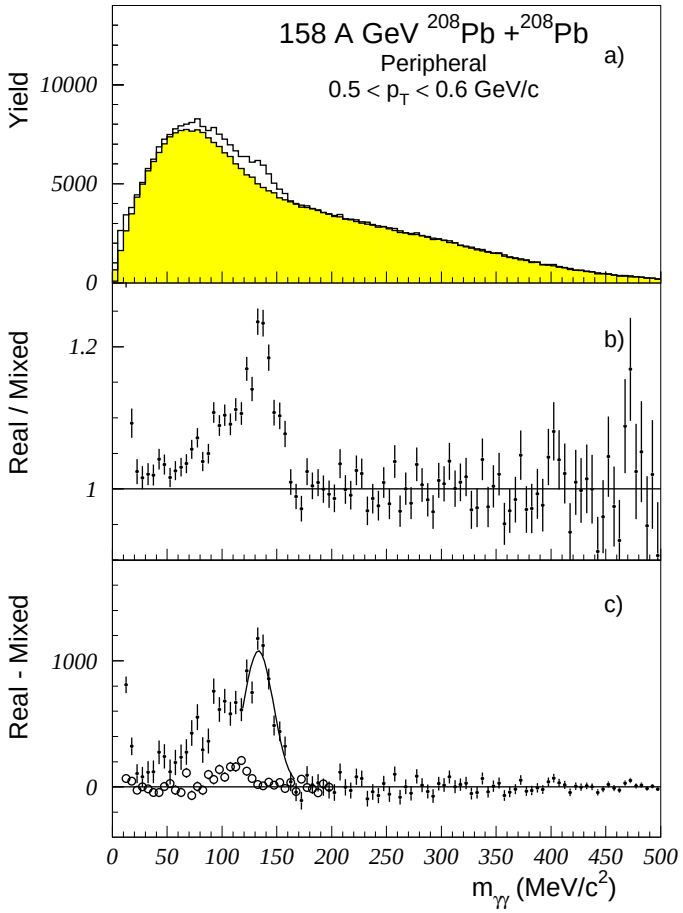

FIG. 16. The two-photon invariant mass distribution for peripheral events in the π^0 mass region with pair transverse momentum $0.5 < p_T < 0.6$ GeV/c. Results are shown for the 1996 magnet on data sample. Part a) shows the invariant mass distribution for all shower pairs for real events (solid histogram) and mixed events (filled histogram). Part b) shows the ratio of real and mixed event mass distributions. Part c) shows the real invariant mass distribution after subtracting the normalized mixed event distribution. The normalized target out background contribution is shown by the open circles in part c).

The mixed event $m_{\gamma\gamma}$ invariant mass distributions are shown as the shaded histograms in part a) of Figs. 16 and 17. The ratios of the real to mixed invariant mass distributions are shown in part b). The ratios have been normalized to unity in the region outside of the π^0 mass interval. For peripheral collisions the normalization has been calculated as the ratio of integrated yields in the mass intervals $50 - 60$ and $200 - 430$ MeV/c^2. The normalization extracted in

this way was then fit to a smooth function of p_T to determine the final mixed event background normalization. The normalized background subtracted results are shown in part c). The mixed event distribution is seen to provide a good description of the combinatorial background outside the π^0 mass region. However, a low-mass tail on the π^0 peak is observed at the lowest p_T (see Fig. 16c). Such a tail can result from π^0's produced downstream from the target, such as from K^0_S decays (see Sec. III D) or from background interactions on downstream materials. This will be further discussed below.

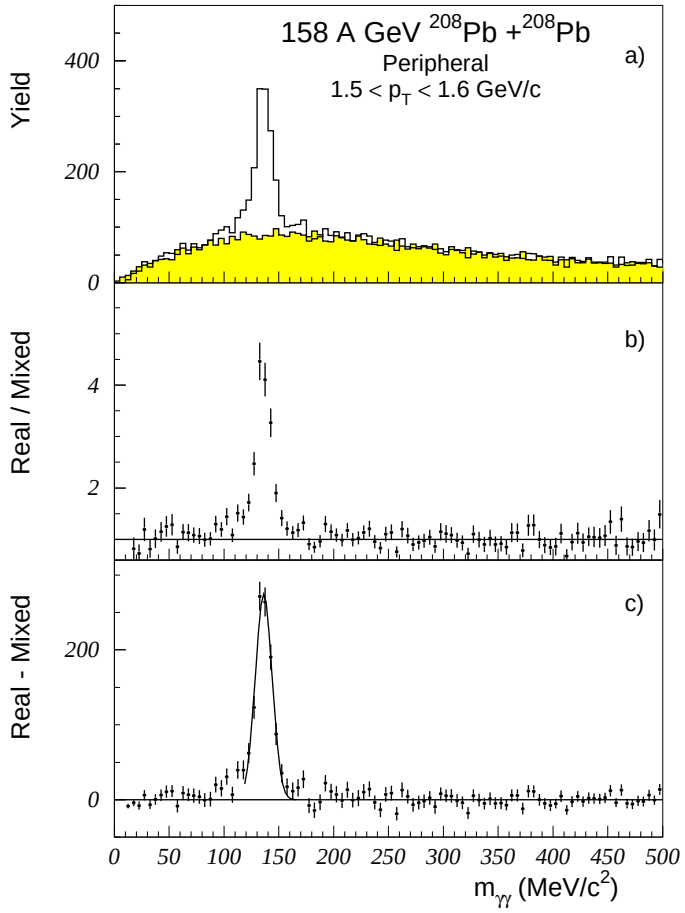

FIG. 17. The two-photon invariant mass distribution for peripheral events in the π^0 mass region with pair transverse momentum $1.5 < p_T < 1.6$ GeV/c. Results are shown for the 1995 magnet on data sample. Part a) shows the invariant mass distribution for all shower pairs for real events (solid histogram) and mixed events (filled histogram). Part b) shows the ratio of real and mixed event mass distributions. Part c) shows the real invariant mass distribution after subtracting the normalized mixed event distribution.

The $m_{\gamma\gamma}$ invariant mass distributions for central ^{208}Pb+^{208}Pb collisions are shown in part a) of Figs. 18 and 19 for photon pair transverse momenta in the range of $0.5 < p_T < 0.6$ GeV/c and $1.5 < p_T < 1.6$ GeV/c, respectively. Due to the much higher photon multiplicity in central events (see Fig.5) the combinatorial backgrounds are much greater. As a result it is seen that the π^0 peak is hardly visible at low p_T. In the same way as for peripheral events, the combinatorial background has been calculated using mixed events and normalized to the real event invariant mass distribution using the mass intervals $70 - 95$ and $220 - 430$ MeV/c^2 with the normalizations fitted to a smooth p_T dependence. The real/mixed event invariant mass distribution ratios are shown in part b) and the final normalized background subtracted invariant mass distributions are shown in part c). As for the case of peripheral collisions, the event mixed background is seen to provide a good reproduction of the combinatorial background in the region around the π^0 peak.

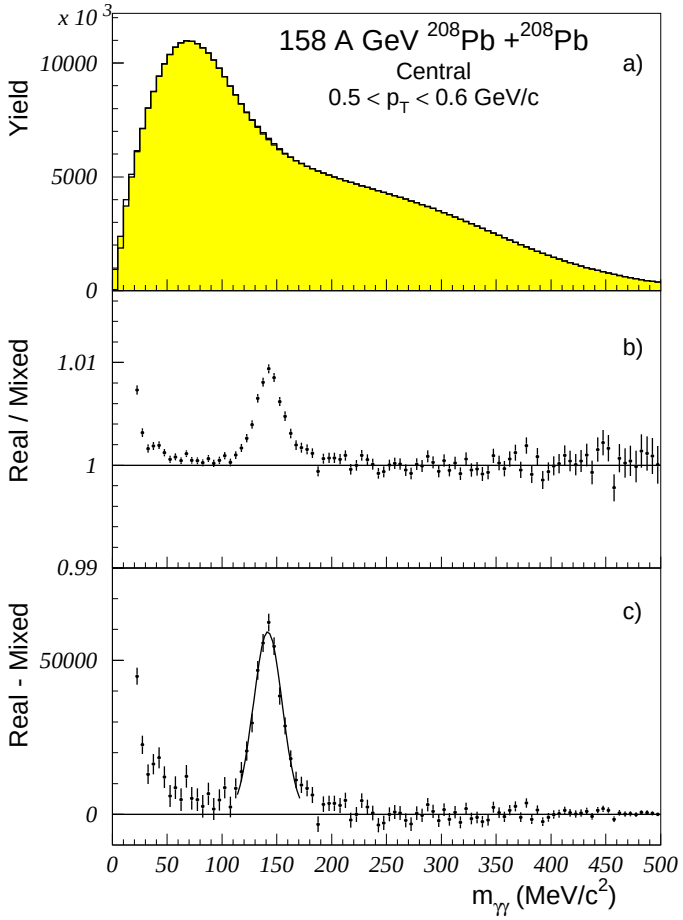

FIG. 18. The two-photon invariant mass distribution for central events in the π^0 mass region with pair transverse momentum $0.5 < p_T < 0.6$ GeV/c. Results are shown for the 1995 magnet on data sample. Part a) shows the invariant mass distribution for all shower pairs for real events (solid histogram) and mixed events (filled histogram). Part b) shows the ratio of real and mixed event mass distributions. Part c) shows the real invariant mass distribution after subtracting the normalized mixed event distribution.

Several features of the results for central collisions are notable in comparison to the results for peripheral collisions. First, it is observed that the π^0 peak is broader and shifted to higher mass as compared to the case for peripheral collisions. This is due to the effects of shower overlap and the modification of the energy and position of the original shower. Secondly, the π^0 peak is seen to exhibit a long non-gaussian tail to high mass which is also attributed to shower overlap effects. And finally, the low mass tail on the π^0 peak at low p_T is not present. The mixed event invariant mass normalization regions were chosen differently for central collisions due to these last two observations. In addition, the invariant mass distribution is observed to show structure in the very low mass region below about 50 MeV/c^2. This structure is attributed to several effects, such as splitting of overlapping showers and the above-mentioned details of the treatment of the mixed events for nearby showers. It does not affect the analysis presented here and will not be discussed further.

The π^0 transverse momentum spectra are obtained by integration of the yield in the π^0 peak region of the combinatorial background subtracted $m_{\gamma\gamma}$ invariant mass distributions for each p_T bin. The integration regions used were $110 < m_{\gamma\gamma} < 170$ MeV/c^2 for peripheral collisions and $110 < m_{\gamma\gamma} < 200$ MeV/c^2 for central collisions. The wider integration region used for central collisions is due to the previously discussed high mass tail on the π^0 peak which results from overlap effects. The uncorrected transverse momentum distributions are shown in Fig. 20 for peripheral and central collisions. The results are obtained using the full 1995 and 1996 magnet on data sample with the narrow shower identification criterion (S2) (see Sec. III B). The distributions are observed to extend over about four orders of

magnitude with similar p_T coverage but lower statistical accuracy as compared to the inclusive photon result shown in Fig. 12. The distributions are observed to be cut off at low p_T at around 0.5 GeV/c due to the acceptance limit (see Fig. 2) imposed by the 750 MeV shower energy threshold.

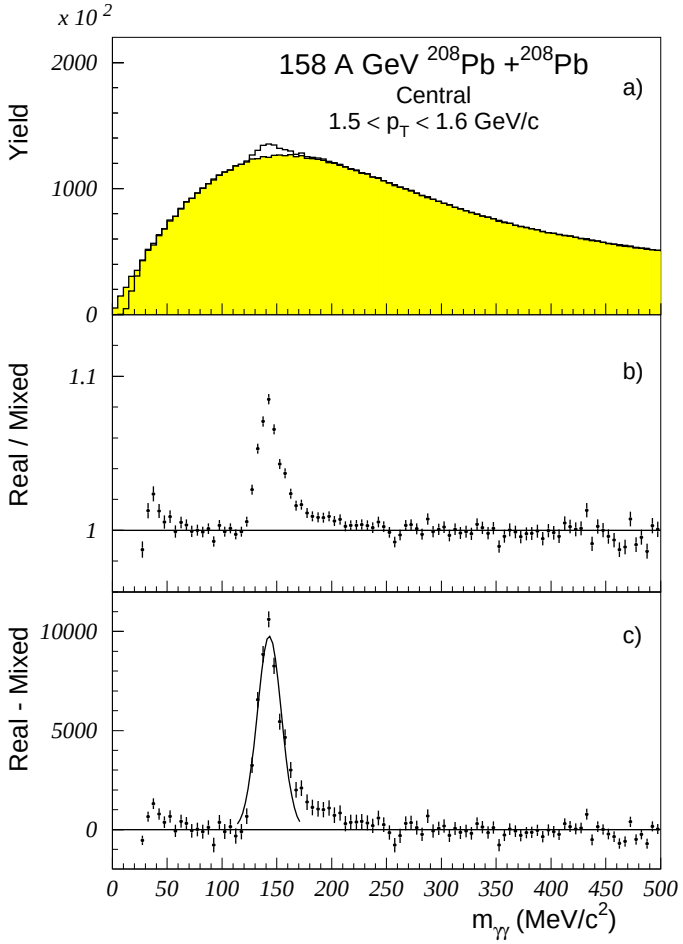

FIG. 19. The two-photon invariant mass distribution for central events in the π^0 mass region with pair transverse momentum $1.5 < p_T < 1.6$ GeV/c. Results are shown for the 1995 magnet on data sample. Part a) shows the invariant mass distribution for all shower pairs for real events (solid histogram) and mixed events (filled histogram). Part b) shows the ratio of real and mixed event mass distributions. Part c) shows the real invariant mass distribution after subtracting the normalized mixed event distribution.

As noted in the discussion of the inclusive photon result, no empty target events satisfy the central collision trigger requirement with the result that no background corrections to the photon and π^0 spectra are necessary for central collisions. On the other hand, as discussed with regard to Fig. 16, the $m_{\gamma\gamma}$ invariant mass distributions for low p_T peripheral events show a low mass tail which suggests a contribution of π^0's produced downstream of the target location. In principal, this can be verified by comparison to the $m_{\gamma\gamma}$ distribution obtained for runs taken with no target. However, when the empty target events are analyzed with the trigger requirement of a hit in the forward region of the Plastic Ball detector to eliminate downstream interactions, as used for analysis of the peripheral events, no significant peak is observed in the empty target $m_{\gamma\gamma}$ distribution. On the other hand, when the Plastic Ball hit condition is removed, a small low mass peak is observed in the empty target $m_{\gamma\gamma}$ distribution, as shown by the open symbols in Fig. 16c. With the same Plastic Ball condition as used for the Pb target the empty target contribution is reduced by a factor of more than five (see the discussion of Fig. 12). Even with the Plastic Ball condition removed, the empty target yield, appropriately normalized according to the relative number of live beam triggers, is about a factor of three lower than the observed low mass yield with the Pb target.

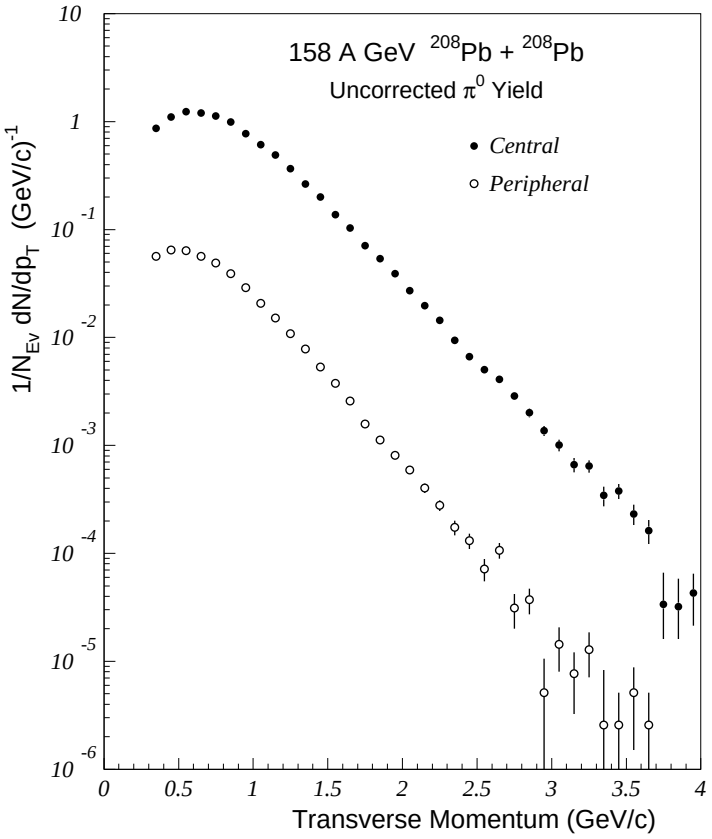

FIG. 20. The uncorrected π^0 multiplicity as a function of the transverse momentum for peripheral (open circles) and central (solid circles) 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The results are for the full magnet on data sample. Narrow showers with energy above 750 MeV have been used in the invariant mass calculation. The data have not been corrected for efficiency or acceptance. These spectra are used as the first iteration in the iterative efficiency correction.

The results shown in Fig. 16 are for the 1996 magnet on data sample. A slightly larger low mass contribution with a more distinctive peak at around $m_{\gamma\gamma} \approx 100$ MeV/c^2 is observed for the 1995 data sample. As for the 1996 data, there is no such contribution seen for central collisions or for high p_T peripheral collisions (the 1995 results are shown in Figs.17,18,19). The additional 1995 low mass contribution is attributed to downstream interactions on an aluminum ring on the vacuum exit window which was removed for the 1996 run period (see Sec. II A). For the 1995 run period the Plastic Ball hit requirement was implemented directly in the online trigger. With this condition, as for the 1996 run, no significant low mass contribution was observed in the 1995 empty target data. The explanation for these observations is that the Plastic Ball condition was in fact effective to remove downstream interactions when there was no target in place. However, when the target was in place, δ-electrons produced in the target could be detected in the Plastic Ball and satisfy the Plastic Ball trigger requirement. This meant that more downstream interactions could be accepted with target in place than without target. Nevertheless, even with the Plastic Ball trigger requirement removed, the empty target result is about a factor of three below the observed low mass excess, as noted above. This observation is not understood.

For the direct photon analysis the effect of the empty target contribution has been studied under two extreme assumptions. In the first case it has been ignored completely, while in the second case the result without the Plastic Ball condition has been renormalized to be as large as possible consistent with the result for the Pb target. That is, the empty target result was increased to remove as much as possible of the low mass excess in the $m_{\gamma\gamma}$ distribution at low p_T. While these two assumptions will give different photon and π^0 p_T distributions, it might be expected that the direct photon result is not too dependent on this assumption as long as both the photon and π^0 yields from all sources are taken into account consistently. Finally, we emphasize again that this non-target background uncertainty is only relevant for the low p_T (below ~ 1 GeV/c) peripheral data sample.

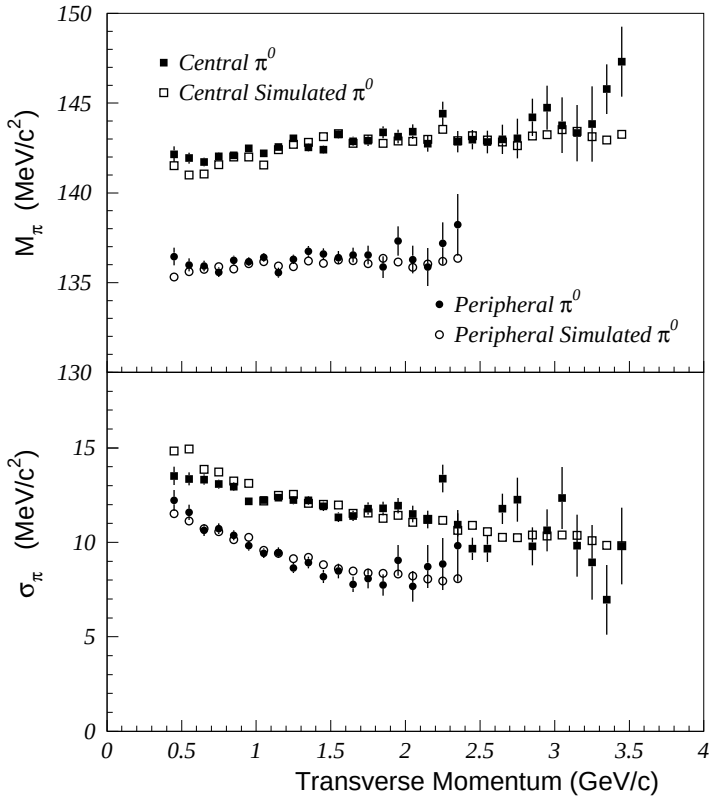

FIG. 21. The π^0 mass peak position and width, σ, resulting from a gaussian fit to the two-photon invariant mass distribution is shown as a function of the transverse momentum in the upper and lower portions of the figure, respectively. The solid symbols show results for real π^0's while the open points show the results for simulated π^0's superimposed on real events. Results are shown for peripheral (circles) and central (squares) 158 *A* GeV ^{208}Pb+^{208}Pb collisions using all shower candidates. The same fit region is used for the real and simulated data.

2. π^0 Reconstruction Efficiency

The procedure to determine the π^0 reconstruction efficiency is similar to the one for photons described in Sec. IV C 3. As described in Sec. III C, the π^0 reconstruction efficiency is extracted by inserting test π^0's into real events and determining how the test π^0's are modified or lost. The test π^0's were initially generated uniformly in transverse momentum and pseudo-rapidity. Only those π^0's which decayed to give two photons within the nominal LEDA acceptance were recorded and those photons were tracked with GEANT. The efficiency is extracted as the ratio of the transverse momentum spectrum of found π^0's divided by the transverse momentum spectrum of input π^0's. The input π^0 and its associated found π^0 are weighted such that the input distribution reproduces the measured transverse momentum distribution for each event class. The initial input weights are taken according to the raw π^0 distribution (see Fig. 20) after application of the acceptance correction and an initial estimated efficiency correction. The weights and resulting efficiency are iterated until the weighted input distribution agrees with the final result. The input π^0 distribution is weighted according to a Gaussian rapidity distribution centered on mid-rapidty with an rms width of $\sigma_y = 1.3$ [92], consistent with the final result.

After being superimposed onto real events the simulated π^0's are considered to be found if both photons are recovered and the reconstructed invariant mass of the photon pair falls within the same π^0 mass window as applied in the analysis of the real events (see Sec. IV D 1). For an accurate efficiency determination it is essential that the simulated photon showers have the same characteristics as the measured photon showers. This can be verified by comparison of the extracted π^0 mass peak for real events with that of the simulated π^0's after superposition onto real events. Such a comparison is shown in Fig. 21. The fitted mass and width of the π^0 peak are shown as a function of transverse

momentum for central and peripheral event selections for the case of using all shower candidates (S1) for the invariant mass calculation. As noted in the discussion of the invariant mass spectra, the mass and width of the π^0 peaks are observed to be significantly larger for central collisions in comparison to peripheral collisions due to the effects of shower overlap. With the narrow shower condition (S2), the π^0 peak position is about 3 MeV/c^2 lower and the π^0 peak width is about 1.5 MeV/c^2 smaller for central conditions compared to the results shown in Fig. 21. The characteristics of the reconstructed simulated π^0's are seen to be in good agreement with those of the real π^0's for both peripheral and central event selections. This indicates that the energy calibration and resolution, and their modification due to detector occupancy effects, are accurately reproduced in the simulation and therefore are properly taken into account in the efficiency determination.

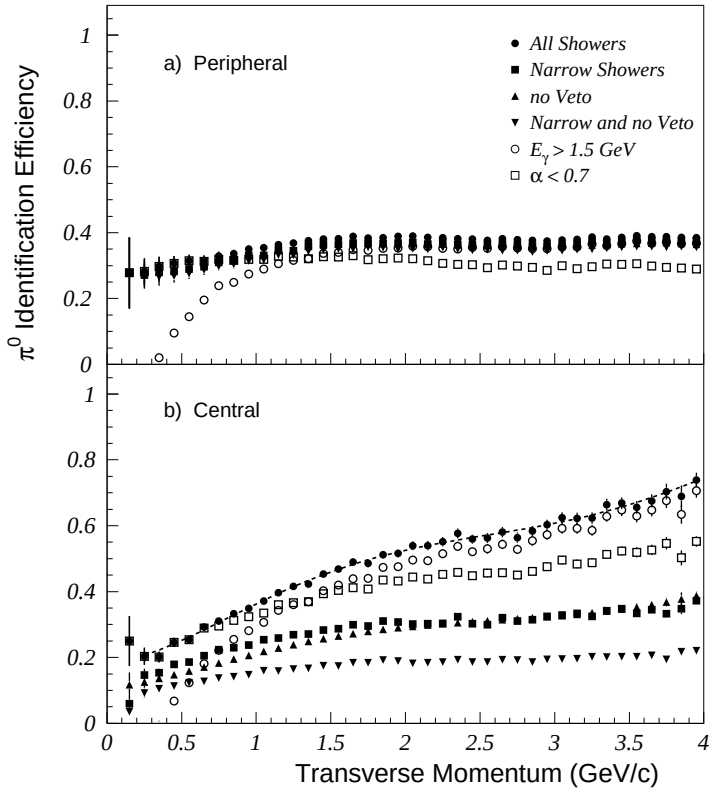

FIG. 22. The π^0 identification efficiency including effects of resolution, shower overlap, and excluded lead-glass modules. The π^0 identification efficiency is shown as a function of transverse momentum for a) peripheral and b) central 158 *A* GeV ^{208}Pb+^{208}Pb collisions. A 750 MeV shower energy threshold has been applied. The efficiency is shown for the 1996 magnet on data for the following criteria: all showers (solid circles), showers satisfying a dispersion cut (solid squares), all showers with no associated hit in the CPV (solid triangles), all showers satisfying a dispersion cut with no associated hit in the CPV (inverted solid triangles), all showers but with shower energy threshold increased to 1.5 GeV/c (open circles), and all showers with the requirement that the shower-pair energy asymmetry is less than 0.7 (open squares). An example of the fitted parameterization of the efficiency is shown by the dashed curve in part b) for the criterion of using all showers.

The final π^0 identification efficiencies are shown in Fig. 22 for peripheral and central collisions in parts a) and b), respectively. The results are shown for the various photon identification criteria (see Sec. III B): all showers (S1); narrow showers surviving a shower dispersion cut (S2); all showers with no associated CPV hit (S3); and narrow showers with no associated CPV hit (S4); all showers but with the photon energy threshold increased from 750 MeV to 1.5 GeV; shower pairs which satisfy an energy asymmetry cut $\alpha = |E_1 - E_2|/|E_1 + E_2| < 0.7$. As previously mentioned, what is called the identification efficiency should more properly be called a response correction. It includes acceptance losses resulting from the fiducial cuts to define the useable detector region as well as dead or

bad modules eliminated from the analysis. The acceptance is calculated for the full geometrical area of the LEDA while the identification efficiency corrects for modules removed from the acceptance in the analysis.

For peripheral reactions it is seen that the π^0 identification efficiency is only about 30%, nearly independent of transverse momentum, which reflects the loss of acceptance due to eliminated modules. With the 1.5 GeV shower energy threshold the efficiency is seen to drop sharply at low transverse momentum due to the loss of acceptance which results from the higher energy threshold. Similarly, the shower energy asymmetry cut results in a loss of π^0 acceptance, and hence a decreased efficiency, at large transverse momenta. Otherwise, the π^0 efficiency is nearly independent of the identification method for peripheral collisions. Again, this indicates that few photons are lost by these identification criteria or by shower overlap effects.

Similar to the photon identification efficiency, the π^0 efficiency dependence is quite different for the case of central collisions. A large difference in the π^0 identification efficiency is obtained for the different identification criteria. For the case of using all recovered showers the efficiency is seen to rise strongly with transverse momentum, exceeding the efficiency for peripheral collisions. This is understood as a shower overlap effect which results in an increase in the shower energy, and hence transverse momentum, as a result of absorbing the energy of underlying showers which get overlapped. Due to the steeply exponential transverse momentum distribution of the π^0's (see Fig. 20) there is a large feeddown of the π^0 yield from low p_T to high p_T when the shower energy is increased due to overlap. When the shower dispersion cut is applied this rise in the efficiency is dramatically reduced, and becomes more similar to the result for peripheral collisions. This indicates that many overlapping showers are eliminated because they are found to be too broad to be single photons. The π^0 identification efficiency is reduced further when it is required that there be no associated hit in the CPV detector (methods S3 and S4). This reduction is due to conversions and the elimination of photon showers which overlap with charged hadrons which would otherwise appear as a single photon shower.

The π^0 identification efficiencies are fitted (see Fig. 22) to remove fluctuations[4] and the fitted efficiency corrections are applied to the raw π^0 spectra to obtain the final π^0 transverse momentum distributions which need only be corrected for the LEDA acceptance. The systematical error on the π^0 identification efficiency is estimated to be 3% for peripheral collisions and 4% for central collisions.

3. Systematical error

The systematical errors relevant for the direct photon analysis which enter only for the inclusive π^0 yield extraction are listed in Table III at two representative transverse momenta. The errors are estimated for the case of photons identified with the narrow shower criterion (S2). Based on a comparison of the magnetic field on and field off results, and a comparison with and without the CPV requirement a 0.5% uncertainty in the π^0 yield due to photon conversions has been assumed. As mentioned above, the uncertainty in the π^0 identification efficiency has been assumed to be 3% and 4% for peripheral and central collisions, respectively. An important source of systematical error in the π^0 yield extraction at low p_T for central collisions is the error associated with the combinatorial background subtraction. The statistical error of the combinatorial background subtraction is included in the statistical error on the π^0 yield. An additional systematical error of 10^{-3} of the background yield has been assumed. This error contribution is estimated from the variability of the results at low p_T for central collisions for the different analysis methods (see Fig. 23). Besides the small peak/background ratios at low p_T for central collisions, the curvature of the background under the π^0 peak may futher complicate the extraction of the π^0 yield and increase the error beyond expectations from the magnitude of the background. The systematical errors are added in quadrature to give the total systematical error on the π^0 yield extraction listed in Table III. Other sources of systematical error, such as the energy calibration and non-target backgrounds, which affect both the photon and π^0 yield extraction will be discussed below.

As for the photon yield determination, the total systematical error estimate on the π^0 yield extraction can be investigated by comparison of the inclusive π^0 results obtained with the different identification criteria. The results of such a comparison for peripheral and central collisions are shown in Fig. 23 where the π^0 transverse momentum spectra obtained with the various conditions are divided by the π^0 spectrum obtained using the criterion of all showers (S1). Since the π^0 identification efficiencies vary by a factor of 2-3 for central collisions depending on the identification criterion (see Fig. 22) this comparison provides a sensitive indication of the accuracy of the efficiency determination. Also, the uncertainty in the π^0 peak yield extraction is probed since, for example, the application of the shower dispersion cut reduces the non-photon shower contamination and therefore improves the π^0 peak/background ratio by nearly

[4]Note: The fluctuations for different identification methods are correlated since the efficiencies are extracted from the same simulated shower sample for all methods.

a factor of two, which reduces the necessary background correction. Since the corrections are largest for the condition of using all showers, it is the method expected to have the largest systematical error, with errors which should be larger than those which have been estimated for the narrow shower condition. The p_T dependent upper and lower systematical errors on the π^0 yield measurement are indicated by the horizontal lines. In general, to the extent allowed by the statistical uncertainties, one may conclude that the various results are consistent within the given systematical error estimates. The increasing systematical deviations at low transverse momentum for central collisions are due to the above-mentioned systematical error of the combinatorial background subtraction.

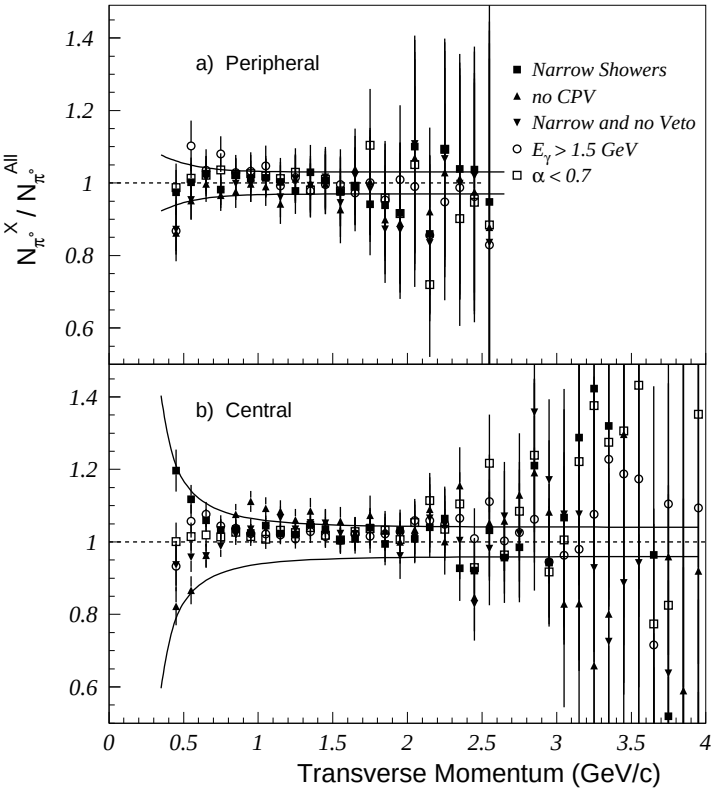

FIG. 23. The ratio of the efficiency-corrected π^0 yield for various shower identification methods compared to the method of using all showers is shown as a function of transverse momentum. The results are shown for a) peripheral and b) central 158 *A* GeV ^{208}Pb+^{208}Pb collisions for the 1996 data set. The error bars indicate statistical errors only. The horizontal lines indicate the estimated systematical errors. The deviation from unity, beyond statistical error, is indicative of the systematical error in the π^0 yield extraction.

E. η Analysis

The method to extract the η transverse momentum spectrum is similar to that used for the π^0 analysis described in Sec. III B and discussed in Sec. IV D. As for the π^0, the procedure is to calculate the $m_{\gamma\gamma}$ invariant mass spectrum for each p_T bin and extract the yield in the η peak. The extraction of the η yield is much more difficult due to the lower η production cross section and smaller branching ratio to two photons together with the very large combinatorial background in the $m_{\gamma\gamma}$ invariant mass distribution. An example of the two-photon invariant mass distributions for central ^{208}Pb+^{208}Pb collisions in the η mass region is shown in part a) of Fig. 24 for photon pair transverse momenta in the range of $1.0 < p_T < 1.2$ GeV/c. The distributions are obtained using all narrow showers which pass the 750 MeV energy threshold and include the full 1995 and 1996 magnet on data samples. The invariant mass distribution for real events is shown by the open histogram while the invariant mass distribution constructed with photons from mixed

events is shown by the shaded histogram. The difference in the two distributions is scarcely visible, even in the η peak region.

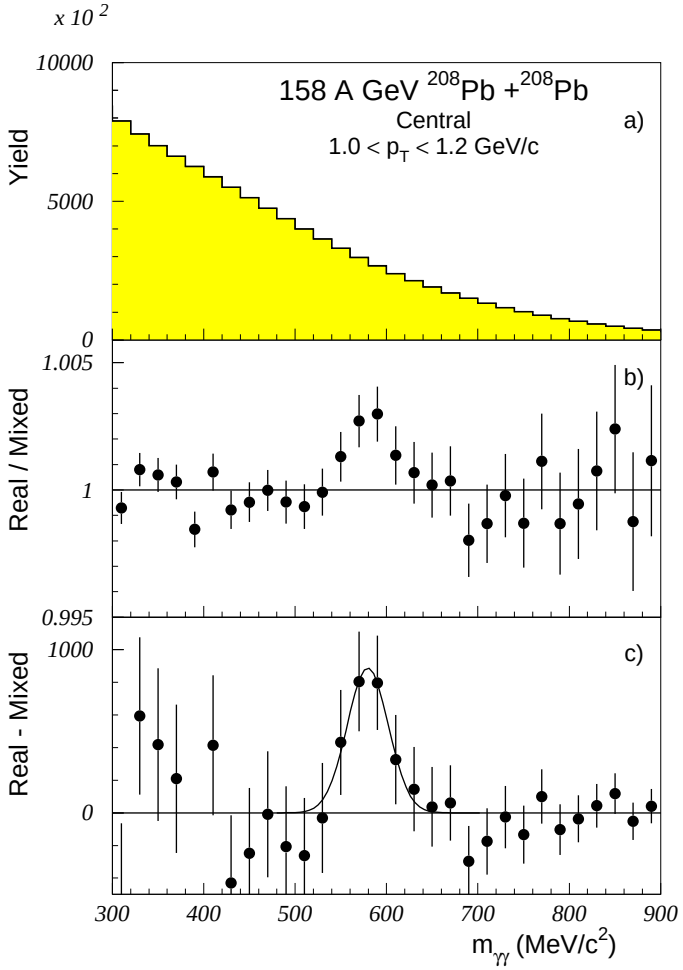

FIG. 24. The two-photon invariant mass distribution for central events in the η mass region with photon pair transverse momentum $1.0 < p_T < 1.2$ GeV/c. Part a) shows the invariant mass distribution for all shower pairs for real events (solid histogram) and mixed events (filled histogram). Part b) shows the ratio of real and mixed event mass distributions. Part c) shows the real invariant mass distribution after subtracting the normalized mixed event distribution.

The η peak yield is extracted in the same way as the π^0 yield extraction but with one additional step. To insure that the high mass tail of the π^0 peak does not affect the normalization of the background the π^0 content is first removed from the invariant mass distribution. This is done by extraction of the π^0 peak yield, as described in Sec. III B, and then subtraction of the corresponding invariant mass distribution of simulated π^0's after event overlap, normalized to the same π^0 yield, from the invariant mass distribution. This removes the π^0 peak and high mass tail from the invariant mass distribution of real photon pairs. The ratio of the π^0 subtracted real event to mixed event invariant mass distributions is shown in part b) of Fig. 24. The mixed event background normalization is given by fixing to unity the ratio of integrated yields in the mass interval $355 - 450$ and above 710 MeV/c^2. The normalized background subtracted invariant mass distribution is shown in part c). While the η peak is clearly seen to contain several thousand counts, the statistical significance of the peak is weak due the low signal to background ratio of less than 0.5%. The η peak is seen to be shifted to higher mass due to the effect of shower overlap in central collisions, similar to observation for the π^0 (see Fig. 21). The η yield is obtained by integration over the invariant mass region $500 - 640$ MeV/c^2.

The η and π^0 yields are extracted from the invariant mass distribution for each transverse momentum bin and are corrected for identification efficiency, acceptance, and the two-photon decay branching ratios. The ratio of corrected

yields, η/π^0, is shown as a function of transverse momentum in Fig. 25. While the statistical error at each point is large, due to the large combinatorial background for extraction of the η yield, there is a general tendency for a rise in the ratio with increasing p_T. This is the expected behavior if the η and π^0 yields have the same functional dependence on the transverse mass. The solid curve in Fig. 25 is the calculated ratio expected from the fit to the π^0 spectrum (see Fig. 26 and discussion below) assuming m_T-scaling. The absolute normalization is the m_T-scaling parameter which is fitted to the results of Fig. 25 to be $R_{\eta/\pi^0} = 0.486 \pm 0.077$(stat.)$\pm 0.097$(syst.). A 20% systematical error has been assumed on the absolute normalization of the η yield relative to the π^0 yield. This systematical error reflects the uncertainty due to the worse ratio of η yield to combinatorial background in the η region, and a less thorough investigation of the η efficiency corrections due to the limited statistics.

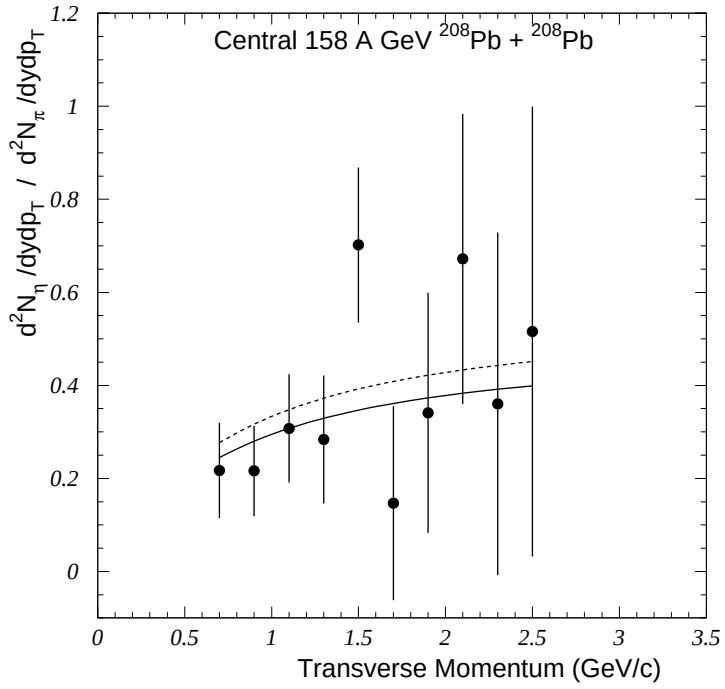

FIG. 25. The η/π^0 ratio as a function of transverse momentum for central 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The solid curve is the ratio expected for m_T-scaling of the fitted π^0 result of Fig. 26 with a fitted normalization $R_{\eta/\pi^0} = 0.486$. The dashed curve is the expected result with fixed normalization$R_{\eta/\pi^0} = 0.55$.

Within errors, the fitted R_{η/π^0} ratio is in agreement with previous results. A value of $R_{\eta/\pi^0} = 0.55 \pm 0.02$ has been obtained from a compilation of previous measurements [76,77] as discussed in Sec. III C and listed in Table I. The present η measurement excludes any large enhancement of the η yield in central Pb+Pb collisions as has been suggested might occur as a consequence of chiral symmetry restoration [82,83] (see discussion of Sec. III C). The result also indicates that the m_T-scaling assumption is valid, or at least not significantly distorted by collective flow effects, for the transverse momentum range of interest for the present direct photon analysis.

Finally, we note that due to the limited data sample and lower η multiplicity it was not possible to obtain a significant η measurement for the peripheral Pb+Pb event selection. Instead, m_T-scaling has been assumed as given by the measured peripheral π^0 result with a m_T-scaling parameter of $R_{\eta/\pi^0} = 0.55$.

V. RESULTS

In this section the final inclusive π^0 and inclusive photon results are presented. The inclusive π^0 measurement is used, together with the η result of the previous section, as input to a calculation of the expected inclusive photon distribution from radiative decays. The difference between the measured and calculated photon distributions is extracted as the direct photon excess. The measured excess is presented and discussed in comparison to other measurements and model calculations.

A. π^0 and η Production

The final inclusive π^0 transverse momentum spectra for central and peripheral 158 *A* GeV ^{208}Pb+^{208}Pb collisions are shown in Fig. 26. The results presented are the sum of the 1995 and 1996 data samples with magnet on. The details of the data selection have been discussed in Sec. IV A and the characteristics of the peripheral and central data samples are summarized in Table II. The distributions have been corrected for the π^0 identification efficiency and acceptance as described in Secs. III B and IV D. The indicated errors are the total statistical errors which include also the statistical errors introduced by the combinatorial background subtraction. The systematical errors on the π^0 yield extraction have been discussed in Sec. IV D 3 and will be summarized again in Sec. V D. It should be noted that the π^0 yield per event is given rather than the absolute π^0 cross section. For the direct photon analysis the measured photon multiplicity per event will be compared to the background multiplicity calculated from the measured π^0 yield per event for the same event sample. Therefore there are no systematical errors associated with the absolute cross section determination. Also, it is recalled that the definitions of the peripheral data samples were slightly different for the 1995 and 1996 runs so that the result presented is for an averaged peripheral class. The peripheral π^0 distribution has not been corrected for target-out background (see Sec. IV D).

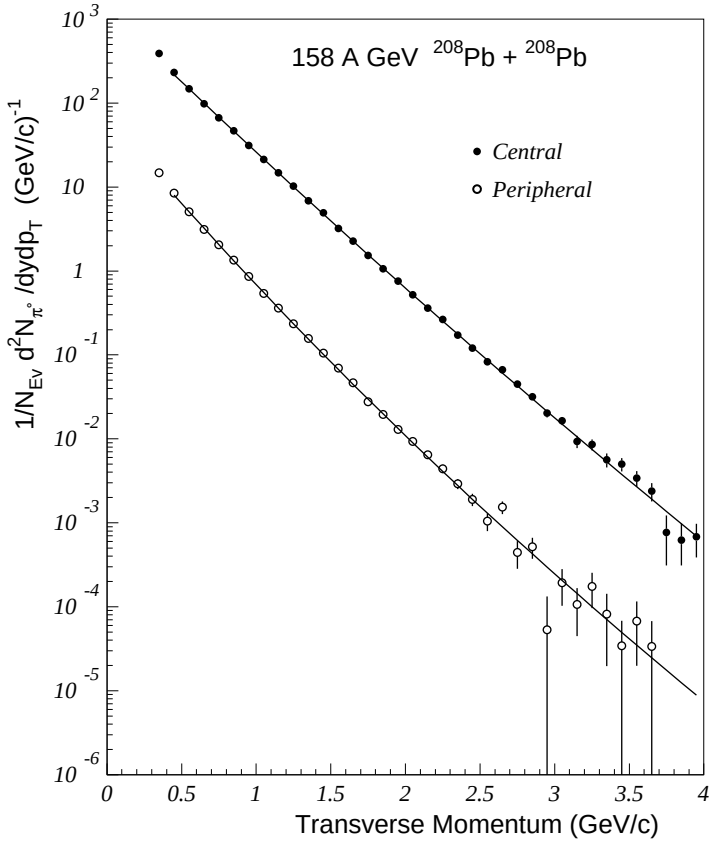

FIG. 26. The π^0 transverse momentum distribution for peripheral (open circles) and central (solid circles) 158 *A* GeV ^{208}Pb+^{208}Pb collisions for the sum of 1995 and 1996 magnet on data sets. The narrow shower photon identification criterion has been used. The data have been corrected for efficiency and acceptance. Only statistical errors are shown. The solid curves show the fit results described in the text.

The π^0 transverse mass distributions are observed to be nearly exponential over more than five orders of magnitude. On the other hand, the distributions exhibit a weak curvature which is best described by a power-law. The spectra have therefore been fitted with a QCD-inspired power-law functional form [98],

$$\frac{1}{N_{Event}}\frac{d^2N}{dydp_T} = C \cdot \left(\frac{p_0}{p_0 + p_T}\right)^n . \tag{5.1}$$

The fit region and fit results are shown by the solid curves in Fig. 26. The extracted fit parameter values are $C = 66.5 \pm 2.3, p_0 = 9.6 \pm 1.3$ GeV/c, and $n = 44.5 \pm 5.6$ with $\chi^2/33 = 1.25$ for peripheral collisions and $C = 1295 \pm 21, p_0 = 19.98 \pm 0.24$ GeV/c, and $n = 80.0 \pm 0.7$ with $\chi^2/36 = 1.06$ for central collisions.

For the power-law functional form of Eq. 5.1 the local inverse slope is calculated as

$$T = -\frac{f(p_T)}{\frac{\partial f(p_T)}{\partial p_T}} = \frac{p_0}{n} + \frac{p_T}{n}. \tag{5.2}$$

The ratio p_0/n characterizes the slope of the distribution as $p_T \rightarrow 0$, while $1/n$ characterizes the strength of the curvature. The above fit results give $p_0/n = 215.7$ and 249.8 MeV/c for peripheral and central collisions, respectively. The large fitted values of n confirm the nearly exponential spectral shapes.

More properly [98–100], the invariant π^0 yields per event can be fitted to the same functional form to provide a similarly good description.

$$\frac{1}{N_{Event}} E \frac{d^3N}{dp^3} = C' \cdot \left(\frac{p_0'}{p_0' + p_T} \right)^{n'}. \tag{5.3}$$

Fitting the invariant transverse momentum distributions in the region above 500 MeV/c gives fit parameters $C' = 46.7 \pm 2.1, p_0' = 3.64 \pm 0.06$ GeV/c, and $n' = 24.9 \pm 0.2$ with $\chi^2/32 = 1.41$ for peripheral collisions and $C' = 813. \pm 21., p_0' = 5.08 \pm 0.18$ GeV/c, and $n' = 29.3 \pm 0.8$ with $\chi^2/35 = 1.56$ for central collisions. This corresponds to $p_0'/n' = 146.0$ and 173.4 MeV/c for peripheral and central collisions, respectively. The fitted slope and curvature parameters are similar to those which have been extracted for the π^0 invariant cross sections for sulphur-induced reactions [100].

The fit results of Eq. 5.1 shown in Fig. 26 are the main experimental input to the calculation of the radiative decay background. In addition, the π^0 fit result for central collisions has been used to fit the η/π^0 ratio shown in Fig. 25 assuming m_T-scaling and to extract the m_T-scaling ratio $R_{\eta/\pi^0} = 0.486$ for central collisions, as discussed in Sec. IV E. The calculated inclusive photon distribution from radiative decays is compared to the measured inclusive photon distribution to extract the excess which may be attributed to direct photons.

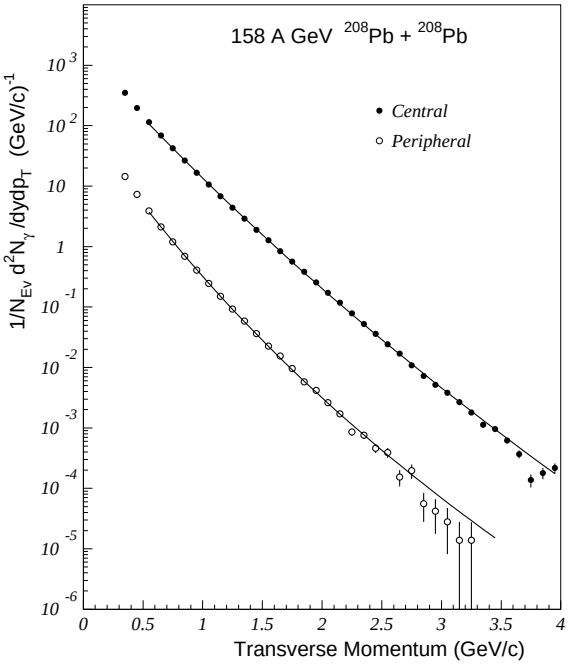

FIG. 27. The inclusive photon transverse momentum distribution for peripheral (open circles) and central (solid circles) 158 *A* GeV ^{208}Pb+^{208}Pb collisions for the sum of 1995 and 1996 magnet on data sets. The narrow shower photon identification criterion has been used. The data have been corrected for efficiency and acceptance. Only statistical errors are shown. The solid curves show the fit results described in the text.

B. Inclusive Photon Results

The final inclusive photon transverse momentum spectra for central and peripheral 158 *A* GeV ^{208}Pb+^{208}Pb collisions are shown in Fig. 27. The results presented are the sum of the 1995 and 1996 data samples with magnet on, which is exactly the same data sample as used for the final π^0 and η result. The details of the data selection have been discussed in Sec. IV A and the characteristics of the peripheral and central data samples are summarized in Table II. The distributions have been corrected for the photon identification efficiency and acceptance as described in Secs. III B and IV C. The indicated errors are statistical errors only. The systematical errors on the photon yield extraction have been discussed in Sec. IV C 4 and will be summarized again in Sec. V D. It is again noted that there are no systematical errors associated with the absolute cross section determination for the direct photon analysis. Also, it is again noted that the peripheral data sample definitions were slightly different for the 1995 and 1996 runs which means that the result represents an average peripheral class. The peripheral photon distribution has not been corrected for target-out background (see Sec. IV C 1).

Similar to the π^0 transverse mass distributions, the inclusive photon transverse momentum distributions are nearly exponential over more than six orders of magnitude. The inclusive photon distributions have been fitted with the power-law functional form of Eq. 5.1 with the fit region and results shown by the solid curves in Fig. 27. The extracted fit parameter values are $C = 115.9 \pm 3.3, p_0 = 3.2 \pm 0.4$ GeV/c, and $n = 21.8 \pm 5.6$ for peripheral collisions and $C = 1570 \pm 18, p_0 = 7.35 \pm 0.19$ GeV/c, and $n = 37.2 \pm 0.8$ for central collisions.

The measured inclusive photon distributions are to be compared to the background inclusive photon distributions calculated from radiative decays of the π^0 and other hadrons to extract the direct photon excess.

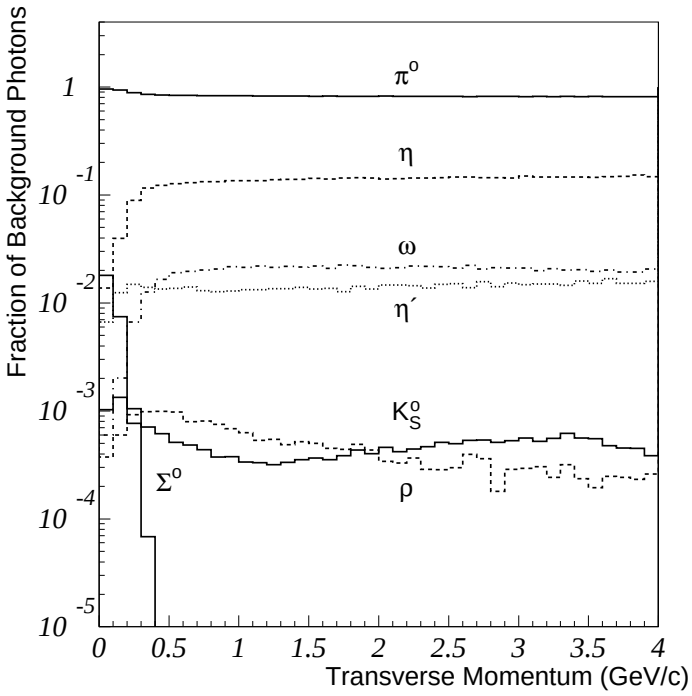

FIG. 28. The calculated fraction of all background inclusive photons from various radiative decay sources is shown as a function of the transverse momentum for central 158 *A* GeV ^{208}Pb+^{208}Pb collisions.

C. Background Photon Calculation

For each data sample or event selection in which the inclusive yield is extracted, the expected inclusive photon background from long-lived radiative decays is calculated using a Monte Carlo program which uses the JETSET 7.3 routines [91] to implement the hadron decays with proper branching ratios and decay distributions. As described in Sec. III D, the most important input to that calculation is the measured inclusive π^0 yield per event for the same

event sample. In the present analysis, the direct photon excess is to be extracted for central and for peripheral Pb+Pb collisions. The peripheral data sample is used to provide a control measurement. Therefore, the fits to the final inclusive π^0 transverse momentum distributions of Fig. 26 are the primary input to the calculations. The output of the simulation is the calculated decay photon yield per π^0 into the LEDA acceptance. This calculated γ/π^0 ratio, is to be compared to the measured ratio. Since the simulated π^0 distribution must agree with the measured π^0 distribution by construction, the difference in the measured and calculated inclusive γ yield per event gives the direct photon excess.

While photons from π^0 decay constitute the dominant source of background photons, other radiative decays are also included in the background calculation. The calculated fraction of the total background photons due to each of the various photon sources is shown in Fig. 28 for central Pb+Pb collisions. As discussed in Sec. III D, the yields of the various hadrons has been calculated with the assumption of m_T-scaling. This implies that the transverse momentum distributions of the other hadrons are determined by the measured π^0 transverse momentum distributions. The m_T-scaling normalization factors R_{X/π^0} are taken from the literature as discussed in Sec. III D and given in Table I. The quoted m_T-scaling factors are used for both peripheral and central collisions, with the exception that the measured m_T-scaling value of $R_{\eta/\pi^0} = 0.486$ extracted for the results shown in Fig. 25 and discussed in Sec. IV E is used for central collisions. As seen from Fig. 28, the η radiative decay contribution is the most significant source of background photons, beyond the π^0 contribution.[5] As will be discussed in the next section, the uncertainty on the η yield constitutes one of the largest sources of systematical error on the background photon calculation.

For the background calculations, a Gaussian rapidity distribution of particle production is assumed centered on mid-rapidity ($y = 2.9$) with an rms width of $\sigma_y = 1.3$ according to measured results for photon production in 158 *A* GeV ^{208}Pb+^{208}Pb collisions [92]. Since the LEDA is near to mid-rapidity (see Fig. 2) the rapidity distribution varies little over the detector acceptance consistent with the $\sigma = 1.3$ width. As an extreme, the background calculation has been performed with the assumption of a flat rapidity distribution. Under this assumption the calculated background photon yield would increase by about 2% for all transverse momenta above $p_T = 1$ GeV/c. The increase is greater at low p_T with an increase in the photon yield of about 5% at $p_T = 500$ MeV/c. This modest sensitivity to the assumed rapidity distribution can be understood from the limited acceptance for photons from π^0's which are emitted away from LEDA, as seen in part a) of Fig. 2. More important however, is that the calculated γ/π^0 ratio, which is the quantity relevant for the direct photon analysis, is much less sensitive to the assumed rapidity distribution. With the assumption of a flat rapidity distribution the γ/π^0 ratio is increased by only 2% at $p_T = 500$ MeV/c, 0.5% at $p_T = 1$ GeV/c, with the size of the increase rapidly decreasing at higher transverse momenta. Therefore, one may conclude that the uncertainty in the calculated γ/π^0 ratio due to extrapolation and uncertainty of the π^0 rapidity distribution is negligible.

D. Direct Photon Excess

In this section the final direct photon result is obtained and compared to results from proton-induced reactions at similar $\sqrt{s}$ and to model calculations. The direct photon yield is extracted as a function of the photon transverse momentum for central and peripheral 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The results presented are the sum of the 1995 and 1996 magnet on data samples. The details of the data selection have been discussed in Sec. IV A and the characteristics of the peripheral and central data samples are summarized in Table II. As described in Sec. III A, the direct photon excess is extracted on a statistical basis as the difference between the measured inclusive photon distributions discussed in Sec. V B and the background photon distributions calculated from radiative decays of long-lived final state hadrons discussed in Sec. V C.

1. Results

Since π^0 radiative decays comprise the dominant source of background photons (see Fig. 28), it is instructive to first investigate the γ/π^0 ratio as a function of the transverse momentum. As a result of the steeply falling π^0 transverse momentum spectra (see Fig. 26), photons of a given p_T predominantly result from asymmetric π^0 decays in which the photon carries most of the momentum of the parent π^0. (Since photons from symmetric decays carry roughly half of the parent π^0 momentum they are suppressed by the lower π^0 yield at the two times higher p_T, compared to the asymmetric decay π^0's.) Therefore, the error on the predicted photon yield at a given p_T will be most strongly

[5] Note that decay photons from π^0's which are themselves decay products of other hadrons are included in the measured π^0 decay contribution, and therefore not included as decay photons from the original hadron.

correlated with the error in the measured π^0 yield at a similar, slightly higher, p_T. For the ratio γ/π^0 many sources of systematical errors partially cancel, such as errors in the energy scale calibration for the measurement, or errors in the assumed π^0 rapidity distribution for the background calculation (as discussed in Sec. V C). Therefore a comparison of the measured and calculated γ/π^0 ratios provides a sensitive indication whether a direct photon excess is observed.

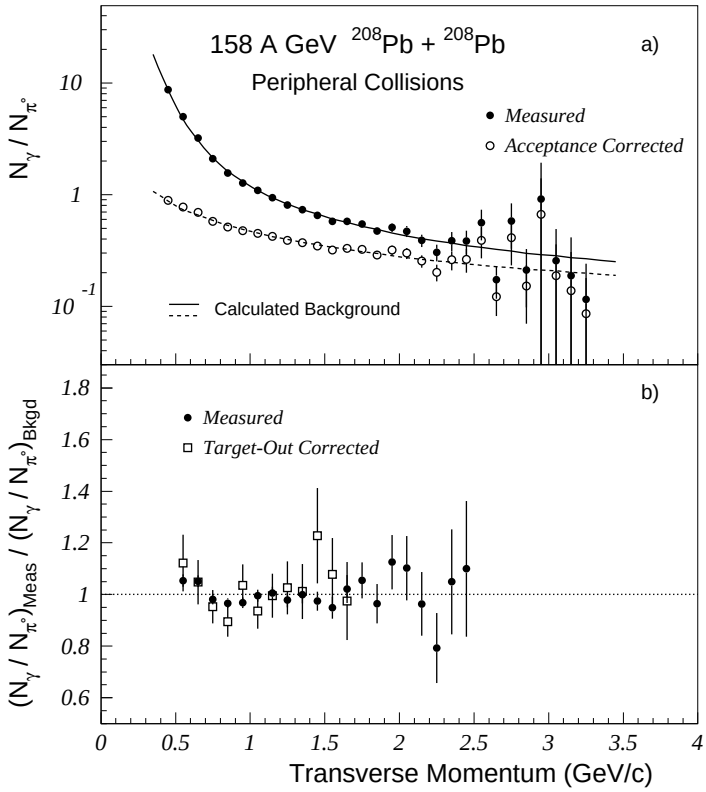

FIG. 29. The efficiency corrected (solid circles) and efficiency and acceptance corrected (open circles) γ/π^0 ratio is shown in part a) as a function of transverse momentum for peripheral 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The calculated background $(\gamma/\pi^0)_{\rm Bkgd}$ ratio in the WA98 acceptance is shown by the solid curve. The dashed curve shows the calculated background with acceptance corrections. The ratio of measured $(\gamma/\pi^0)_{\rm Meas}$ ratio to calculated $(\gamma/\pi^0)_{\rm Bkgd}$ ratio for the WA98 acceptance is shown in part b). The errors on the data points indicate the statistical errors only.

The measured γ/π^0 ratio for peripheral ^{208}Pb+^{208}Pb collisions is shown as a function of transverse momentum in part a) of Fig. 29. The solid points show the measured γ yield per event divided by the measured π^0 yield per event in the LEDA acceptance, fully corrected for efficiencies and backgrounds. The errors indicate the total statistical error on the ratio from the γ and π^0 yield extraction at each p_T. The open points show the measured results additionally corrected for the γ and π^0 acceptances. The results shown are obtained using the photon identification criterion in which all showers are considered photon candidates (condition S1 of Sec. III B). This shower identification criterion provides the greatest γ and π^0 efficiency, but also requires the largest corrections and therefore has the largest expected systematical error. The measured result is compared to the predicted γ/π^0 ratio shown by the solid curve in part a). The predicted result is from the Monte Carlo calculation of the background radiative decay photons discussed in Sec. V C which is based on the measured peripheral π^0 spectrum of Fig. 26. The simulation provides the yield per event of photons and π^0's into the LEDA acceptance. The calculated result is also shown with the γ and π^0 acceptance corrections.

The predicted $(\gamma/\pi^0)_{\rm Bkgd}$ ratio from background decays is seen to be in good agreement with the measured results. This is shown more clearly in part b) of Fig. 29 where the solid points show the ratio of the measured $(\gamma/\pi^0)_{\rm Meas}$ ratio to predicted background $(\gamma/\pi^0)_{\rm Bkgd}$ ratio. Even without consideration of possible systematical errors, the rather

good agreement between the measured and calculated ratio, within statistical errors, suggests that no significant direct photon excess is observed for peripheral collisions over the transverse momentum region of measurement.

The results in part a) and solid points in part b) of Fig. 29 have not been corrected for target out backgrounds. As discussed in Sec. IV C 1 the measured target out background rate implied less than 10% of the events of the peripheral data sample were due to non-target background. The photon multiplicities per non-target background event were measured to be similar to peripheral events, but with a steeper falling p_T distribution (see Fig. 12). From the low p_T $m_{\gamma\gamma}$ invariant mass distributions for peripheral events (see Fig. 17) the non-target background events were deduced to be due to downstream interactions, as indicated by a π^0 peak shifted to lower mass, with indications for a non-target contamination larger than determined by the target out measurements, as discussed in Sec. IV D 1. The peripheral result has therefore been checked with the assumption of the maximum possible non-target correction consistent with the low mass structure observed in the low p_T invariant mass spectra. It was only possible to do this for the 1996 data sample since no low mass peak was observed in the target out data for the 1995 run due to the Plastic Ball multiplicity condition requirement in the online trigger (see Sec. IV D 1). The result is shown by the open squares in part b) of Fig. 29. Due to the smaller 1996 peripheral data sample and the maximally increased target out correction of roughly 50% of the 1996 peripheral events, the statistical errors on the corrected results are very large. Nevertheless, the corrected γ/π^0 is found to be consistent with the uncorrected ratio and confirms the lack of a significant photon excess for the case of peripheral collisions.

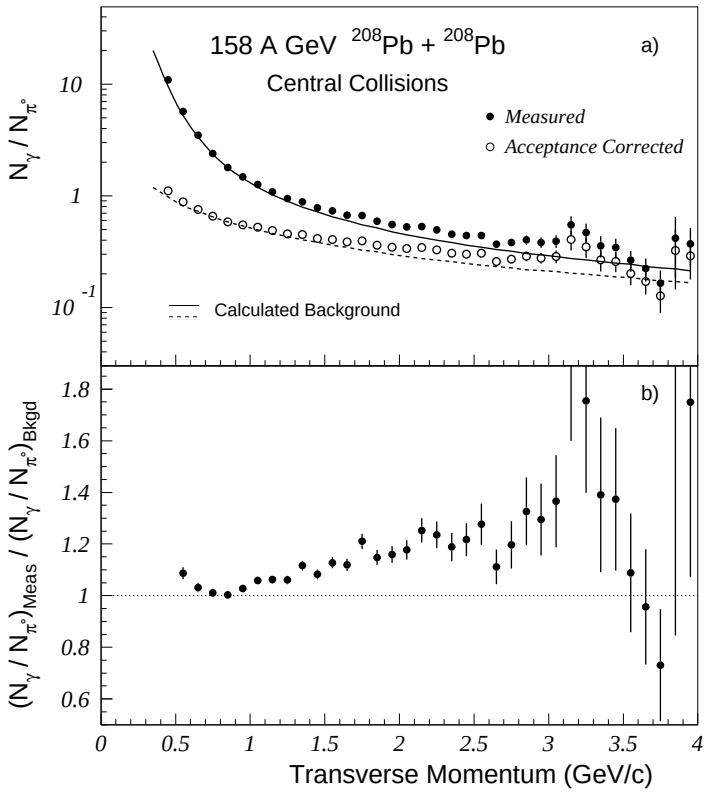

FIG. 30. The efficiency corrected (solid circles) and efficiency and acceptance corrected (open circles) γ/π^0 ratio is shown in part a) as a function of transverse momentum for central 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The calculated background $(\gamma/\pi^0)_{\rm Bkgd}$ ratio in the WA98 acceptance is shown by the solid curve. The dashed curve shows the calculated background with acceptance corrections. The ratio of measured $(\gamma/\pi^0)_{\rm Meas}$ ratio to calculated $(\gamma/\pi^0)_{\rm Bkgd}$ ratio for the WA98 acceptance is shown in part b). The errors on the data points indicate the statistical errors only.

The corresponding γ/π^0 ratio results for central ^{208}Pb+^{208}Pb collisions are shown in Fig. 30. The results are obtained using the photon identification criterion in which all showers are considered photon candidates, as was used for the results of Fig. 29. The background photon calculation is based on the measured central π^0 spectrum of Fig. 26

and uses the measured R_{η/π^0} ratio for central collisions deduced from the results of Fig. 25. Compared to the result for peripheral collisions, the statistical uncertainty on the measured γ/π^0 ratio for the case of central collisions is greatly reduced due to the slightly larger event sample, and more importantly, the much higher particle multiplicities per event.

In contrast to the case for peripheral collisions, the background calculation does not account well for the measured γ/π^0 ratio for central collisions. Instead, an excess in the measured γ/π^0 ratio compared to the background calculation is clearly seen in part b) of Fig. 30. The observed excess increases with p_T up to about a 20% excess at high transverse momentum.

To determine whether the observed excess is significant, a detailed consideration of the various sources of systematical error is necessary. The final direct photon excess is to be extracted as

$$\gamma_{\rm Excess} = \gamma_{\rm Meas} - \gamma_{\rm Bkgd} = \left(1 - \frac{\gamma_{\rm Bkgd}}{\gamma_{\rm Meas}}\right) \cdot \gamma_{\rm Meas}. \tag{5.4}$$

If the ratio $\gamma_{\rm Meas}/\gamma_{\rm Bkgd}$ is equal to one within errors, then no significant photon excess is observed. The ratio $\gamma_{\rm Meas}/\gamma_{\rm Bkgd}$ and its error are determined from the measured $(\gamma/\pi^0)_{\rm Meas}$ and calculated $(\gamma/\pi^0)_{\rm Bkgd}$ ratios. Since, by construction, $(\pi^0)_{\rm Bkgd} \equiv (\pi^0)_{\rm Meas}$ within uncertainties we have

$$\frac{\gamma_{\rm Meas}}{\gamma_{\rm Bkgd}} = \frac{(\gamma/\pi^0)_{\rm Meas}}{(\gamma/\pi^0)_{\rm Bkgd}}. \tag{5.5}$$

Additional systematical errors on $\gamma_{\rm Meas}$ which partially cancel in Eq.5.5 must also be included in Eq. 5.4. Furthermore, when the absolute excess photon cross section is extracted the absolute cross section normalization errors on $\gamma_{\rm Meas}$ must be introduced.

The total systematical error on $\gamma_{\rm Meas}/\gamma_{\rm Bkgd}$ is obtained from the separate error contributions to $(\gamma/\pi^0)_{\rm Meas}$, $(\gamma/\pi^0)_{\rm Bkgd}$, and $(\pi^0)_{\rm Meas}/(\pi^0)_{\rm Bkgd}$. These various systematical error contributions to the direct photon result are summarized in Table III. The errors quoted correspond to the shower identification criterion of using narrow showers (S2), which minimizes the background corrections and therefore is expected to have the smallest systematical error. This shower identification criteria will be used to extract the final WA98 result. A comparison of the final result with the results of Figs. 29 and 30 where all showers (S1) have been used provides an additional check of the overall systematical errors. In general, many of the systematical errors are dependent on the transverse momentum and so must be estimated for each p_T. The systematical errors are listed at $p_T \approx 1$ GeV/c and 2.5 GeV/c for peripheral and central collisions to give an indication of the p_T and centrality dependence of the systematical error contributions.

TABLE III. Various sources of systematical error in the WA98 158 *A* GeV ^{208}Pb+^{208}Pb direct photon analysis specified as a percentage of $(\gamma/\pi^0)_{\rm Meas}$ (items a)), $(\gamma/\pi^0)_{\rm Bkgd}$ (items b)), or $(\pi^0)_{\rm Meas}/(\pi^0)_{\rm Bkgd}$ (item c)). The systematical errors are quoted at two p_T values to give an indication of the dependence on transverse momentum. The errors are estimated for the narrow shower identification criterion (S2). The total estimated systematical error on $\gamma_{\rm Meas}/\gamma_{\rm Bkgd}$ is given as the quadratic sum of the various contributions.

Source of Error	Peripheral Collisions ($20\%\ \sigma_{\rm mb}$)		Central Collisions ($10\%\ \sigma_{\rm mb}$)	
	$p_T \approx 1.0$ GeV/c	$p_T \approx 2.5$ GeV/c	$p_T \approx 1.0$ GeV/c	$p_T \approx 2.5$ GeV/c

$^+$ Included in γ yield measurement error. * Included in π^0 yield measurement error.

The separate systematical errors on the photon and π^0 measurement as they contribute to $(\gamma/\pi^0)_{\rm Meas}$ have been discussed previously in Secs. IV C 4 and IV D 3. As discussed in Sec. IV C 4, the photon error includes an assumed 30% uncertainty in the charged particle correction related to the results shown in Fig. 11, and an assumed 50% uncertainty in the neutron+anti-neutron correction related to the results shown in Fig. 13. A 2% uncertainty is assumed for the photon identification efficiency. The overall systematical error on the determination of the photon yield is $\sim 3\%$ which was shown to be consistent with observed systematic variations by a comparison of the γ yield determination using different shower identification methods (see Fig. 15).

The systematical errors on the π^0 yield determination listed in Table III were discussed in Sec. IV D 3. The systematical error associated with the determination of the π^0 identification efficiency was estimated to be 3% and 4% for peripheral and central collisions, respectively. An additional source of systematical error on the π^0 yield extraction is attributed to the subtraction of the combinatorial background underlying the π^0 peak in the $\gamma\gamma$ invariant mass distributions which becomes important for the case of central collisions at low p_T. This error was estimated to contribute at the level of $\sim 10^{-3}$ of the background. The overall systematical error estimate on the determination of the π^0 yield was shown by a comparison of the π^0 yield results using different shower identification methods (see Fig. 23) to be consistent with observed systematical variations.

Other systematical error contributions to the measured $(\gamma/\pi^0)_{\rm Meas}$ ratio listed in Table III are the target out background contribution and the calibration of the energy scale. Although the magnitude of the non-target correction was found to have large uncertainties, as discussed in Secs. IV C 1 and IV D 1, the peripheral $(\gamma/\pi^0)_{\rm Meas}$ ratio showed little systematic dependence on the non-target background correction, as discussed in regard to Fig. 29. No target out background correction was necessary for central collisions, as previously discussed.

Based on the observed agreement between the measured and simulated π^0 peak positions shown in Fig. 21, the calibration of the energy scale is estimated to be accurate to 0.5%. Using the measured γ and π^0 transverse momentum distributions the error on the $(\gamma/\pi^0)_{\rm Meas}$ ratio is calculated as a function of p_T assuming a 0.5% uncertainty in the p_T scale.

The uncertainty in the detector acceptance listed in Table III is relevant for the background photon calculation. As discussed in Sec. V C, the calculated $(\gamma/\pi^0)_{\rm Bkgd}$ ratio is not very sensitive to the uncertainty in the detector acceptance, or to extreme assumptions on the extrapolation of the hadron distributions outside of the detector acceptance. The quoted error estimate of 0.5% includes both effects.

One of the larger contributions to the systematical error in this analysis is attributed to the uncertainty in the η yield. While the η's constitute a relatively large source of background photons (see Fig. 25), their yield has not been measured very precisely in the present analysis (see discussion of Sec. IV E). According to the discussion of Sec. V C, m_T-scaling has been assumed in order to allow to relate the p_T spectrum of the η to the measured π^0 spectrum with only a single overall normalization factor R_{η/π^0}. For peripheral collisions the η yield has not been measured. In this case, it should be a good approximation to use the m_T-scaling factor of $R_{\eta/\pi^0} = 0.55 \pm 0.02$ [76,77] obtained from a compilation of proton and π-induced results, where the m_T-scaling assumption has also been shown to be valid. Nevertheless, we assume a larger systematical error of 20% on R_{η/π^0} since it is an unmeasured quantity and also to accommodate deviations from the m_T-scaling assumption. This results in a systematical error contribution to $(\gamma/\pi^0)_{\rm Bkgd}$ of about 3% for peripheral collisions, as shown in Table III.

For central collisions, the transverse momentum dependence of the η yield was extracted with modest precision, as discussed in Sec. IV E. The measured η/π^0 ratio was found to be consistent with the m_T-scaling assumption with a best fit overall normalization of $R_{\eta/\pi^0} = 0.486 \pm 0.077$(stat.)$\pm 0.097$(syst.). For the direct photon analysis, we have added these statistical and systematical errors in quadrature to obtain a low estimate on the η/π^0 ratio of $R_{\eta/\pi^0} = 0.36$ which is used for the lower error estimate on the γ/π^0 ratio due to the η background contribution. For the upper error estimate on the γ/π^0 ratio due to the η we have assumed a high estimate of $R_{\eta/\pi^0} = 0.66$, which is the same upper estimate used for the case of peripheral collisions. This results in a larger upper error than lower error on the $(\gamma/\pi^0)_{\rm Bkgd}$ ratio with the associated asymmetric errors listed in Table III[6].

The expected total background contribution from radiative decays other than those of the π^0 and η (predominantly the ω and η') is of the order of a few percent only (see Fig. 28). Since this contribution is unmeasured, a systematical error of $\sim 30\%$ in their yield, or 1% on the background photon contribution, has been assumed.

From the results shown in Fig. 26 it is apparent that the statistical error on the π^0 measurement limits the significance of the γ/π^0 results shown in Figs. 29 and 30, especially at high transverse momenta. This statistical error may be removed by fitting the π^0 spectra of Fig. 26, but at the cost of an additional source of systematical error. The last error listed in Table III is the estimated π^0 fit error. This error was estimated by fitting separately the π^0 spectra for the

[6]Note that an upper error estimate on the background photons contribute to the lower error estimate on the photon measurement.

1995, 1996, and sum 1995+1996 data samples and separately for the shower condition of all showers (S1) or narrow showers (S2) (*i.e.* 6 different spectra each for peripheral and central) in the high p_T region only ($p_T > 1.5$ GeV/c) and using the half-width of the maximum variation of the fit results over the full p_T region to define the fit error as a function of p_T. This error is observed to be strongly p_T dependent and increases rapidly outside of the range of measurement.

Since $(\pi^0)_{\rm Meas}/(\pi^0)_{\rm Bkgd} \equiv 1$ within uncertainties by construction, the individual systematical errors on $(\gamma/\pi^0)_{\rm Meas}$, $(\gamma/\pi^0)_{\rm Bkgd}$, and $(\pi^0)_{\rm Meas}/(\pi^0)_{\rm Bkgd}$, can be combined to give the total systematical error on $\gamma_{\rm Meas}/\gamma_{\rm Bkgd}$. The various systematical errors listed in Table III are added in quadrature to obtain the total systematical error on the $\gamma_{\rm Meas}/\gamma_{\rm Bkgd}$ ratio. While some of the errors are correlated, the correlations are such that they tend to cancel in the final ratio. Also, the π^0 fit error includes some of the errors of the π^0 yield extraction. Therefore, the assumption of independent errors is considered a conservative assumption.

The $\gamma_{\rm Meas}/\gamma_{\rm Bkgd}$ ratio as a function of transverse momentum is shown in Fig. 31 for peripheral and central 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The results are shown for photons identified using the narrow shower condition (S2). As expected according to the discussion of Eq. 5.5, the $\gamma_{\rm Meas}/\gamma_{\rm Bkgd}$ ratios of Fig. 31 show the same behavior as the $(\gamma/\pi^0)_{\rm Meas}/(\gamma/\pi^0)_{\rm Bkgd}$ ratios of Figs. 29 and 30. This comparison provides an additional systematic check since the two sets of results were obtained with different shower identification criteria. As discussed previously, in addition to the larger systematical errors expected when using all showers as photon candidates, the results of Figs. 29 and 30 have larger statistical error because the π^0 measurement at each p_T is used and contributes to the statistical error, while on the other hand, the fitted π^0 results of Fig. 26 are used for the results of Fig. 31, which reduces the statistical error but increases the systematical error. The general agreement of the two sets of results again suggests that the systematical errors are not large.

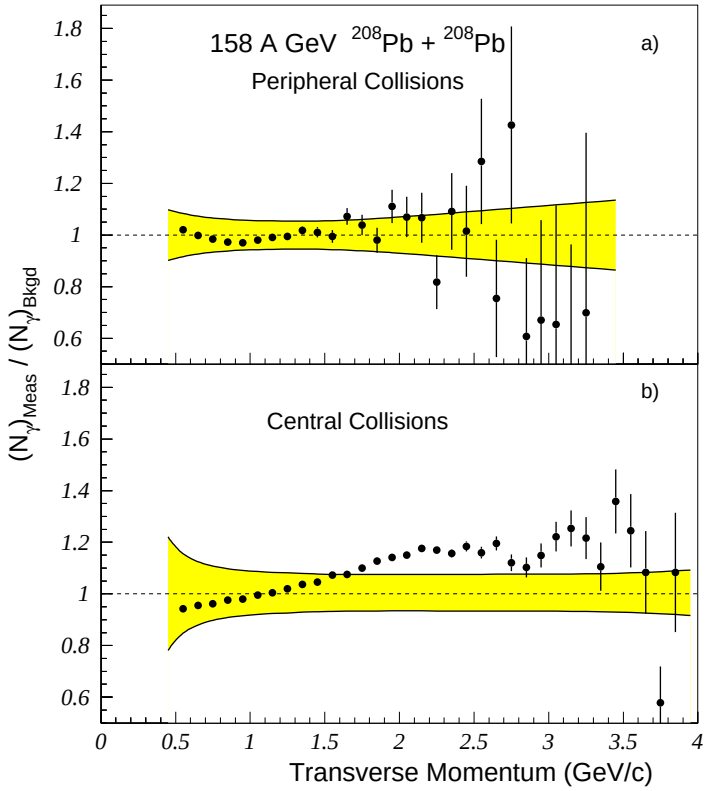

FIG. 31. The $\gamma_{\rm Meas}/\gamma_{\rm Bkgd}$ ratio as a function of transverse momentum for peripheral (part a)) and central (part b)) 158 *A* GeV ^{208}Pb+^{208}Pb collisions for the sum of 1995 and 1996 magnet on data sets. The narrow shower photon identification criterion has been used. The errors on the data points indicate the statistical errors only. The p_T-dependent systematical errors are indicated by the shaded bands ($\equiv 1^{+\sigma_L}_{-\sigma_U}$). (Note: Upper and lower errors are inverted for display purposes.)

The total p_T-dependent systematical errors listed in Table III are shown by the shaded regions in Fig. 31. The systematical errors increase strongly at low transverse momenta due the combinatorial background uncertainties in the π^0 yield extraction. They increase also at large transverse momenta due to the uncertainties in the fits to the π^0 distributions. For peripheral collisions, all measured results fall within $\sigma_{\rm stat.} + \sigma_{\rm syst.}$ of $\gamma_{\rm Meas}/\gamma_{\rm Bkgd} = 1$, which indicates that no significant photon excess is observed. On the other hand, the results for central collisions do indicate a significant photon excess in the region above about 1.5 GeV/c.

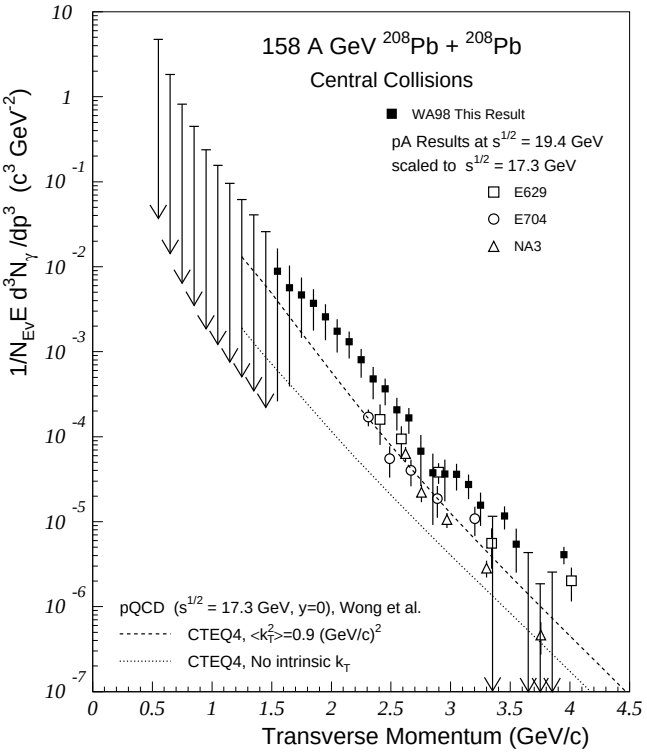

FIG. 32. The invariant direct photon multiplicity for central 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The error bars indicate the combined statistical and systematical errors. Data points with downward arrows indicate unbounded 90% CL upper limits. Results of several direct photon measurements for proton-induced reactions have been scaled to central 158 *A* GeV ^{208}Pb+^{208}Pb collisions for comparison. The calculation is described in the text.

The direct photon excess for central ^{208}Pb+^{208}Pb collisions is shown in Fig. 32. The results are presented as the invariant direct photon yield per central collision. The direct photon excess is obtained according to Eq. 5.4 with the measured results of Fig. 31 and Fig. 27. The statistical and asymmetric systematical errors of Fig. 31 are added in quadrature to obtain the total upper and lower errors shown in Fig. 32. An additional p_T-dependent error is included to account for that portion of the uncertainty in the energy scale which cancels in the $(\gamma/\pi^0)_{Meas}$ ratio, but enters again with γ_{Meas} in Eq. 5.4. In the case that the lower error is less than zero a downward arrow is shown with the tail of the arrow indicating the 90% confidence level upper limit ($\gamma_{Excess} + 1.28\sigma_{Upper}$). The results are also tabulated in Table IV.

For comparion, other published fixed target prompt photon measurements for proton-induced reactions at 200 GeV are also shown in Fig. 32. Results are shown from FNAL experiment E704 [25] ($-0.15 < x_F < 0.15$) for proton-proton reactions, and from FNAL experiment E629 [21] ($-0.75 < y_{cm} < 0.2$) and CERN SPS experiment NA3 [22] ($-0.4 < y_{cm} < 1.2$) for proton-carbon reactions. These results have been divided by the total pp inelastic cross section ($\sigma_{int} = 30$ mb) and by the mass number of the target to obtain the invariant direct photon yield per nucleon-nucleon collision. They have then been multiplied by the calculated number of nucleon-nucleon collisions for the central Pb+Pb event selection for comparison with the present measurements. Based on a Glauber model calculation, the number of nucleon-nucleon collisions is calculated to be 660 for the 635 mb most central event selection used for the present analysis. This scaling of the proton-induced results is estimated to have an uncertainty of less than 10% due to uncertainties in the assumed nuclear density distribution and nucleon interaction cross section. The proton-

induced results have also been scaled from $\sqrt{s} = 19.4$ GeV to the lower $\sqrt{s} = 17.3$ GeV of the present measurement. The proton-induced results have also been scaled from $\sqrt{s} = 19.4$ GeV to the lower $\sqrt{s} = 17.3$ GeV of the present measurement under the assumption that $Ed^3\sigma_\gamma/dp^3 = f(x_T)/s^2$, where $x_T = 2p_T/\sqrt{s}$ [36]. The $\sqrt{s}$-scaling effectively reduces the 19.4 GeV proton-induced results by about a factor of two. This comparison suggests an excess direct photon production in central ^{208}Pb+^{208}Pb collisions as compared to proton-induced reactions at the same $\sqrt{s}$ of 17.3 GeV. The interpretation of the present result is further discussed in the next section.

TABLE IV. The direct photon invariant yield per event $1/N_{events} \cdot Ed^3N_\gamma/dp^3$ for central 158 *A* GeV ^{208}Pb+^{208}Pb collisions. The central event selection is defined as those events with the largest measured transverse energy with a total cross section of 635 mb for the selected central sample. The lower and upper region of uncertainty ($\pm\sigma$, including statistical and systematical errors added in quadrature) are indicated. In the case that the lower limit is less than or equal to zero, only the 90% confidence level ($+1.28\sigma$) upper limit is listed.

2. Comparison to Calculations

Considerable progress has been made in the theoretical description of prompt photon production in hadron-induced reactions. It is now possible to perform a complete and fully consistent next-to-leading order (NLO) QCD calculation of the prompt photon cross section and obtain a quite good description of the data at incident energies from $\sqrt{s} = 23$ GeV up to Tevatron energies ($\sqrt{s} = 1.8$ TeV) [37]. On the other hand, these same calculations which provide a

good description at high incident energy, underpredict prompt photon production at $\sqrt{s} = 19.4$ GeV. For the results shown in Fig. 32 the E704 and NA3 results are underpredicted by about a factor of two, while the E629 result is underpredicted by about a factor of five [37].

It has been proposed [36] that the intrinsic transverse momentum of the partons, as a consequence of confinement within the hadron, or of soft gluon radiation, may significantly increase the theoretical prompt photon predictions at low incident energies, or low transverse momenta. The effect of intrinsic k_T is normally neglected in state of the art perturbative QCD calculations due to the formidable technical difficulty to perform the integration over transverse degrees of freedom in the NLO calculations. Nevertheless, there has been a renewed interest to investigate intrinsic k_T effects in prompt photon production [101,102,33] largely motivated by recent high precision prompt photon measurements of FNAL experiment E706 [31,32], although the necessity for such intrinsic k_T effects remains a topic of debate [39].

Recently, Wong and Wang [101] have investigated the effects of parton intrinsic k_T on photon production under the assumption that the NLO corrections are independent of intrinsic k_T. Correction factors, or K-factors, were determined as a function of photon transverse momentum as the ratio of the NLO+LO calculation result to the leading-order (LO) result, without intrinsic k_T. The LO calculations were reevaluated with the inclusion of parton intrinsic k_T assumed to be characterized by a Gaussian distribution with $\langle k_T^2 \rangle = 4 \langle k_T \rangle / \pi$, where $\langle k_T \rangle$ is the average intrinsic k_T of a parton. The K-factors determined without intrinsic k_T were then applied to the LO result with intrinsic k_T included to obtain the final prompt photon prediction.

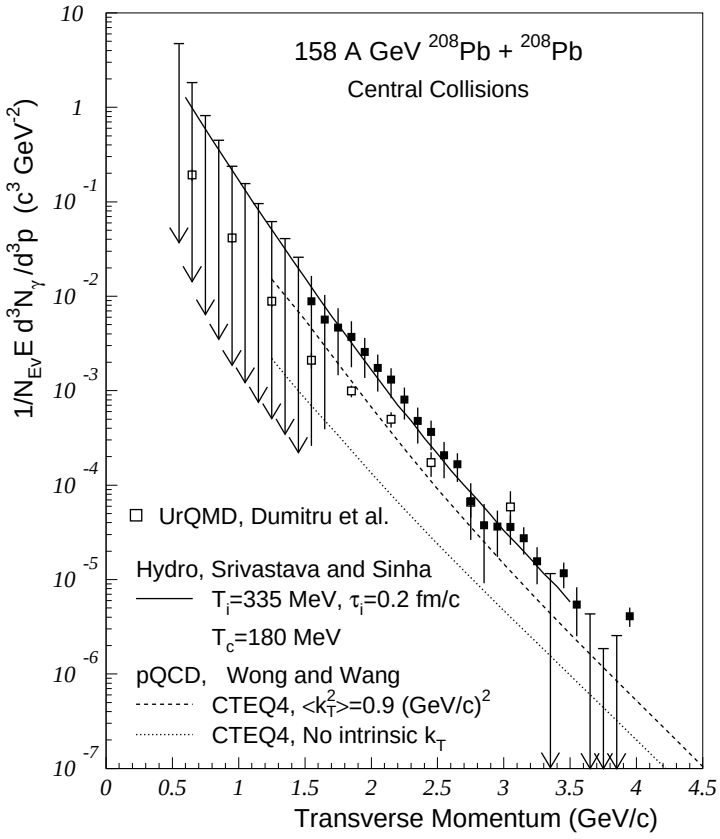

FIG. 33. The invariant direct photon multiplicity for central collisions of 158 *A* GeV ^{208}Pb+^{208}Pb compared to various predictions discussed in the text. The error bars indicate the combined statistical and systematical errors. Data points with downward arrows indicate unbounded 90% CL upper limits.

With this prescription the E704 and NA3 results shown in Fig. 32 were well described with a parton intrinsic k_T of $\langle k_T^2 \rangle = 0.9$ (GeV/c)^2 [101]. The importance of the intrinsic k_T effect decreases with increasing $\sqrt{s}$ and increasing photon p_T such that the prompt photon data at higher $\sqrt{s}$ are equally well described with or without intrinsic k_T.

Predictions of the direct photon production for $\sqrt{s} = 17.3$ GeV central ^{208}Pb+^{208}Pb collisions calculated in this manner [101] are compared to the measured results in Fig. 32 and also in Fig. 33. The calculation has been scaled to central ^{208}Pb+^{208}Pb collisions in the same way as described above for the proton-induced data. Results are shown with and without the effects of parton intrinsic k_T by the long-dashed and short-dashed curves, respectively. At this low incident energy, the parton intrinsic k_T is seen to increase the predicted photon yield by a factor which increases with decreasing p_T from about 4 to 8. The predicted direct photon yield with intrinsic k_T effects included is in good agreement with the $\sqrt{s} = 19.4$ GeV proton-induced results scaled to $\sqrt{s} = 17.3$ GeV. It is also in general agreement with the shape of the observed photon spectrum in central ^{208}Pb+^{208}Pb collisions, but underpredicts the observed yield by about a factor of 2.5. This discrepancy could be a result of further deficiencies in the prompt photon calculations when applied at low incident energy, or it may indicate new effects attributable to nuclear collisions. A possible explanation might be additional p_T broadening of the incoming partons due to soft scatterings prior to the hard scattering which produces the photon [102]. Alternatively, it may be expected that the photon production is enhanced by the additional scatterings which occur as a result of rescattering in nucleus-nucleus collisions.

It is anticipated that if a quark gluon plasma is formed in relativistic heavy ion collisions, it will evolve from the initial hard-scattering partonic stage, through a preequilibrium stage, to a finally thermalized partonic QGP phase. Therefore the Parton Cascade Model (PCM) [103] has been widely regarded as a promising tool to investigate the evolution of the initial partonic state. The VNI [104] implementation of the PCM has recently been used to predict direct photon production in central Pb+Pb collisions at the SPS [105]. Those predictions are in reasonable agreement with the present result, although they slightly overpredict the yield above $p_T = 3$ GeV/c while underpredicting the yield below 2.5 GeV/c. However, it has recently been pointed out that the method which was used to implement higher order pQCD corrections in those calculations, by rescaling Q^2 in the running coupling constant α_s, is highly questionable at SPS energies [106].

Non-equilibrium direct photon emission has also been investigated within the context of the Ultrarelativistic Quantum Molecular Dynamics model (UrQMD) [107]. The UrQMD predictions of the total direct photon production in central Pb+Pb collisions are shown by the open squares in Fig. 33 [108]. It is interesting that the UrQMD predictions are very similar to the the VNI parton cascade predictions [105]. In the UrQMD calculations, the direct photon production results strictly from meson-meson scattering, predominantly $\pi\pi \rightarrow \rho\gamma$ and $\pi\rho \rightarrow \pi\gamma$. In these calculations it was observed that the photon production in the transverse momentum region with $p_T > 1.5$ GeV/c is dominated by pre-equilibrium emission in which the scattering mesons have locally non-isotropic momentum distributions. The thermal photon emission was found to be important only in the low transverse momentum region below $p_T < 1.5$ GeV/c.

It is of particular interest to compare the observed direct photon yield to predictions of the expected yield in the event of quark gluon plasma formation. Hydrodynamic model calculations of the predicted direct photon yield are shown by the solid curve in Fig. 33 [20,109]. The hydrodynamic calculations include transverse expansion [110] with a rich hadronic equation of state including all hadrons and resonances with mass up to 2.5 GeV. The photon emission rates used for the hadronic phase are those which have been obtained from a two-loop approximation of the photon self energy using a model where the $\pi\rho$ interactions have been included [18], and also include the important contribution from the A_1 resonance [111]. The photon emission rates from the quark matter phase include the lowest order contributions from the Compton ($q(\overline{q})g \rightarrow q(\overline{q})\gamma$) and annihilation ($q\overline{q} \rightarrow g\gamma$) processes, as well as the new contributions from two-loop diagrams which have recently been shown [19] to give a large bremsstrahlung ($qq(g) \rightarrow qq(g)\gamma$) contribution and a previously neglected process of $q\overline{q}$ annihilation accompanied by q(g) rescattering which is found to dominate the photon emission rate.

As shown in Fig. 33, very good agreement with the experimental result is obtained for the case of an equation of state which includes a QGP phase transition which occurs at a critical temperature of $T_C = 180$ MeV [109] with a hadron thermal freeze-out temperature of $T_F = 100$ MeV. The calculation has been performed for the 10% most central Pb+Pb collisions for a particle density $dN/dy = 750$ with the assumption of a fast equilibration time of $\tau_0 = \frac{1}{3}T_0$ given by the uncertainty relation. This results in an initial temperature of $T_0 = 335$ MeV with a thermalization time of $\tau_0 = 0.2$ fm/c. The contribution from the quark matter in the QGP and mixed phase dominates the calculated high p_T photon yield [109]. This is attributed to the "annihilation with rescattering" process which is a special feature of dense quark matter. This calculation does not include prompt or preequilibrium contributions.

Further study will be necessary to improve the theoretical predictions of the prompt photon contribution as well as the non-equilibrium contributions. On the other hand, the hydrodynamical model calculations which provide a time integration of the emission rate with a very short initial formation time and high initial temperature may provide a reasonable approximation of the contributions from the early non-equilibrium phase of the collision [109]. Further studies will also be necessary to determine how the present direct photon results might further constrain the QGP and non-QGP scenarios. The WA80 direct photon upper limit for central S+Au collisions [43] was able to rule out thermal emission from purely hadronic matter in which the hadronic matter consisted of a simple pion gas with few degrees

of freedom [44–47] due to the constraints which the result implied on the initial temperature [48]. The S+Au direct photon limit has been shown to be consistent with the QGP transition using the new rates for quark matter, although with somewhat different parameters than presented here [112,109]. It will be important to determine whether the present result, combined with other measurements including the S+Au direct photon upper limit, can provide further constraints and provide compelling evidence for the QGP phase transition scenario.

VI. SUMMARY AND CONCLUSIONS

A search for direct photons in ^{208}Pb+^{208}Pb collisions at 158 *A* GeV has been performed using the large-area finely-segmented lead-glass calorimeter of the WA98 experiment. The analysis has been performed on nearly equal-sized event samples of the 10% most central and 20% most peripheral fractions of the total minimum bias cross section. The inclusive photon and π^0 transverse momentum distributions were measured for each event sample. Constraints were also obtained on the η transverse momentum distribution for central collisions with a modest accuracy which was limited by statistics. The systematical error sources were discussed at length with particular attention to demonstrate the accuracy of the systematical error estimates. The total systematical error for the direct photon analysis varied from about 6% to 10% over the p_T region of interest, and varied with the centrality selection. The direct photon excess was extracted on a statistical basis as the difference between the measured inclusive spectrum of photons within the detector acceptance and the calculated spectrum of photons which result from all hadrons with significant radiative decay contributions. The dominant decay contributions are those from the measured π^0's and η's.

No significant direct photon excess was observed for the peripheral event sample for transverse momenta up to about 2.5 GeV/c. This upper p_T limit of the measurement was imposed by the increasing statistical error at large p_T due to the low particle multiplicity for peripheral collisions.

In contrast, a significant direct photon excess was observed over the p_T region of about 1.5 GeV/c to 3.5 GeV/c for central ^{208}Pb+^{208}Pb collisions. At transverse momenta where the observed excess was not significant, a 90% confidence level upper limit on the direct photon excess was given. This extended the result to the full region of measurement from 0.5 GeV/c to 4 GeV/c.

The observed direct photon yield was compared to a next-to-leading order perturbative QCD calculation at the same $\sqrt{s}$ (=17.3 GeV) and scaled according to the number of nucleon-nucleon collisions calculated for the selected central event class. The measured direct photon yield was about a factor of 2-3 above the pQCD calculation which included the effects of partonic intrinsic k_T with a parameter which gave a good description of proton-induced prompt photon results at the nearest incident energy ($\sqrt{s}$=19.4 GeV). A NLO pQCD calculation without intrinsic k_T was about an order of magnitude below the measured result.

The results suggest that the additional direct photon yield in central ^{208}Pb+^{208}Pb collisions is the result of additional rescatterings in the dense matter. The measured results can be well-described by hydrodynamical model calculations which include a quark gluon plasma phase transition with an initial temperature of $T_0 = 335$ MeV and a critical temperature of $T_C = 180$ MeV [109]. The photon emission from the quark matter is found to dominate over the contribution from the hadronic matter due to the recently identified process of annihilation with rescattering [19] which is only expected to occur in dense quark matter. It will be important to determine the uniqueness of this interpretation.

ACKNOWLEDGMENTS

We wish to express our gratitude to the CERN accelerator division for the excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians and support staff who have participated in the construction of this experiment. We acknowledge helpful discussions with D.K. Srivastava and C.-Y. Wong.

This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR and FRN, the Dutch Stichting FOM, the Stiftung für Deutsch-Polnische Zusammenarbeit, the Grant Agency of the Czech Republic under contract No. 202/95/0217, the Department of Atomic Energy, the Department of Science and Technology, the Council of Scientific and Industrial Research and the University Grants Commission of the Government of India, the Indo-FRG Exchange Program, the PPE division of CERN, the Swiss National Fund, the INTAS under Contract INTAS-97-0158, ORISE, Grant-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science and Culture, the University of Tsukuba Special Research Projects, and the JSPS Research Fellowships for Young Scientists. ORNL is managed by UT-Battelle, LLC, for the U.S. Department of Energy under contract DE-AC05-00OR22725. The MIT group has been supported by the US Dept. of Energy under the cooperative agreement DE-FC02-94ER40818.

Abstract

The Δ^{++}-resonance production in central 158 A GeV ^{208}Pb + ^{208}Pb collisions at the CERN SPS has been studied. The Δ^{++} production was estimated from the invariant mass spectrum of $p\pi^{+}$-pairs by subtracting a mixed event background. The measured Δ^{++} abundance is compared with the results from other experiments at lower energies, and with a model calculation assuming thermal and chemical equilibrium. © 2000 Elsevier Science B.V. Keywords: Ultra-relativistic heavy ion collisions; Δ^{++} resonance production; Mixed event technique; Freeze-out temperature

Energetic heavy ion collisions provide the means for studies of nuclear matter under extreme conditions in the laboratory. The copious interactions between pions and nucleons in the final state of ultra-relativistic heavy ion collisions make the determination of the $\Delta(1232)$ abundance an interesting probe of the thermal conditions during the collision.

[1] E-mail: david.silvermyr@kosufy.lu.se

The Δ-resonance, apart from playing a role in particle production and interaction dynamics, may probe the conditions in heavy-ion collisions at early freeze-out times and high freeze-out densities [1]. It has been suggested that a chemical freeze-out temperature can be extracted from the $\Delta(1232)$/nucleon ratio [2]. The Δ-resonance is known to be readily produced in photon [3]- lepton [4]- and hadron [5]-induced nuclear interactions and the cross sections for production of Δ-resonances in elementary nucleon-nucleon collisions are large [6].

Recently, results on $\Delta(1232)$ production in nucleus-nucleus collisions at 95 A MeV [7], at 1 and 2 A GeV [8] and at 13.7 A GeV [9] have been reported. In this paper we present measurements on the production of Δ^{++} by means of an invariant mass analysis of $p\pi^+$-pairs in 158 A GeV central ^{208}Pb $+^{208}$Pb central collisions at the CERN SPS. The measurement utilizes the new high resolution tracking arm of WA98 [10], which consists of multi-step avalanche chambers, streamer tube detectors and a high resolution Time-Of-Flight system.

The fixed target experiment WA98 is a large-acceptance photon and hadron spectrometer designed to study ultra-relativistic heavy-ion collisions. Charged particles, produced in the interactions, traverse a large magnet and are deflected into two tracking arms, horizontally placed on both sides of the beam which allow for momentum determination and particle identification. For the Δ^{++} measurements, reported in this paper, we use the full data sample from the tracking arm for the positively charged particles [11]. This second tracking arm was installed and operated for only a portion of the final WA98 run period.

The tracking arm consists of two planes of Multi-Step Avalanche Chambers (MSACs) [12,13] and two planes of streamer tube detectors, all equipped with electronic pad readout and a highly segmented Time-Of-Flight (TOF) wall. Fig. 1a shows a schematic drawing of the second tracking arm as seen from above, with two tracks entering the acceptance. Here the *z*-axis is pointing along the beam and the *x*-axis is parallel to the bending plane of the magnet. The position resolution of the MSACs was $\sigma_x = 0.5$ mm in the horizontal direction, and $\sigma_y = 1.7$ mm in the vertical direction whereas the streamer tube detectors had an intrinsic resolution of $\sigma_x = 3.0$ mm and $\sigma_y =$ 6.5 mm. The time resolution of the TOF wall was better than 90 ps and its spatial resolution was $\sigma_x = 12.5$ mm and $\sigma_y = 26.4$ mm. Fig. 1b and 1c show p versus $t_{\mathrm{tof}} - t_{\mathrm{exp}}$ assuming pion and proton mass, respectively. Here p is the momentum, t_{tof} the measured flight time of the particle and t_{exp} the expected flight time calculated from the track length and momentum of the particle. Separation between different particle species, especially for pions and protons, is good over a wide range of momenta. Kaons and pions are no longer separable at momenta above 4 GeV/c and thus a small contamination of kaons is present among the pions at larger momenta. The momenta of the particles are first approximated assuming a uniform magnetic field and straight line fits through the tracking arm and then corrected by GEANT [14] calculations using the measured field. The momentum resolution, $\Delta p/p$, is limited by the multiple scattering, mainly in the air between the target and the detectors, the intrinsic detector resolution and by methodical uncertainties. Based on GEANT simulations we estimate $\Delta p/p$ to be about 1% at 2 GeV/c and 2% at 5 GeV/c.

The most interesting events are those where the bulk of the nuclear matter interacts, i.e. the most central events. A trigger based on the transverse energy as measured by the Mid-Rapidity Calorimeter (MIRAC) is used to enhance central collisions. The present analysis has been performed using the 8.5% most central events of the WA98 minimum bias cross section (6450 mb for the used data set) based on an offline cut on the measured transverse energy. To reject beam particles other than Pb and possible event pile-up, lower and upper cuts in the ADC and TDC values from the start-counters, placed in the beam, were performed.

During and shortly after electrical discharges, the MSACs exhibited reduced efficiencies. This has been discussed in a previous paper [12]. Thus events recorded within a short time after such a discharge, are removed from the analysis.

The tracking procedure connects hits in at least three out of the four tracking planes, by means of straight line fits, and combines a track with a valid time measurement in the TOF wall at the correct position. Due to the excellent two-track resolution and two-dimensional position resolution of the tracking planes, this procedure works almost without

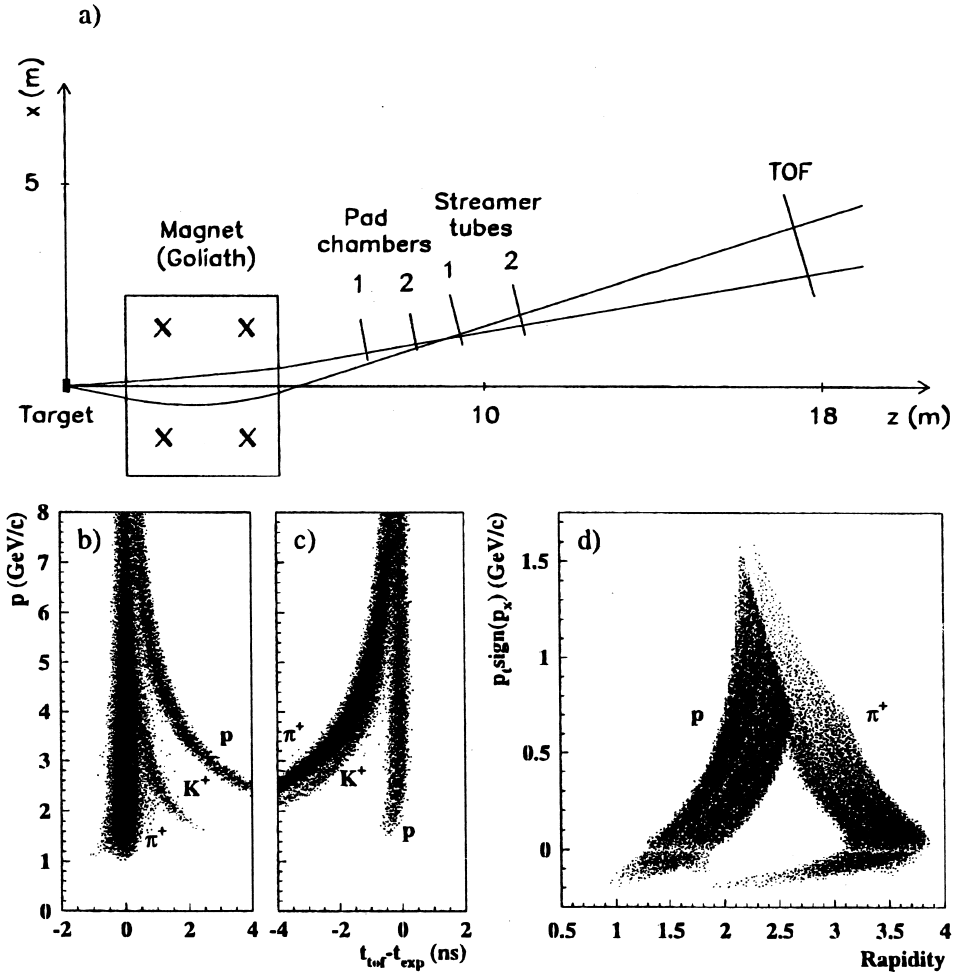

Fig. 1. (a) Overview of the tracking arm with two tracks within the acceptance. (b) Particle identification bands calculated assuming that all particles have the pion mass. (c) as in (b) assuming proton mass. (d) The distribution of accepted particles in terms of p_t and rapidity for protons and π^+.

ambiguities, in spite of the large track multiplicity within the acceptance. Cuts have been applied on the hit association in the TOF wall and on the vertical distance between the track extrapolation and the interaction point. Finally, the particle identity is obtained by cuts in $t_{\mathrm{tof}} - t_{\mathrm{exp}}$. This works up to a particle momentum of 8 GeV/c, where the separation no longer can be done unambiguously. In order not to lose any observed Δ^{++} resonances, we have chosen to use particles up to 16 GeV/c, thereby introducing a small systematic error. The small amount of contaminating kaons among pions above 4 GeV/c only gives marginal effects on the extracted Δ^{++} yield. This sort of contamination will also be present in the mixed events and its effects are to a large extent removed.

Fig. 1d shows the distributions of accepted particles for the second tracking arm in terms of transverse momentum p_t and rapidity for protons and pions. Notice the sign(p_x) factor, which unfolds the spectrum for particles with negative p_x and momentum low enough to bend across the beam line. Furthermore, a momentum cut of 8 GeV/c has been applied.

For all pairs of identified p and π^+, the invariant mass, $M_{\rm inv}$, was calculated from

$$M_{\rm inv} = \sqrt{\left(E_\pi + E_{\rm p}\right)^2 - \left(\boldsymbol{p}_\pi + \boldsymbol{p}_{\rm p}\right)^2}\,.$$

The mass resolution of the pπ^+-pair, estimated from the momentum resolution, is a few MeV. An invariant mass spectrum of such pairs (real spectrum) will consist of one part where the pion and the proton are coming from the same Δ^{++}-decay and an essentially uncorrelated combinatorial background. Due to the high multiplicity of protons and pions, the combinatorial background will be by far the dominant contribution to the invariant mass spectrum. To account for this combinatorial background, the invariant mass spectrum was calculated also with protons and pions taken from different events (mixed event). To extract the fraction ξ, of Δ^{++}, among the pπ^+-pairs, $N_{\rm pair}$, we assume that the mixed event invariant mass spectrum has the same shape as the combinatorial background in the real spectrum. This assumption has been verified by studies of ratios between real spectra and mixed event spectra. To essentially eliminate the statistical errors in the mixed event spectrum, it contains about ten times the statistics in that of the real spectrum. The real spectrum, $F(M_{\rm inv})$ can then be written as

$$F(M_{\rm inv}) = N_{\rm ev}\cdot N_{\rm pair}\big(\xi\cdot BW(M_{\rm inv},M_0,\Gamma) + (1-\xi)\,g(M_{\rm inv})\big). \qquad (1)$$

BW$(M_{\rm inv},M_0,\Gamma)$ is a modified Breit-Wigner function, filtered through our geometrical acceptance, normalized to unity. M_0 and Γ are the peak position and width respectively of the modified Breit-Wigner function. Note that neither the real spectrum nor the mixed event spectrum are corrected for acceptance. $N_{\rm ev}$ is the number of events and $g(M_{\rm inv})$ is the unit normalized mixed event spectrum. The modified Breit-Wigner function, before filtering, is given by

$$BW(M_{\rm inv},M_0,\Gamma) \propto \frac{q^3}{\left(q^3+\mu^3\right)}\,\frac{1}{\left(\left(M_{\rm inv}-M_0\right)^2+\left(\Gamma/2\right)^2\right)},$$

where q is the momentum of the proton (or pion) in the rest-frame of the pair, i.e half of the relative momentum, and $\mu = 180$ MeV/c [15]. The real spectrum can now be fitted using Eq. (1), treating ξ, M_0 and Γ as free parameters.

Fig. 2a shows the distribution of accepted Δ^{++} obtained from FRITIOF7.02 [16] events filtered through GEANT, i.e. for Δ^{++} where both decay particles fall inside the acceptance of the arm. The spectrum is unfolded in the same way as in Fig. 1d. Fig. 2b shows the invariant mass spectrum of

$$F(M_{\rm inv}) - N_{\rm ev}\cdot N_{\rm pair}\cdot(1-\xi)\,g(M_{\rm inv}),$$

i.e. the real spectrum with the background subtracted. Also shown by the solid curve is

$$N_{\rm ev}\cdot N_{\rm pair}\cdot\xi\cdot BW(M_{\rm inv},M_0,\Gamma),$$

i.e. the acceptance-filtered modified Breit-Wigner function obtained from the best fit.

The extracted number of Δ^{++} has to be corrected for acceptance and inefficiencies. Table 1 gives the values of the different correction factors with their estimated errors.

The efficiency for Δ^{++} detection is the product of the efficiencies for protons and pions. The efficiency factors given in the table are the ratio between those Δ^{++} efficiencies and the corresponding efficiencies for protons. $k_{\rm trk}$, which is about 80%, is the probability for a particle entering the arm, resulting in a track seen in at least three out of the four

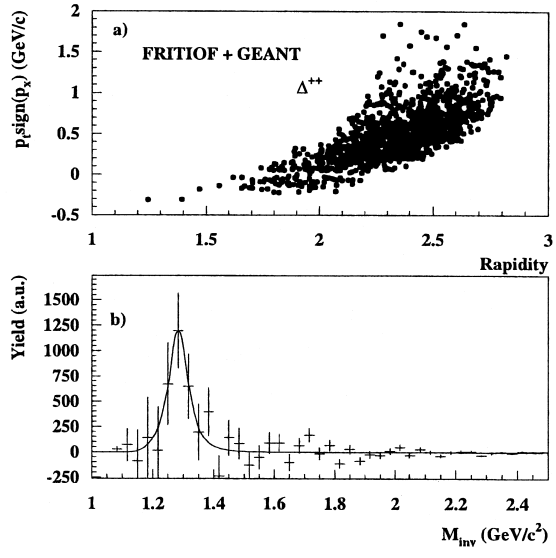

Fig. 2. (a) The distribution of accepted Δ^{++} obtained from Fritiof events. (b) The extracted Δ^{++} resonance together with the corresponding acceptance-filtered modified Breit-Wigner.

Table 1
Summary of the different correction factors and their estimated systematic errors.

Correction factors	Value
tracking efficiency, k_{trk}	0.79 ± 0.02
identification efficiency, k_{pid}	0.60 ± 0.02
geometrical acceptance, k_{geo}	0.145 ± 0.005

tracking planes and with a quality sufficient to pass the applied cuts, i.e. vertex association, χ^2 of the straight-line fit, et cetera. The k_{pid} factor corrects for the particle identification efficiency, including hardware efficiencies, effects of applied cuts on the flight times and particles decaying before reaching the TOF wall. The k_{geo} factor corrects the Δ^{++}/proton ratio for the limited azimuthal coverage of the arm estimated by GEANT simulations. The values of all the correction factors depend on the cuts we apply on the data and the systematic errors were estimated by varying these cuts within reasonable limits.

Table 2 gives the reconstructed and corrected ratio between the number of Δ^{++} and protons within the arm. Within our acceptance RQMD2.3 [17] predicts about 2.4 protons/central event and FRITIOF7.02 predicts about 5.5 protons/central event. Thus our proton multiplicity, which is about 1.83 proton per central event after efficiency corrections, seem to be in fair agreement with RQMD, whereas FRITIOF seems to overestimate.

The extraction of the Δ^{++} signal is by no means trivial as the peak is broad and the combinatorial background is large. Three different extraction methods were applied to simulated data to investigate the influence of the methods on the reconstructed number of Δ^{++} [18]. The method described above proved to be the most robust for different projectiles p, Si and Pb upon Pb target at the relevant beam energy.

Regarding the error of the extracted ratio we note that this is dominated by the statistical fluctuations in the number of combinatorial pairs under the resonance peak. Thus it is impossible to obtain the ratio with higher precision with the given statistics, independent of the extraction method. A study based on simulation results with different event generators, and variation of cuts applied to the data, indicates that the systematic error contributions resulting from the various cuts and correction factors applied to the data are considerably smaller (of the order of 10% of the obtained value) and therefore negligible in comparison to the statistical error.

However, it was observed that the chosen extraction method tended to systematically overestimate the number of Δ^{++} in simulations. A special simplified Monte Carlo event generator was constructed in order to study this effect. With this generator, several hundreds of samples of the same size as the real data sample was studied [19]. The reason for the overestimation is that although the background estimated with mixed events is almost identical to the background in the data, small differences are present. For instance, correlations between the decay products from different Δ^{++} resonances are believed to add to the systematic error of the extraction method. Pairs with the pion and proton from two different Δ^{++} decays, are almost identical to a pair originating from the same Δ^{++} due to the restricted acceptance of the tracking arm. The magnitude of the overestimation and associated error has been determined from the simulations and a correction has been applied for the ratio and error as shown in Table 2. The correction leads to an increased relative error in the ratio.

The ratio of $\Delta(1232)$/nucleons has been studied and an increase as a function of incoming beam energy has been established [8]. In a thermal model this can be interpreted as an increase of the freeze-out temperature which determines the relative population of the nucleonic resonances. The same ratio can be estimated from our data. In an isospin symmetric system, one could obtain the total number of $\Delta(1232)$ resonances, i.e. Δ^-, Δ^0, Δ^+ and Δ^{++}, by multiplying the number of Δ^{++} by an isospin factor four. In the same way, the number of nucleons, including those from resonance decays, could be estimated by multiplying the measured number of protons with a factor two. In our case, where we have an isospin

Table 2
Summary of the results.

119677 central events	Δ^{++}/proton ratio
reconstructed (uncorrected)	0.031 ± 0.015
corrected for systematic fitting error	0.021 ± 0.013
full ϕ and eff. corrected	0.309 ± 0.190

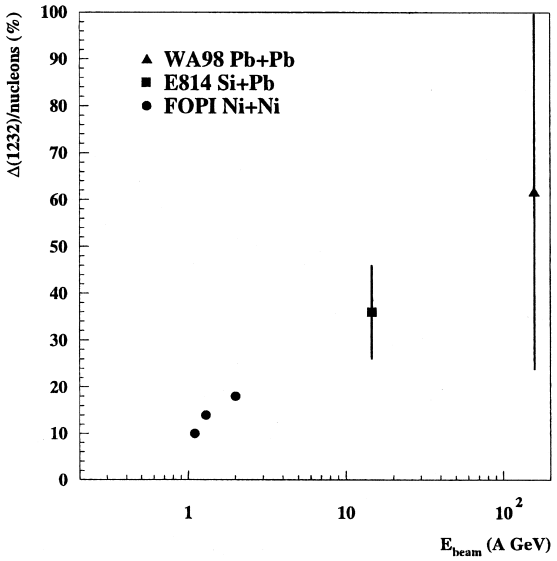

Fig. 3. The ratio $\Delta(1232)$/nucleons as a function of beam energy/nucleon.

asymmetry, in a first approximation the nucleons and the Δ-resonances are affected in the same way, and thus no correction for the isospin asymmetry is applied. Only a small contribution of baryon number is present in deuterons and weakly decaying hyperons, where the decay proton might be lost in the tracking due to the secondary vertex being far from the interaction point.

Our obtained ratio for nucleons originating from $\Delta(1232)$ resonances, is found to be quite large at central rapidities, 0.62 ± 0.38. Fig. 3 shows our results in comparison with similar results from experiments at lower beam energies. Note that the target and projectile rapidities are separated by 5.8 units at 158 A GeV. In this experiment the influence of spectator matter is thus much less than at lower beam energies.

Our obtained value of the $\Delta(1232)$/nucleon ratio can be compared to the ratio obtained from thermal model calculations, assuming chemical and thermal equilibrium. In such a calculation the maximum ratio obtained is around 0.33 [2]. Furthermore this ratio is obtained over a large range of temperatures and baryon densities, used as input to the calculations.

However, it should be pointed out that the experimental ratio also contain contributions from prior to freeze-out. For this and other reasons, e.g. the saturation of the ratio as a function of temperature, it is premature to use the experimentally extracted ratio for a precise temperature estimation and any temperature above 100 MeV seems to be in qualitative agreement with the obtained ratio.

Besides the yield, the fitting procedure also provides the width and mass of the delta peak. However the systematic errors in these values, estimated by changing cuts and extraction methods and by applying the methods to Monte Carlo samples with known parameters, are sufficiently large to preclude a meaningful discussion of a possible mass shift or changes of the width of the delta peak.

Abstract. Two-particle correlations have been measured for identified π^- from central 158 A GeV Pb+Pb collisions and fitted radii of about 7 fm in all dimensions have been obtained. A multi-dimensional study of the radii as a function of k_T is presented, including a full correction for the resolution effects of the

apparatus. The cross term $R^2_{out-long}$ of the standard fit in the Longitudinally CoMoving System (LCMS) and the v_L parameter of the generalised Yano-Koonin fit are compatible with 0, suggesting that the source undergoes a boost invariant expansion.

The shapes of the correlation functions in Q_{inv} and $Q_{space} = \sqrt{Q_x^2 + Q_y^2 + Q_z^2}$ have been analyzed in detail. They are not Gaussian but better represented by exponentials. As a consequence, fitting Gaussians to these correlation functions may produce different radii depending on the acceptance of the experimental setup used for the measurement.

1 Introduction

The study of Bose-Einstein correlations between pairs of identical hadrons is an essential tool to obtain information on the space-time evolution of the extended hadron sources created in heavy ion collisions [1]. In particular, a strong correlation between the momenta and the space-time production points of the particles suggests expanding sources as predicted by hydrodynamic models [2]. The dynamical evolution of such systems can then be studied with interferometry via selection on the transverse momenta and rapidity of the correlated particle pairs.

In this paper, we present the analysis of two-particle correlations of identified π^- measured in the WA98 experiment for central 158 A GeV Pb+Pb collisions at the CERN SPS.

2 Experimental setup and data processing

The WA98 experiment shown in Fig. 1 combined large acceptance photon detectors with a two arm charged particle tracking spectrometer. The incident 158 A GeV Pb beam interacted with a Pb target near the entrance of a large dipole magnet. Non-interacting beam nuclei, or beam fragments were detected in a forward calorimeter located at zero degree. A mid-rapidity calorimeter measured the total transverse energy in the rapidity region $3.2 \leq \eta \leq 5.4$, which was also used in the trigger for online centrality selection. The Plastic-Ball calorimeter measured the fragmentation of the target, and silicon detectors were used to measure the charged particle multiplicity. The photon detectors consisted of a large area photon multiplicity detector and a high granularity lead-glass calorimeter for single photon, π^0, and η physics [3].

The charged particle spectrometer made use of a 1.6 Tm dipole magnet with a 2.4×1.6 m^2 air gap for magnetic deflection of the charged particles in the horizontal plane. The results presented in this paper are taken from the 1995 WA98 data set obtained with the negative particle tracking arm of the charged particle spectrometer. The second tracking arm was added to the spectrometer in 1996 to measure positive particles [4]. The first tracking arm consisted of six multistep avalanche chambers with optical readout [5] located downstream of the magnet. The active area of the first chamber was 1.2×0.8 m^2, while that of the other five was 1.6×1.2 m^2. The chambers contained a photoemissive vapour (TEA) which produced UV photons along the path of traversal of the charged particles. These were converted into visible light via wavelength shifter plates. On exit the light was reflected by mirrors at 45° to CCD cameras equipped with two image intensifiers. Each pixel of a CCD viewed a 3.1×3.1 mm^2 area of a chamber. In addition, a 4×1.9 m^2 Time of Flight wall positioned behind the chambers at a distance of 16.5 m from the target allowed for particle identification with a time resolution better than 120 ps.

Figure 2 shows the Monte Carlo generated p_T-rapidity acceptance for π^-. The acceptance ranges from y=2.1 to 3.1 with an average at 2.70. The momentum resolution of the spectrometer was $\Delta p/p$=0.005 at p=1.5 GeV/c, resulting in an average accuracy better than or equal to 10 MeV/c for all the Q variables used in the interferometry analysis and defined in section 5: $\sigma(Q_{inv})$=7 MeV/c, $\sigma(Q_{TO})$=10 MeV/c, $\sigma(Q_{TS})$=5 MeV/c, $\sigma(Q_L)$=3 MeV/c, $\sigma(Q_T)$=8 MeV/c, $\sigma(Q_0)$=5 MeV/c.

The analysis of the complete 1995 data set is presented here. These data have been taken with the most central triggers corresponding to about 10% of the minimum bias cross section of 6190 mb. Severe track quality cuts were applied at the expense of statistics resulting in final samples of 4.2×10^6 π^- for the correlation analysis and 4.6×10^5 π^- for the single particle spectrum.

3 Single particle spectra

The m_T=$\sqrt{m_\pi^2 + p_T^2}$ distribution of identified π^-, averaged over the rapidity acceptance, is shown in Fig. 3. The data were corrected for geometrical acceptance and efficiency of the chamber-camera-Time of Flight system using a full simulation of the experimental setup. The parameters of the simulation were optimized in an iterative way by comparing various distributions with the real data. The simulated data were then treated exactly like the real data. The measured $1/m_T\, dN/dm_T\, dy$ distribution was then fitted to the form $C\exp(-m_T/T)$, expected for a source in thermal equilibrium [6]. Such fits were applied to the data for different ranges of m_T, such as the one shown in Fig. 3. These fits do not reproduce the overall concave shape of the data, which is partly due to particles originating in resonance decays and could also be an indication of transverse flow [7]. The shape of the π^- m_T distribution was found to be in good agreement with that of π^0 obtained in the lead-glass calorimeter [3].

4 One-dimensional interferometry analysis

For the Bose-Einstein correlation studies, the data were Coulomb corrected in an iterative way [8]. The Gamow correction was abandoned as it overcorrects the data for

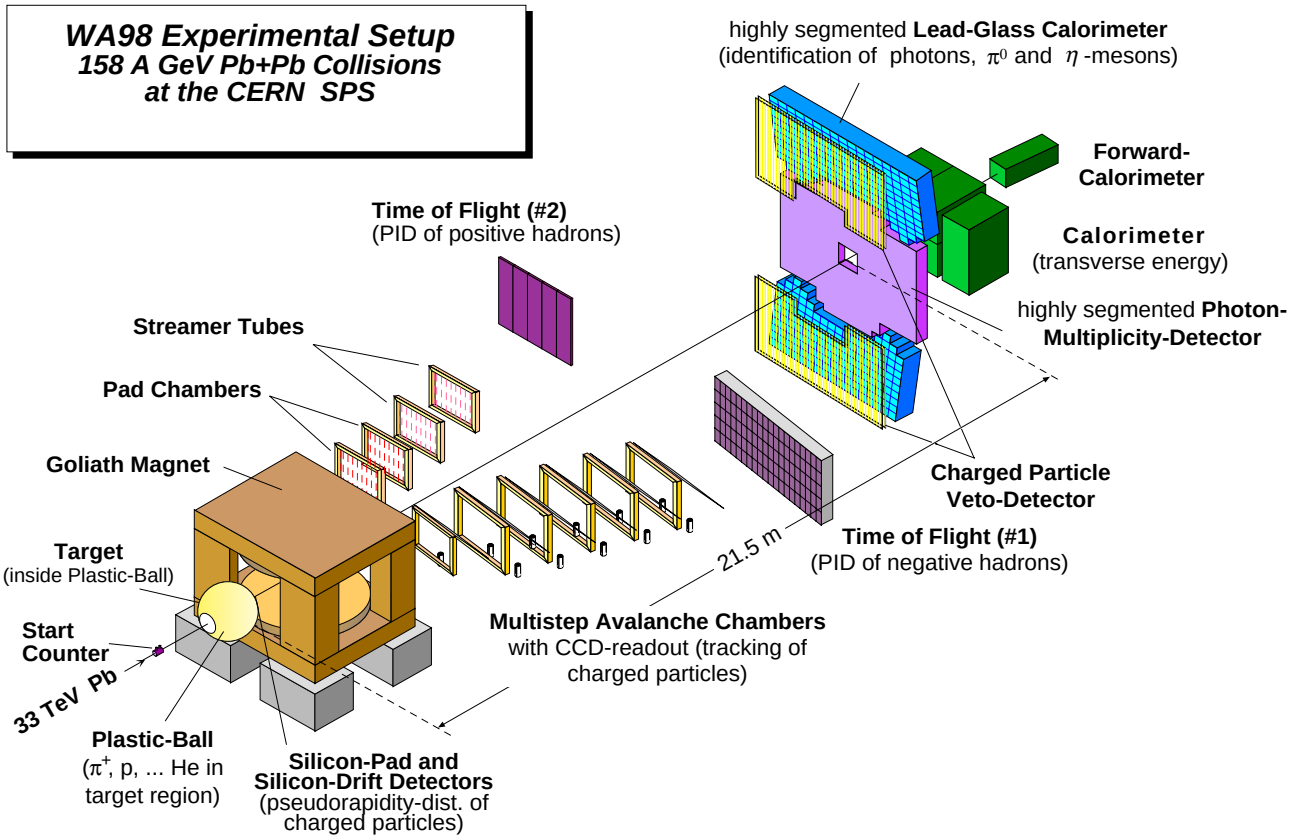

Fig. 1. Experimental setup

Q_{inv} in the range of 0.1 to 0.3 GeV/c. A fit of the form $1+\lambda\exp[-Q_{inv}^2 R_{inv}^2]$ was made to the Q_{inv} correlation function yielding $R_{inv} = 6.83 \pm 0.10$ fm and $\lambda = 0.307 \pm 0.008$. An expanded view of the correlation distribution (Fig. 4) shows that the Gaussian fit used (full line) is not perfect, especially in the Q_{inv} range of 40 to 80 MeV/c where the tail of the experimental distribution shows an excess which is not well reproduced by the fit. In addition to this Gaus-

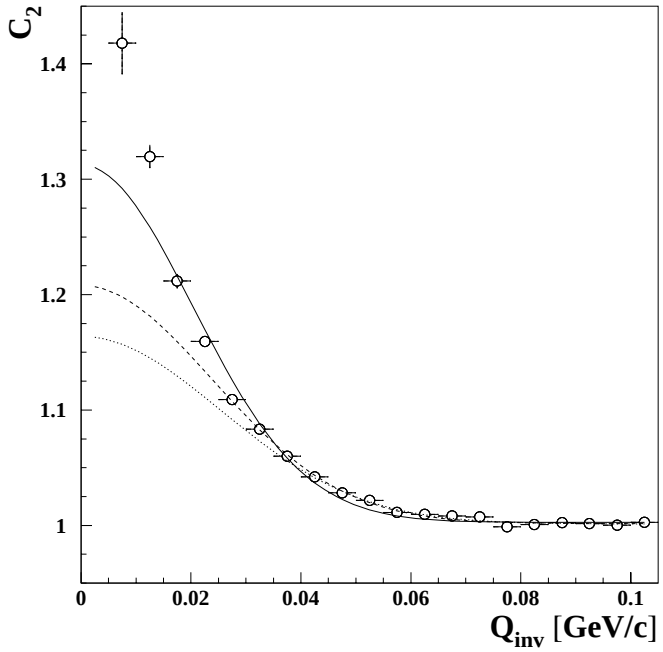

Fig. 4. Q_{inv} distribution with Gaussian fits. The full line is a fit made with all the points. The dashed line is a fit for $Q_{inv} \geq 25$ MeV/c and the dotted line is a fit for $Q_{inv} \geq 40$ MeV/c

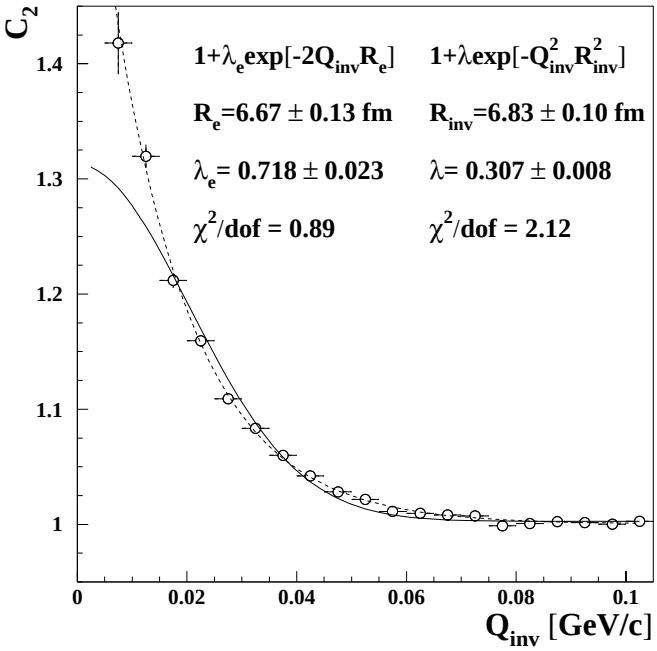

Fig. 5. Q_{inv} distribution with the Gaussian fit (full line) and the exponential fit (dashed line)

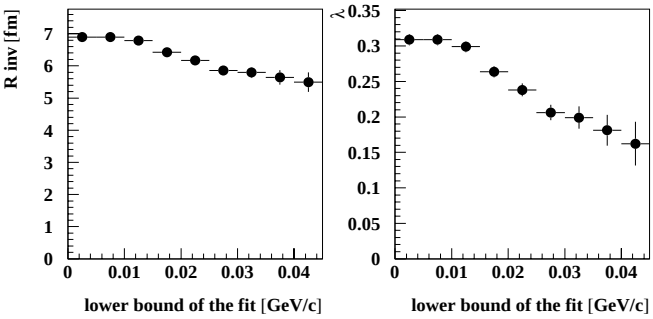

Fig. 6. Gaussian fit stability

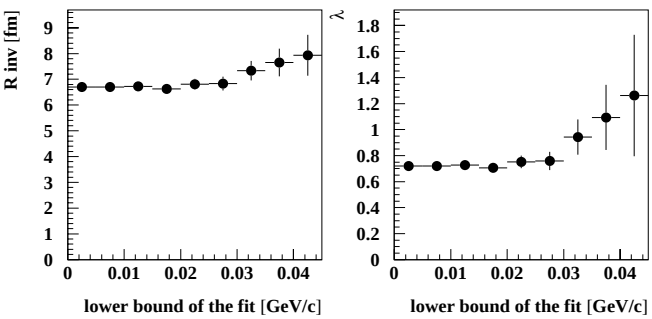

Fig. 7. Exponential fit stability

sian fit made over the whole range of Q_{inv}, Fig. 4 shows also different Gaussian fits using data in the ranges 25 MeV/c $\leq Q_{inv} \leq$ 200 MeV/c (dashed line) and 40 MeV/c $\leq Q_{inv} \leq$ 200 MeV/c (dotted line). These fits do not coincide. Different radii are then obtained for different starting points of the fit because the shape of the distribution is not Gaussian. This effect is independent of the severity of the track selection, and is therefore not due to spurious tracks. This is summarized in Fig. 6 where R_{inv} and the corresponding λ are plotted as a function of the lower bound of the fit. There is a statistically significant drop when using a Gaussian fit. A similar behaviour is observed when, instead of Q_{inv}, $Q_{space} = \sqrt{Q_x^2 + Q_y^2 + Q_z^2}$ is used, calculated in the longitudinally comoving system (LCMS) and fitted with $1+\lambda\exp[-Q_3^2R_3^2]$. This method of fitting in varying ranges has a good sensitivity to the shape. It has been repeated by replacing the Gaussian fit by an exponential fit of the form $1+\lambda_e\exp[-2Q_{inv}R_e]$ where the factor 2 is added to make the radius R_e more comparable with R_{inv}. The results (Fig. 7) show that the stability is better with the exponential fit. Figure 5 directly compares the Gaussian and exponential fits for Q_{inv}. Although the Gaussian fit still gives an acceptable χ^2/d.o.f., the exponential fit is better everywhere. A similar conclusion is reached when the first data point is excluded from the fit. This result is not based on the first bins which might be more affected by systematics due to large Coulomb correction or noise correlated with the true track signals in the chambers. It is rather based on the high statistics tail of the distribution which contributes in a different way to a Gaussian or an exponential fit. This quasi exponential behaviour is expected by different models including resonance decays [9]. As a consequence small acceptance experiments may obtain a larger radius if a Gaussian fit is used because they are less sensitive to the tail. On the contrary large acceptance experiments have higher statistics at large Q-values, and the Gaussian fit will yield lower values of the radius.

Table 1. 3-dimensional analysis

Standard fit in LCMS			Generalized Yano-Koonin fit		
R_{TS}	=	6.41±0.13 fm	R_T	=	6.54±0.11 fm
R_{TO}	=	6.60±0.16 fm	R_0	=	0.01±0.69 fm
R_L	=	7.50±0.18 fm	R_4	=	7.51±0.18 fm
λ	=	0.350±0.010	λ	=	0.325±0.009
$R^2_{out-long}$	=	-1.0±1.3 fm^2	v_L	=	0.03±0.05
χ^2/d.o.f.	=	1.06	χ^2/d.o.f.	=	1.02

5 Multi-dimensional interferometry analysis

The multi-dimensional analysis has been done with Gaussian fits to allow comparison with other experiments. Two different parameterizations have been used in the LCMS:

a) The standard fit in the 3-dimensional space of momentum differences Q_{TS} (perpendicular to the beam axis and to the transverse momentum of the pair), Q_{TO} (perpendicular to the beam axis and parallel to the transverse momentum of the pair), and Q_L (parallel to the beam axis) [10]. The fitted formula

$$C_2 = 1 + \lambda \exp[-Q^2_{TS}R^2_{TS} - Q^2_{TO}R^2_{TO} - Q^2_L R^2_L - 2Q_{TO}Q_L R^2_{out-long}]$$

includes a cross term in $Q_{TO}Q_L$ as predicted [11].

b) The generalized Yano-Koonin (GYK) fit [12] in the Q_0 (energy difference of the pair), Q_T,Q_L space according to

$$C_2 = 1+\lambda \exp[-Q^2_T R^2_T + (Q^2_0 - Q^2_L)R^2_4 - (Q\cdot U)^2(R^2_0 + R^2_4)]$$

where $U = \gamma(1, 0, 0, v_L)$, $\gamma = 1/\sqrt{1 - v^2_L}$ with v_L in units of c=1.

In the GYK approach, the radius parameters remain invariant under longitudinal Lorentz boost, the parameter v_L connecting the "arbitrary" measurement frame (LCMS) to the Yano-Koonin frame. In addition, the extraction of the duration of emission, R_0, is straightforward.

The consequence of the finite resolution in the measurement of the Q variables is an underestimate of the radii and λ parameters. Morever, as the resolution is different for each Q variable, this causes a bias which varies from parameter to parameter, leading to errors in the interpretation of the results in a multi-dimensional analysis. It is therefore essential to take into account the effect of the resolution in the fitting procedure. One way to do this is to replace the formula $C_2(\mathbf{Q})$ used to fit the data by

$$C^{rc}_2(\mathbf{Q}) = \iiint r(\mathbf{Q}, \mathbf{Q}')\, C_2(\mathbf{Q}')\, d\mathbf{Q}'$$

which is the convolution of $C_2(\mathbf{Q})$ with the resolution function $r(\mathbf{Q}, \mathbf{Q}')$. The resolution function is chosen to be Gaussian:

$r(\mathbf{Q}, \mathbf{Q}') = 1/(2\pi)^{3/2}\, 1/|V|^{1/2}$

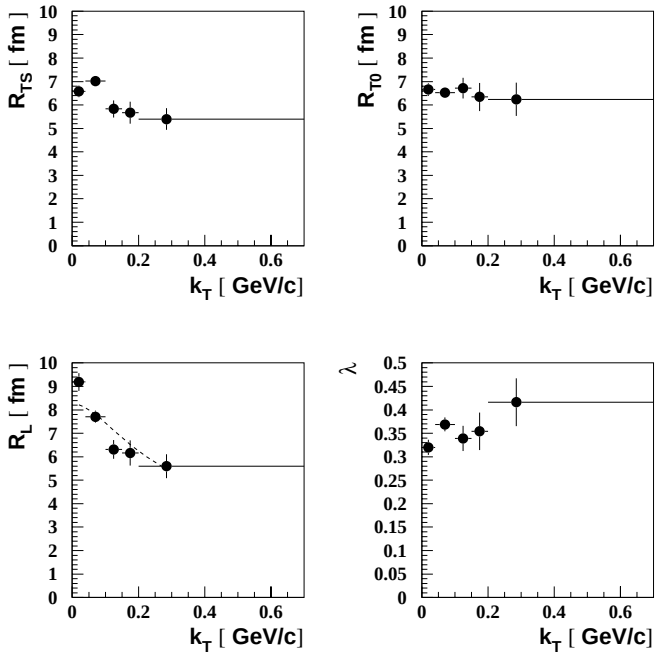

Fig. 8. 5-parameter fit as a function of k_T. The horizontal bars indicate the bin width and the points are plotted at the average k_T of the bin. The dashed line in the bottom left figure shows the result of a fit explained in the text

$$\times \exp[-1/2\, (\mathbf{Q} - \mathbf{Q}')^T\, V^{-1}\, (\mathbf{Q} - \mathbf{Q}')]$$

The diagonal elements of the covariance matrix V are equal to the square of the resolution of the different Q variables and are estimated separately as a function of $k_T = |\mathbf{p}_{T1} + \mathbf{p}_{T2}|/2$ of the pairs. The non-diagonal elements are neglected. For the one-dimensional Gaussian fit case with $\mathbf{Q} = Q_{inv}$, the resolution corrected values of the fitted parameters are $R_{inv} = 7.30 \pm 0.12$ fm and $\lambda = 0.328 \pm 0.009$.

The results of the multi-dimensional fits are presented in Table 1 for the full 1995 data sample. A multi-dimensional analysis as a function of k_T, both with the standard 5-parameter fit and with the GYK fit is shown in Figs. 8, 9, and 10.

The R_{TS} and R_L parameters from the standard fit are found to be compatible respectively with R_T and R_4 from the GYK fit. The cross term $R^2_{out-long}$ from the standard fit and v_L from the GYK fit are compatible with 0. In a source undergoing a boost invariant expansion, the lo-

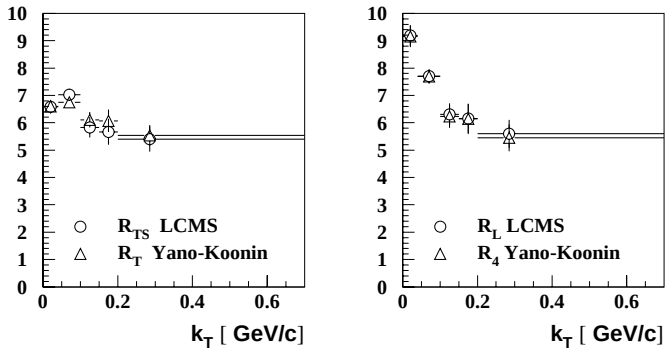

Fig. 9. Comparison of the R_{TS} and R_L parameters from the standard fit respectively with R_T and R_4 from the GYK fit as a function of k_T

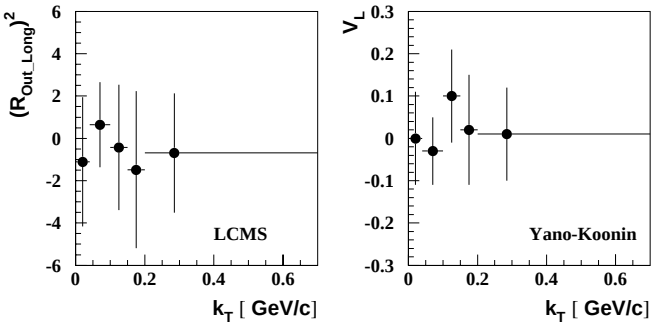

Fig. 10. The cross term $R^2_{out-long}$ from the standard fit and v_L from the GYK fit, both estimated in the LCMS, are compatible with 0 for all k_T bins

cal rest frame coincides with the LCMS. Both the cross term and v_L estimated in the LCMS are then expected to vanish [12]. As this is the case, it suggests that the source seen within the acceptance of the experiment has a strictly boost invariant expansion. The strong decrease of the longitudinal radius R_L or R_4 with k_T compared to the behaviour of the transverse radii R_T, R_{TS}, R_{TO} suggests a longitudinal expansion larger than the lateral expansion. The longitudinal radius R_L is shown with a fit of the form $1/\sqrt{m_T}$ with m_T=$\sqrt{m_\pi^2 + k_T^2}$ inspired by the hydrodynamical expansion model. Using $R_L = \tau_0\sqrt{T_0/m_T}$ with a freeze out temperature T_0 of 120-170 MeV/c, we may extract a freeze out time τ_0 in the range of 7.5-8.9 fm/c. Finally, the R_0 parameter from the GYK fit, which reflects the duration of emission, is compatible with 0 for all k_T bins, excluding a long-lived intermediate phase.

Two other experiments, NA49 and NA44, have studied charged particle interferometry in Pb+Pb collisions at CERN energies. The WA98 analysis is in good agreement with the NA49 results[13], when the comparison is made for the same mean y range of 2.70, although WA98 has used identified π^- while the NA49 analysis used unidentified negative particles. Only the R_0 parameter tends to be smaller in WA98. The direct comparison with the NA44 experiment is not possible because NA44 and WA98 do not have the same y range. The smaller radii measured by NA44[14] can be explained by the larger y range of its acceptance ($3.1< y <4.1$).

6 Conclusion

The analysis of the two-particle correlation of identified π^- from central Pb+Pb collisions at 158 A GeV gives fitted radii of about 7 fm. This should be compared to the equivalent rms radius of the initial Pb nucleus of 3.2 fm, which indicates a large final state emission volume.

The one-dimensional correlation functions analyzed in terms of Q_{inv} or Q_{space} are not Gaussian. They are better represented by exponentials. This study is based on the tail of the distributions and not on the first bins which might be subject to systematic effects. One possible explanation is that this behaviour is due to resonance effects. Fitting Gaussians to these correlation functions may produce different results depending on the acceptance of the experimental setup.

The generalized Yano-Koonin analysis gives similar results to within the error bars as the standard 3-dimensional analysis in the LCMS.

The cross term $R^2_{out-long}$ is found to be compatible with 0 in the LCMS and the same is true of v_L in the GYK fit. This suggests that the source undergoes a boost invariant expansion.

A clear dependence of the longitudinal radius parameter on k_T is observed, suggesting a larger longitudinal than transverse expansion of the source. In addition the short duration of emission disfavours any long-lived intermediate phase.

Abstract

An event-by-event analysis of the azimuthal angular correlation with respect to the reaction plane has been carried out for K^+ and π^+ emission near mid-rapidity in 158 $A\cdot$GeV Pb + Pb collisions. In semi-central collisions, K^+ mesons are found to be preferentially emitted out of the reaction plane, while π^+ mesons are emitted in the reaction plane. The results suggest that the kaon emission is influenced by in-medium potential effects in addition to collective flow effects. © 1999 Published by Elsevier Science B.V. All rights reserved.

1. Introduction

Relativistic heavy ion collisions provide a unique tool for the study of nuclear properties at high temperature and density. The study of collective motion in the final state of the produced hadrons is expected to provide information on both the dynamics of heavy-ion collisions and the equation of state [1]. The observation of collective behavior in the system provides a validation of a hydrodynamical description of the dynamics. Once a hydrodynamical interpretation is established the collective motion will result from pressure gradients in the matter, which will reflect the compressibility of the underlying equation of state. In the case of a phase transition from ordinary matter to quark-gluon plasma, it is expected that the compressibility should exhibit a softening due to the increased number of degrees of freedom [2].

A standard way to search for collective motion in the final state is to analyze the azimuthal distribution of particle emission with respect to the reaction

plane in terms of a Fourier expansion. The first two coefficients in the Fourier decomposition are termed the directed and elliptic flow components. The importance of collective motion measurements has been emphasized by several authors [2–5] and measurements have been reported over a range of energies; directed and elliptic flow at $0.1 \sim 1$ $A \cdot$GeV [6–9], at 10 $A \cdot$GeV [10] and also at 158 $A \cdot$GeV [11,12]. One of the striking features of these results is the change of the elliptic flow direction from out-of-plane (squeeze-out) to in-plane in the region between 1 $A \cdot$GeV and 100 $A \cdot$GeV incident energy.

The azimuthal distribution of a particular particle species in the final state is also expected to be sensitive to the in-medium potential of the particle. Namely, it is interesting to study the distributions of K^+ and K^- mesons because the kaon-nucleon potential in nuclear matter is expected to be repulsive for K^+ but attractive for K^- mesons [13–15].

Recently, the elliptic emission of nucleons, pions, and K^+ mesons has been observed in the mid-rapidity region in $0.8 \sim 1$ $A \cdot$GeV ^{197}Au + ^{197}Au and ^{209}Bi + ^{209}Bi collisions [7–9]. The observed out-of-plane emission of K^+ mesons is claimed as a consequence of the repulsive K^+-nucleon potential. On the other hand, pions and nucleons also show out-of-plane emission at this energy, which is interpreted as dominantly due to the shadowing effect of the spectator nucleons [7,16,17].

At higher incident energies, particles produced near mid-rapidity are not expected to interact with the spectator matter due to the short crossing time of the collisions. Therefore, the in-medium potential effects might be more clearly visible at SPS energies [18]. In this letter we present the azimuthal distributions, relative to the reaction plane, of K^+ and π^+ mesons near mid-rapidity in 158 $A \cdot$GeV Pb + Pb collisions. This is the first observation of the elliptic emission of K^+ mesons at SPS energies.

2. Experimental setup

The data presented here were taken with a subset of the WA98 experiment detector system using the 158 $A \cdot$GeV ^{208}Pb beams of the CERN-SPS on a Pb target of 213 μm thickness. In the WA98 setup the incident Pb beam provides a trigger by a valid signal in a gas Cherenkov start counter with a timing resolution of 30 ps and no signal in a downstream veto counter with a 3 mm diameter hole. The minimum bias trigger and centrality of the collision is determined by the total transverse energy, E_T, measured with the mid-rapidity calorimeter (MIRAC) which covers the pseudo-rapidity range of $3.5 < \eta < 5.5$. The Plastic Ball detector has full azimuthal coverage in the pseudo-rapidity range of $-1.7 < \eta < 0.5$. It identifies pions, protons, deuterons, and tritons with kinetic energies of 50 to 250 MeV by simultaneous ΔE and E measurement using the mass and energy dependence of dE/dx [11]. The measurement of identified particles near mid-rapidity is performed using two tracking spectrometer arms with a large (1.6 m) aperture dipole magnet (GOLIATH) which provides 1.6 Tm bending power. The particle identification is based on a measurement of momentum and time-of-flight.

The present analysis has been performed on the full sample of WA98 positive charged particle tracking arm data. This data sample is limited due to the fact that the positive charged particle tracking arm was installed only for the final run period of WA98. The tracking arm has a momentum resolution of $\Delta p/p \simeq 0.97\% + 0.16\% p + 0.023\% p^2$ (p in GeV/c) and a time-of-flight resolution of < 90 ps. The rapidity and transverse momentum (y, p_T) coverages of the Plastic Ball and the tracking arm are shown in Fig. 1. The (y, p_T) coverages for the

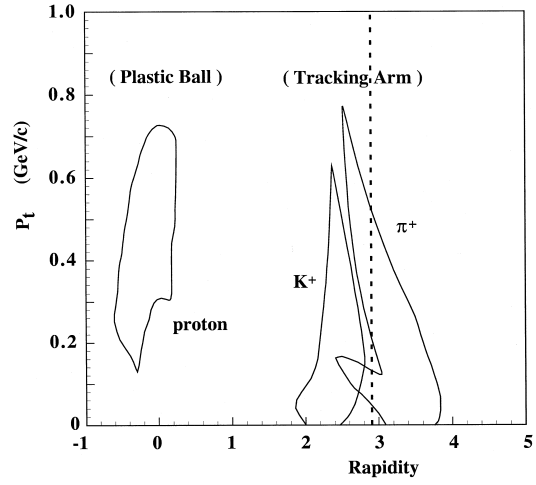

Fig. 1. The rapidity and transverse momentum (y, p_t) coverages of the Plastic Ball detector and the tracking arm. The midrapidity of the collisions is shown as dashed line.

Table 1
Results of the Fourier analysis of K^+ and π^+ mesons for semi-central 158 $A\cdot$GeV Pb + Pb collisions. The values are integrated over the indicated y and p_T ranges. Positive v_1 corresponds to an emission in the same direction as nucleons. Observed negative value of v_1 for π^+ indicates so-called anti-flow of pions. Positive and negative v_2 corresponds to an in-plane and out-of-plane elliptic emission, respectively. The values are obtained numerically by evaluating $\langle\cos(\phi-\Phi_0)\rangle$ and $\langle\cos(2(\phi-\Phi_0))\rangle$, with corrections of the reaction plane resolution at each E_T bin. The errors include the statistical errors and the errors of the experimental resolution of the reaction plane determination

Particle	y	p_T (GeV/c)	v_1	v_2
K^+	2.2–2.8	0.05–0.60	-0.004 ± 0.031	-0.24 ± 0.14
π^+	2.4–3.4	0.05–0.80	-0.010 ± 0.006	0.047 ± 0.024

present analysis are listed in Table 1. Detailed information about the positive tracking arm [20] and the experiment can be found elsewhere [11,19].

3. Experimental results

The reaction plane is determined from the azimuthal direction of the total transverse momentum vector of fragments (p, d, and t) observed by the Plastic Ball detector [11]. The azimuthal angle of the reaction plane, Φ_0 in the laboratory is determined as

$$\Phi_0 = \tan^{-1}\left(\frac{\sum_{i=1}^{N} p_{Ti}\sin(\phi_i)}{\sum_{i=1}^{N} p_{Ti}\cos(\phi_i)}\right), \qquad (1)$$

where the sum runs over all fragments. Here ϕ_i and p_{Ti} are the azimuthal angle in the laboratory and the transverse momentum of the i-th fragment, respectively. The multiplicity of protons in the Plastic Ball detector is around 8 in semi-central collisions and a minimum of three protons is required for this analysis. The Φ_0's accumulated for many events should be uniformly distributed if there is no detector bias. The observed Φ_0 distribution has a variation of less than 2% due to the detector biases such as dead channels and inefficiency. In the following analysis, we have corrected for this effect by weighting with the inverse of the yield although there is no significant difference in the results obtained with or without this correction.

The angular correlation between the azimuthal angle ϕ of K^+ and π^+ near mid-rapidity and the Φ_0 determined in the target rapidity region has been studied. Since the acceptance of π^+ crosses mid-rapidity, Φ_0 was rotated by 180° for particles in the region forward of mid-rapidity. Otherwise, the extracted value of the directed flow would be underestimated since it changes sign at mid-rapidity. Fig. 2 shows the azimuthal distributions of K^+ and π^+ mesons with respect to the reaction plane for semi-central ($50 < E_T < 250$ GeV in MIRAC) and central ($320 < E_T < 500$ GeV) Pb + Pb collisions. For π^+ mesons in semi-central collisions, the azimuthal distribution indicates weak maxima at $\phi-\Phi_0 = 0°$ and $\pm180°$, which indicates an enhanced emission in the reaction plane. On the other hand, the K^+ azimuthal distribution in semi-central collisions exhibits maxima at $\phi-\Phi_0 = \pm90°$ which demonstrates an enhanced emission out of the reaction plane. Although the statistics is limited, the results provide evidence that the K^+ emission axis is orthogonal to the in-plane emission axis of the π^+. In central collisions, as shown in Fig. 2, the azimuthal distributions for both particle types are nearly flat, as expected from the near azimuthal symmetry of the collision system at small impact parameter.

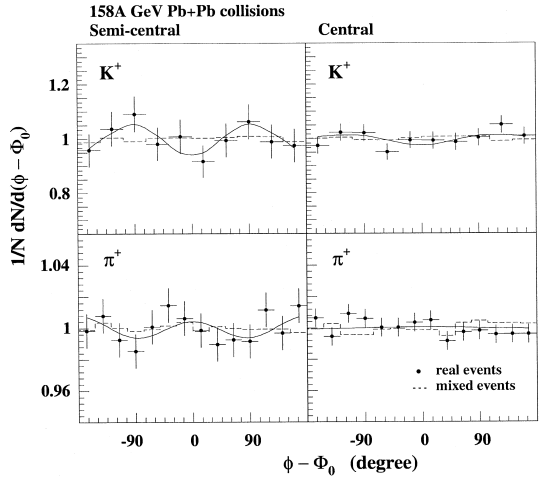

Fig. 2. The azimuthal distributions of K^+ and π^+ mesons with respect to the reaction plane for semi-central and central 158 $A\cdot$GeV Pb + Pb collisions. Solid circles with error bars show the real events and dashed histograms show the results of the mixed events. The solid curves show the fits using Eq. (2). The (y, p_T) coverages for this analysis are listed in Table 1.

To test for detector effects, such as geometrical acceptance and detector efficiency, fake events were created using a mixed-event method which were then analyzed in the same manner as the real events. The mixed-event results are shown as histograms in Fig. 2. The azimuthal distributions for the mixed-events are flat which indicates that the observed anisotropies are not due to detector effects.

The strength of the azimuthal anisotropy is evaluated by means of a Fourier expansion [21,22]. The Fourier coefficients $v_n(n=1,2)$ can be extracted from the azimuthal distribution of identified particles with respect to Φ_0;

$$\frac{1}{N}\frac{dN}{d(\phi-\Phi_0)} = 1 + 2v_1'\cos(\phi-\Phi_0) + 2v_2'\cos(2(\phi-\Phi_0)), \qquad (2)$$

where ϕ is the azimuthal angle of the particle in the laboratory frame. The Fourier coefficient v_1' quantifies the directed flow, whereas v_2' quantifies the elliptic flow. Positive v_1' corresponds to an emission in the same direction as nucleons. (Please note that this definition is opposite to our previous reports [11].) The coefficient v_2' is negative for an out-of-plane emission and positive for an in-plane emission.

The observed distributions are affected by the experimental resolution of the reaction plane determination. Since the measured Fourier coefficients are reduced by this effect, they should be corrected as [21–23]

$$v_n = \frac{v_n'}{\langle\cos(n\Delta\Phi)\rangle}, \quad (n=1,2), \qquad (3)$$

where $\Delta\Phi$ is the deviation from the true reaction plane and $\langle\ \rangle$ indicates the mean value summed over all events. The reaction plane resolution is determined by randomly subdividing the full event into two equal size subevents and extracting $\langle\cos(\Delta\Phi)\rangle \approx \sqrt{2}\cdot\sqrt{\langle\cos(\Phi_a-\Phi_b)\rangle}$, where Φ_a and Φ_b are the azimuthal angles of the reaction plane of two equal size subevents. Using the more accurate interpolation formula of Ref. [22] one obtains $\langle\cos(\Delta\Phi)\rangle = 0.360 \pm 0.018$, $\langle\cos(2\Delta\Phi)\rangle = 0.084 \pm 0.005$ for semi-central collisions.

The values of the Fourier coefficients $v_n(n=1,2)$ are obtained numerically by evaluating $\langle\cos(\phi-\Phi_0)\rangle$ and $\langle\cos(2(\phi-\Phi_0))\rangle$, respectively. The results for semi-central collisions are listed in Table 1 [1]. The values have been corrected for the reaction plane resolution according to Eq. (3) at each E_T bin. The value of v_1, indicating the strength of the directed flow, is negative for π^+, which corresponds to the direction opposite to the nucleons. This so called anti-flow of pions has been previously reported [11,12]. The value of v_1 for the K^+ meson is compatible with zero. The value of v_2 for the K^+ meson is negative with a 1.7σ separation from zero, while the value of v_2 for the π^+ mesons is positive with a 1.9σ separation from zero. Under the assumption of gaussian errors these results correspond to confidence levels of 95.7% and 97.5% for the assignment of the sign of v_2 for K^+ and π^+, respectively. Although the significance of the result is limited by statistics, one may conclude at the 93% confidence level that the elliptic emission planes for K^+ and π^+ are oriented orthogonally to one another. The systematic errors on the v_2 values due to the contamination from other particle species are estimated to be less than 8% for K^+ and 2% for π^+.

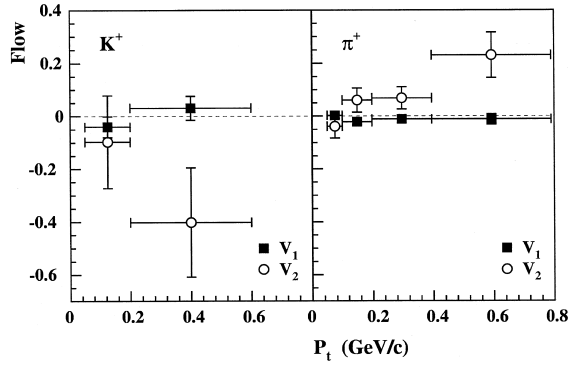

Fig. 3. The p_T dependence of the v_1 and v_2 values of K^+ and π^+ mesons for semi-central 158 $A\cdot$GeV Pb + Pb collisions. The rapidity coverages are listed in Table 1. The results are corrected for the experimental resolution of the reaction plane determination. Solid squares are used for v_1 and open circles for v_2.

Fig. 3 shows the v_1 and v_2 values as a function of the transverse momentum p_T for K^+ and π^+ mesons in semi-central collisions. For the K^+ data

[1] One can obtain the values of v_1 and v_2 from fitting the azimuthal distribution with Eq. (2). Within the errors, the fit values agree with those listed in Table 1.

only two bins are shown due to the limited statistics. The magnitude of v_2 for K^+ and π^+ mesons tends to increase with p_T, while the v_1 values remain close to zero for both particles.

4. Discussion

To compare the present results with other measurements the v_2 values for protons, pions, and kaons near mid-rapidity are plotted as a function of the beam energy in Fig. 4. For both protons and pions a transition from out-of-plane to in-plane emission occurs around 5-10 $A \cdot$GeV. At SPS energy, results from NA49 [12] have shown that protons and pions exhibit in-plane emission near mid-rapidity. Our π^+ data agree with the NA49 results within errors. Unlike the case for protons and pions, the present results indicates that K^+ mesons exhibit out-of-plane emission, which is similar to observations for 1 $A \cdot$GeV Au + Au collisions [8].

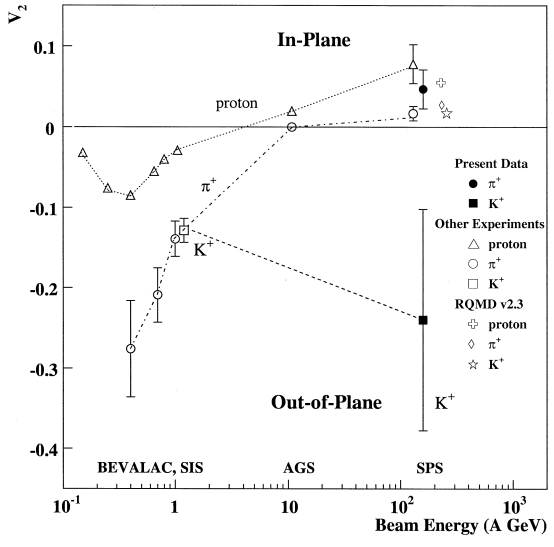

Fig. 4. Beam energy dependence of the v_2 value near mid-rapidity [6–8,10,12]. Solid symbols indicate the present data. Note that the region in (y, p_T) is different for each experiment. The RQMD (v2.3 cascade mode) calculations for proton, π^+ and K^+ in 158 $A \cdot$GeV Pb + Pb collisions are also shown for the impact parameter range $b =$ 6.5–12 fm with the filter of experimental acceptance. The data points are shifted horizontally where they overlap.

Results of RQMD model calculations (v2.3 cascade mode) [24] filtered with the experimental acceptance are also shown in Fig. 4. The RQMD results show in-plane emission for π^+, proton, and also for K^+. The RQMD calculation agrees with the measured results for π^+ and proton, but it fails to reproduce the out-of-plane elliptic emission of K^+. These results might suggest that a new ingredient to the calculation such as the in-medium potentials of the K^+ and K^- mesons is required [13–15]. A simple model calculation [25] in which K^+ mesons propagate through a static anisotropic distribution of nucleons with a repulsive K^+N potential demonstrates that a final out-of-plane elliptic emission pattern can emerge from an initially isotropic azimuthal distribution of K^+.

It is clear that if the azimuthal distribution of the pions reflects their preferential in-plane collective motion, then the out-of-plane K^+ azimuthal distribution would indicate that the kaons carry little direct information about the collective motion of the pion matter. The results therefore appear to question the assumption of a common collective flow velocity for pions and kaons.

5. Summary

In summary, we have measured the elliptic emission patterns of K^+ and π^+ mesons near mid-rapidity in 158 $A \cdot$GeV Pb + Pb collisions. In semi-central collisions, the K^+ mesons are found to be emitted preferentially perpendicular to the reaction plane, while π^+ mesons tend to be emitted in the reaction plane. The RQMD cascade calculation reproduces the v_2 values for π^+ and protons, but it fails to explain the out-of-plane emission of K^+ mesons. The results suggest that the kaon emission is influenced by in-medium potential effects in addition to collective flow effects.

Abstract

The multiplicity of inclusive photons has been measured on an event-by-event basis for $158 \cdot A$ GeV Pb induced reactions on Ni, Nb, and Pb targets. The systematics of the pseudorapidity densities at midrapidity ($\rho_{\max}$) and the width of the pseudorapidity distributions have been studied for varying centralities for these collisions. A power law fit to the photon yield as a function of the number of participating nucleons gives a value of 1.12 ± 0.03 for the exponent. The mean transverse momentum, $\langle p_T \rangle$, of photons determined from the ratio of the measured electromagnetic transverse energy and photon multiplicity, remains almost constant with increasing $\rho_{\max}$. Results are compared with model predictions. © 1999 Published by Elsevier Science B.V. All rights reserved.

1. Introduction

The primary goal of ultra-relativistic heavy ion experiments is to study nuclear matter under extreme conditions, in which hadronic matter is expected to undergo a phase transition to a new state of matter, the Quark-Gluon-Plasma (QGP). For a thermalized system undergoing a phase transition, the variation of the temperature with entropy density is interesting as the temperature is expected to increase while below the transition, remain constant during the transition, and then increase again [1,2]. Temperature

fluctuations have also been proposed as a signature of the existence of a tricritical point in QCD [3]. These behaviours can be studied by two experimentally measured quantities, viz., the mean transverse momentum, $\langle p_T \rangle$, and the pseudorapidity density at midrapidity, $\rho_{\max}$, for varying impact parameter, or centrality, for a number of colliding systems. These variables also provide additional information to characterize the evolving system. $\rho_{\max}$ provides a measure of the energy density which is important to understand the reaction dynamics [4,5]. In addition, the change in shape of the pseudorapidity distribution should be investigated in detail because it may provide a clue to the formation of the QGP phase [6,7].

Except for a few measurements of photon [8–11] and neutral meson [12–15] distributions reported earlier, most studies have been restricted to charged particle measurements (a review of charged particle measurements can be found in Ref. [16,17]), due to the difficulty of precise measurements of photon distributions. The inclusive photons provide a picture of the system at freezeout since the majority of the photons emitted from the reaction are decay products of produced particles, *viz.*, π_0 and η_0, (only a small fraction is emitted directly during the initial stage of the collision [18]). The shape and width of the pseudorapidity distributions of photons may be different compared to those of the charged particles. Photon multiplicity measurements have also become increasingly important because of the recent interest in simultaneous measurements of the multiplicity of photons and charged particles in the search for Disoriented Chiral Condensates (DCC) [19,20]. The formation of a DCC is expected to give rise to large fluctuations in the relative number of emitted charged particles and photons, analogous to the Centauro and the anti-Centauro types of events observed in cosmic ray experiments [21]. Photon measurements can also be used to study flow [22] and intermittency behavior of events accompanying a possible phase transition.

In this letter, we present the first measurement of the photon multiplicity and pseudorapidity distributions, together with the $\langle p_T \rangle$ of photons produced in collisions of $158 \cdot A$ GeV Pb with Ni, Nb, and Pb targets, carried out in the WA98 experiment [23] at the CERN-SPS.

2. Experimental setup

In the WA98 experiment, the main emphasis has been on high precision, simultaneous detection of both hadrons and photons. The experimental setup consists of large acceptance hadron and photon spectrometers, detectors for charged particle and photon multiplicity measurements, and calorimeters for transverse and forward energy measurements. The present analysis makes use of the photon multiplicity detector (PMD), the midrapidity calorimeter (MIRAC) and the zero degree calorimeter (ZDC).

The PMD was placed at a distance of 21.5 meters from the target. It was a preshower detector consisting of 3 radiation length (X_0) thick lead converter plates in front of an array of square scintillator pads of four sizes, varying from 15×15 mm^2 to 25×25 mm^2, placed in 28 box modules. Each box module consisted of a matrix of 38×50 pads and was read out using one image intensifier + CCD camera system. The scintillation light was transmitted to the readout device by using a short wavelength shifting fiber spliced with a long EMA (extra-mural absorber) coated clear fiber. The total light amplification of the readout system was $\sim 40\,000$. Digitization of the CCD pixel charge was done by a set of custom built fastbus modules employing an 8 bit 20 MHz Flash ADC system. Details of the design and characteristics of the PMD may be found in Ref. [24]. The results presented here make use of the data from the central 22 box modules covering the pseudorapidity range of $2.9 \leq \eta \leq 4.2$.

The MIRAC [25] was placed behind the PMD at 24.7 meters from the target. It consisted of 30 stacks, each divided vertically into 6 towers, each of size 20×20 cm^2, and segmented longitudinally into electromagnetic (EM) and hadronic sections. The depth of an EM section is $15.6\,X_0$ (equivalent to 51% of an interaction length) which ensures essentially complete containment of the electromagnetic energy, with 97.4% and 91.0% containment calculated for 1 GeV and 30 GeV photons, respectively. Hadrons also deposit a sizable fraction of their energy in the EM section. The MIRAC measures both the transverse electromagnetic ($E_T^{\rm em}$) and hadronic ($E_T^{\rm had}$) energies in the interval $3.5 \leq \eta \leq 5.5$ with a resolution of $17.9\%/\sqrt{E}$ and $46.1\%/\sqrt{E}$, respectively, where E is expressed in GeV. The ZDC measures the total

forward energy, E_F, with a resolution of $80\%/\sqrt{E} + 1.5\%$, where E is expressed in GeV.

3. Data analysis

3.1. Event selection

The data were taken during the December 1996 Pb beam period at the CERN SPS. The thicknesses of the three targets were 250 μm, 254 μm, and 213 μm for Ni, Nb, and Pb, respectively. The fundamental ''beam'' trigger condition consisted of a signal in a gas Čerenkov start counter located 3.5 meters upstream of the target and no coincident signal in a veto counter with a 3 mm diameter circular hole located 2.7 meters upstream of the target. A beam trigger was considered to be a minimum-bias interaction if the transverse energy sum in the full MIRAC acceptance exceeded a low threshold. The data were taken using an average beam intensity of 200–300 kHz during a 3.5s spill, the number of events recorded per spill being 150–200.

Beam pile up, where a second beam trigger occurs at a time when the detectors are integrating their signals from the triggered event, was rejected by (a) using the timing information from the trigger detectors, and (b) requiring that the sum of energies in the ZDC and the MIRAC were within 3σ from the mean of the distribution. Downstream interactions were also rejected by requiring a coincident signal from the forward hemisphere of the Plastic Ball detector which surrounded the target. To correct for other sources of background, data were also taken with no target in place.

The CCD readout of the PMD was cleared every 10 μs using a clear pulse of 1 μs width generated every 10 μs. This ensured that there was no substantial noise buildup on the CCD pixels between successive event triggers. A gate of 2 μs around the clear pulse was used to veto partially or fully cleared events. The clear clock operated asynchronously and was vetoed with a 5.6 ms wide pulse when a valid trigger occurred to allow complete readout of all pixels. A further check on possible pileup in the CCD cameras was made by using a 10 μs range TDC to measure the time difference between the arrival of the last clear clock and any valid event trigger. Events with multiple interactions within the 10 μs between clear pulses were rejected in the offline analysis.

The centrality of the interaction is determined by the total transverse energy measured in the MIRAC. For the $\langle p_T \rangle$ analysis, which used the MIRAC data directly, the centrality was determined instead by the forward energy, E_F, measured in the ZDC. The centralities are expressed as fractions of the minimum bias cross section as a function of the measured total transverse energy or measured E_F. The most central selection corresponds to the top 5% of the minimum bias cross section and the peripheral selection corresponds to the lower 50–80% range. Extreme peripheral events in the 80–100% range were not analyzed.

3.2. Data reduction in the PMD

The digitized pixel charges are processed by using a pixel-to-fiber map to form fiber signals corresponding to each scintillator pad. The signals from several neighbouring scintillator pads are combined to form clusters, characterized by the total ADC content and the hit positions. On average, there is a 92% probability for photons to shower in the lead converter and produce large signals. Compared to this, hadrons give a signal mostly corresponding to minimum ionizing particles (MIP). The majority of the hadrons are rejected by applying a suitable threshold on the cluster signal. A fraction of hadrons undergoing interaction in the lead converter produce signals larger than the threshold and appear as contaminants in the photon sample. The number of clusters remaining above the hadron rejection threshold is termed as *γ-like*. The characteristics of the preshower PMD are described by the following two quantities [24]:

$$\epsilon_\gamma = N_{\rm cls}^{\gamma,{\rm th}}/N_\gamma^{\rm inc} \quad (1)$$

$$f_p = N_{\rm cls}^{\gamma,{\rm th}}/N_{\gamma\text{-like}} \quad (2)$$

where ϵ_γ is the photon counting efficiency and f_p is the fractional purity of the photon sample. $N_\gamma^{\rm inc}$ is the number of incident photons on the PMD and $N_{\rm cls}^{\gamma,{\rm th}}$ is the number of photon clusters above the threshold. Both ϵ_γ and f_p are determined by a

detailed Monte Carlo simulation using the VENUS 4.12 [27] event generator with default parameter settings and the detector simulation package, GEANT 3.21 [28]. The details of the simulation can be found in Ref. [24]. No lower threshold on the energy spectrum of photons is applied in the simulation. The photon counting efficiency decreases with increasing hadron rejection threshold. The purity improves significantly with increasing threshold only up to ~ 3 MIPs and then rather slowly at higher thresholds. For practical purposes a 3 MIP threshold appears as an optimum choice for hadron rejection. With this value the photon counting efficiencies for the central and peripheral cases are 68% and 73%, respectively. The purity of the photon sample in the two cases are 65% and 54%, respectively.

From the experimental data one determines $N_{\gamma\text{-like}}$, the number of clusters above the hadron rejection threshold. Using the estimated values of ϵ_γ and f_p, one obtains the number of photons incident on the detector in the event from the relation:

$$N_\gamma = N_{\gamma\text{-like}} \cdot f_p / \epsilon_\gamma \tag{3}$$

3.3. Extraction of $\langle p_T \rangle$ of photons

In a given event, the average transverse momentum of the produced photons may be expressed as

$$\langle p_T \rangle = \frac{E_T^{\mathrm{em}}}{N_\gamma} \tag{4}$$

where E_T^{em} is the transverse component of the electromagnetic energy, and N_γ is the number of photons in a given η-region. In the WA98 experiment, E_T^{em} and N_γ are measured with the MIRAC and the PMD, respectively, on an event-by-event basis. These detectors have complete overlap in azimuth in the pseudorapidity region $3.5 \leq \eta \leq 4.0$. Hence the data in this region are used for computing the $\langle p_T \rangle$ using the above equation.

In order to obtain the final E_T^{em} for Eq. (4), the measured electromagnetic energy in the MIRAC towers must be corrected for (1) the hadronic contribution to the EM section of the MIRAC, and (2) the energy deposited in the lead converter of the PMD because of its position in front of the MIRAC. The final expression may be written as:

$$E_T^{\mathrm{em}} = \frac{\sum_{i=1}^{N} \left[E_i^{\mathrm{em}} - f_h \cdot f_{\mathrm{bal}} \cdot \left\{ E_i^{\mathrm{had}} / (1 - f_h) \right\} \right] \sin\theta_i}{1 - f_{\mathrm{PMD}}} \tag{5}$$

where E_i^{em} and E_i^{had} are the energies measured in the electromagnetic and hadronic sections of the MIRAC towers, f_h is the fraction of the hadronic energy deposited in the EM section, f_{bal} is the balance factor taking into account the different responses for electromagnetic and hadronic particles in the EM section [25], N is the number of towers in the MIRAC within the given η range, θ_i is the polar angle of the i^{th} tower, and f_{PMD} is the fraction of the electromagnetic energy deposited in the lead converter of the PMD. By combining results from the test beam data and simulation, the value of f_{PMD} has been found to be 15%. Details of the determination of f_{PMD} and other corrections are similar to those of Ref. [9].

3.4. Systematic errors

Several different sources contribute to the final systematic error in the determination of the number of photons, N_γ. The error due to the effect of clustering of the pad signals is the dominant one. This error is determined from the simulation by comparing the number of known tracks on the PMD with the total number of clusters obtained after clustering. Apart from the effect of multiplicity as discussed in Ref. [10], the arrangement of box modules in the present setup leads to splitting of clusters at the box boundaries. The net result is that the number of clusters exceeds the number of tracks with a deviation of 3% in the case of peripheral events and 7% for high multiplicity central events.

The number of γ-like clusters depends on the ADC value of the MIP peak as determined from Pb + Pb data. It has been estimated [24] that because of an admixture of $\sim 20\%$ photons in the MIP data sample, the extracted MIP ADC value is higher by 2 ADC channels. This causes the extracted photon multiplicity to be lower by 2.5%. We have included

this as a source of systematic error. The error on ϵ_γ because of the variation in pad-to-pad gains is found to be less than 1%.

The purity factor, f_p, depends on the ratio between the number of photons and charged particles within the PMD coverage. The systematic error associated with this ratio has been studied by using the FRITIOF [29] event generator in addition to VENUS. The average photon multiplicity estimated using FRITIOF is found to be higher by about 4% in peripheral and by 1% in central collisions, relative to the values obtained with VENUS.

The combined systematic error on the final photon multiplicity is asymmetric and varies with the centrality of the reaction. The total systematic errors are -3.4% and $+7.5\%$ for peripheral collisions and -7.1% and $+3.4\%$ for central collisions, varying little throughout the PMD acceptance. The negative error implies overestimation of the number of photons.

The photon counting efficiency determined in the present case relies on the energy spectra of photons as given by the VENUS event generator. As the conversion probability for low energy photons falls sharply [26] with decreasing energy below 500 MeV, the estimate of ϵ_γ may be affected if the energy spectra in the actual case is different. Preliminary measurements of the photon energy spectra with the WA98 lead glass spectrometer indicate that there is an enhancement of photons below $p_T = 250$ MeV/c over that given by VENUS. Taking into account this excess of low energy photons in the PMD acceptance, the photon counting efficiency would be overestimated by 2–9% for central events and 3–13% for peripheral events, the smaller value being for large pseudorapidity and the larger value being for the smaller pseudorapidity region of the PMD acceptance. This effect would increase the quoted PMD photon multiplicities. However, this uncertainty in the photon counting efficiency due to the uncertainty in the photon spectrum has not been included in the final errors presented in this letter. The WA98 low energy photon measurements will be described in a separate publication.

The systematic error on the determination of $\langle p_T \rangle$ depends on the error in both $E_T^{\rm em}$ and N_γ. The major source of errors in $E_T^{\rm em}$ are the contributions of hadronic energy deposited in the electromagnetic section of the MIRAC and the fraction of the electromagnetic energy deposited in the lead converter of the PMD. This is estimated to vary from 8.8% to 10.5% from peripheral to central events. Thus the combined systematic error on $\langle p_T \rangle$ has been estimated to vary from 11.5% to 12.7%.

4. Results and discussions

The photon multiplicity is determined using Eq. (3) on an event-by-event basis from the total number of γ-like clusters within the PMD coverage. The target out contribution to N_γ is almost absent because of the 3 MIP threshold for hadron rejection. The resulting minimum bias distributions of N_γ are shown in Fig. 1 for Pb + Ni, Pb + Nb, and Pb + Pb reactions at $158 \cdot A$ GeV. For comparison, the corresponding photon multiplicity distributions from the VENUS 4.12 event generator with default parameter settings, are superimposed in the same figure. The shape of these three distributions is governed by the collision geometry. For asymmetric collisions of Nb and Ni targets, small shoulders are present around N_γ of 300 and 200, respectively. This shoulder is produced when a decrease in the impact parameter leads to little increase in particle production and the cross sections for these small impact parameters pile up at

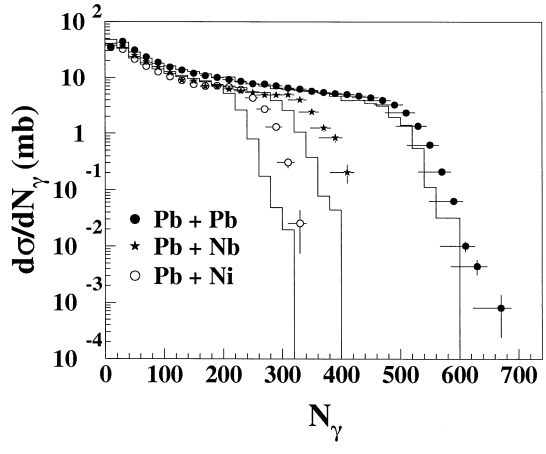

Fig. 1. Minimum bias inclusive photon cross sections for Pb + Ni, Pb + Nb, and Pb + Pb reactions at $158 \cdot A$ GeV. Solid histograms are the corresponding distributions obtained from the VENUS event generator.

a fixed N_γ. The VENUS event generator does not reproduce this shoulder well. The N_γ values are higher for the data compared to those of VENUS.

The pseudorapidity distribution of photons at different centralities are shown in Fig. 2 (a) for Pb + Pb collisions. The data have been corrected for geometry, efficiency, and purity factors. The filled symbols represent the measured data, and the open symbols are reflections of the filled symbols at $\eta_{\rm c.m.}(=2.92)$. The histograms show the corresponding distributions obtained from the VENUS event generator. The discrepancy between the VENUS results and the data is about 10% for central collisions at midrapidity. The pseudorapidity distribution of photons at different centralities for Pb + Nb and Pb + Ni are shown in Fig. 2 (b) and (c), respectively. The discrepancies between the data and VENUS are larger for these reactions compared to that of Pb + Pb.

The pseudorapidity distributions have been fitted with Gaussian functions to extract the peak position of the distribution ($\eta_{\rm peak}$), the pseudorapidity density ($\rho_{\rm max}$), and the width (σ). The fits are good in all cases, χ^2 per degree of freedom being in the range of 2–4. Typical fits for the top centrality class for all the three targets are shown in Fig. 2. The $\eta_{\rm peak}$ values for Pb + Pb distributions remain constant at 2.92 for all centralities. For Pb + Nb, $\eta_{\rm peak}$ decreases from 3.03 ± 0.15 for central collisions to 2.95 ± 0.32 in the case of peripheral collisions. The corresponding values for the Pb + Ni reaction are 3.10 ± 0.16 and 2.99 ± 0.31. Fig. 3(a) and (b) show $\rho_{\rm max}$ and σ for the three reactions as functions of the number of participant nucleons, $N_{\rm part}$, at different centralities. The $N_{\rm part}$ values are determined from the VENUS event generator. $\rho_{\rm max}$ increases with $N_{\rm part}$ while σ doesn't change with increase of $N_{\rm part}$.

More insight into the systematics of the particle production can be obtained by computing the integrated number of photons ($N_\gamma^{\rm tot}$) over the full phase space. This has been obtained from the Gaussian fit parameters to the pseudorapidity distributions.

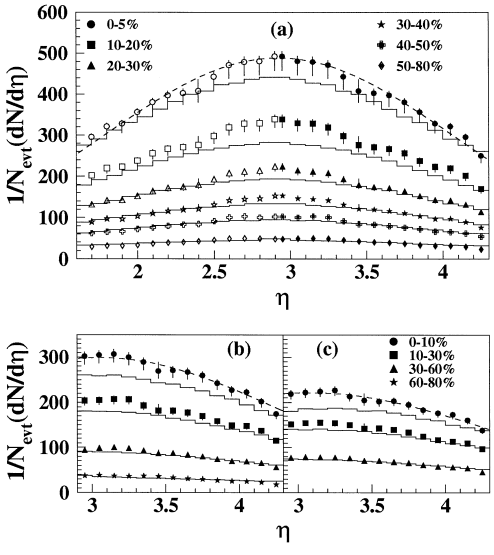

Fig. 2. Pseudorapidity distributions of photons in Pb induced reactions at $158 \cdot A$ GeV on (a) Pb, (b) Nb, and (c) Ni targets. The solid histograms are the corresponding distributions obtained from the VENUS event generator. In the Pb + Pb system, open symbols are the reflections of the measured data points around $\eta = 2.92$. The dashed curves represent gaussian fits to the data points corresponding to the case of 0–5% centrality for Pb + Pb and 0–10% centrality for Pb + Nb and Pb + Ni.

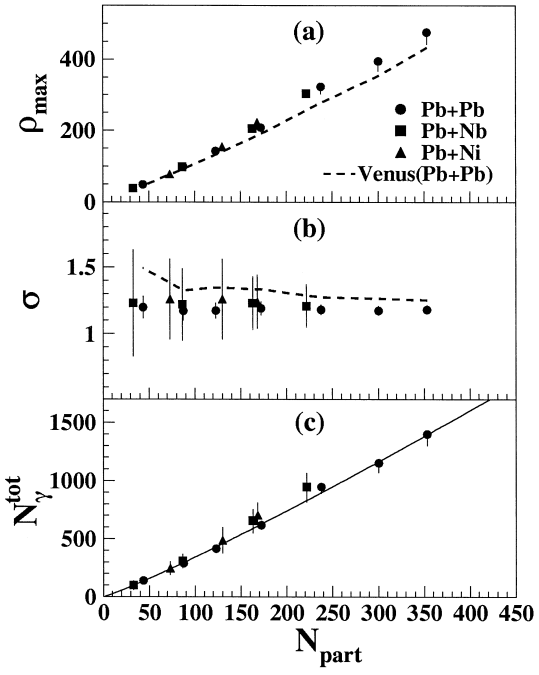

Fig. 3. (a) Pseudorapidity density ($\rho_{\rm max}$), (b) width of the pseudorapidity distributions (σ), and (c) integrated values of number of photons ($N_\gamma^{\rm tot}$), as functions of the number of participant nucleons at different centrality bins for Pb induced reactions on Ni, Nb, and Pb targets at $158 \cdot A$ GeV. The solid line in (c) is a power-law fit to the data, which yields the value of the exponent, $\alpha = 1.12 \pm 0.03$.

Fig. 3(c) shows the extracted values of $N_\gamma^{\rm tot}$ for Pb + Pb as a function of $N_{\rm part}$. The solid line shows a fit to the data using the function:

$$N_\gamma^{\rm tot} = C \cdot \left(N_{\rm part}\right)^{\alpha} \quad (6)$$

where C is a proportionality constant. The value of the exponent, α, is extracted to be 1.12 ± 0.03. To further explore the systematics, we have divided the full η region (0–6) into two parts, one corresponding to the central rapidity region, $2.4 \le \eta \le 3.4$, and the other beyond this. For both of these cases, the Pb + Pb data yields a value of $\alpha = 1.12$. In comparison, fitting the photon distribution from the VENUS event generator in the same two regions yield different exponents, with 1.10 ± 0.07 at mid-rapidity and only 1.0 ± 0.05 for the outer region.

The mean transverse momentum, $\langle p_T \rangle$, as a function of $\rho_{\rm max}$, the pseudorapidity density of photons at midrapidity, is shown in Fig. 4 for Pb + Pb collisions. For the data set considered, the target-out contributions were less than 1% for peripheral collisions and there was no effect for other centralities. The point at $\rho_{\rm max} \simeq 525$ corresponds to the highest centrality bin, 0–1% of the minimum bias cross section for Pb + Pb. The systematic errors on the absolute values are indicated by the upper and lower brackets on the figure. The $\langle p_T \rangle$ values are constant within the quoted error. For comparison, the results obtained from the VENUS event generator are superimposed in the figure. The $\langle p_T \rangle$ values obtained from VENUS are systematically higher compared to data, and show very little change with centrality. The indication of a small rise and saturation of $\langle p_T \rangle$ seen in the data is similar to what has been reported for neutral pions [15].

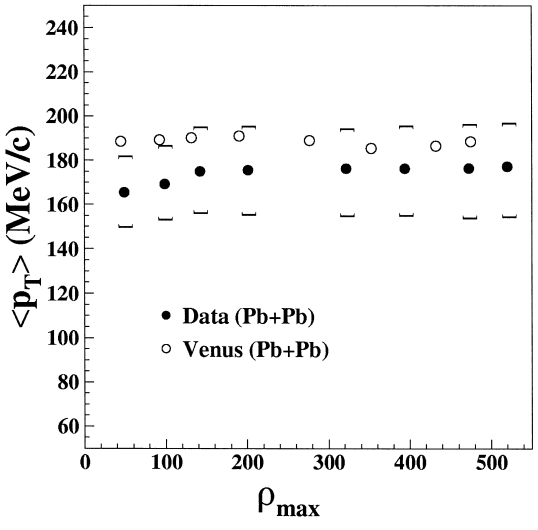

Fig. 4. The mean transverse momentum, $\langle p_T \rangle$, of photons as a function of the pseudorapidity density of photons at midrapidity, $\rho_{\rm max}$, corresponding to different centralities. The $\langle p_T \rangle$ values obtained from the VENUS event generator for Pb + Pb are superimposed for comparison. Statistical errors on the data are within the size of the symbols and systematic errors are shown by the brackets.

5. Summary

Photon multiplicities have been measured, on an event-by-event basis, in the forward region for $158 \cdot A$ GeV Pb induced reactions on Ni, Nb, and Pb targets. The peak positions of the photon pseudorapidity distributions are found to shift forward in going from the Pb target to Nb and Ni, as expected. The photon pseudorapidity densities increase with the number of participant nucleons, while the widths of the pseudorapidity distributions remain constant with centrality. The integrated number of photons scales like $N_{\rm part}^{1.12}$, almost independent of the rapidity range over which the integration is performed. This is similar to the predictions of the VENUS event generator, except that VENUS shows a smaller power for forward rapidities. The photon mean transverse momentum has been determined from the event-by-event ratio of the electromagnetic transverse energy to the number of photons. After an initial rise with increasing $\rho_{\rm max}$, the value of $\langle p_T \rangle$ is observed to remain constant.

Acknowledgements

We wish to express our gratitude to the CERN accelerator division for the excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians, and support staff who have participated in the construction of this experiment.

(Received 29 January 1999)

Neutral pion production in central 158*A* GeV ^{208}Pb + ^{208}Pb collisions has been studied in the WA98 experiment at the CERN Super Proton Synchrotron. The π^0 transverse mass spectrum has been analyzed in terms of a thermal model with hydrodynamic expansion. The high accuracy and large kinematic coverage of the measurement allow one to limit previously noted ambiguities in the extracted freeze-out parameters. The results are shown to be sensitive to the shape of the velocity distribution at freeze-out.

Heavy ion reactions at sufficiently high energies produce dense matter which may provide the necessary conditions for the transition from a hadronic state to a deconfined phase, the quark-gluon plasma. Since a finite thermalized system without external containment pressure will necessarily expand, part of the thermal excitation energy will be converted into collective motion which will be reflected in the momentum spectra of the final hadrons. The dynamics of the expansion may depend on the presence or absence of a plasma phase. The strongly interacting hadrons are expected to decouple in the late stages of the collision. Their transverse momentum spectra should therefore provide information about the conditions of the system at freeze-out, in particular about the temperature and collective velocity of the system, if the thermal assumption is valid.

The application of a thermal description is nontrivial. There is no reason to believe that chemical and kinetic freeze-out should be identical nor that there should be unique thermal freeze-out temperatures for all hadrons or unique chemical freeze-out temperatures for all flavor changing reactions. It is likely that chemical equilibrium is not fully attained (see, e.g., [1]), implying that chemical parameters will also influence momentum spectra through contributions from decays of heavier resonances. Furthermore, it is not obvious that this problem should have a stationary solution since particle emission will occur throughout the full time evolution of the collision and so, in principle, would require a full space-time integration with varying parameters.

Most attempts to extract freeze-out parameters from experiment assume local thermal equilibrium and fit parametrizations of hydrodynamical models to the experimental distributions [2–7]. Already the earliest analyses [2] noted ambiguities in fitting the hadron transverse mass spectra due to an anticorrelation between the fitted temperature T and transverse flow velocity β_T.

Two-particle interferometric (HBT) measurements provide information on the spatial and temporal extent of the emission volume, but are also sensitive to the collective motion of the source (see, e.g., [3,8,9]). Within a hydrodynamical parametrization of the source at freeze-out, the transverse two-particle correlations have been shown to be sensitive only to the ratio β_T^2/T [3]. Hence HBT analyses have a $\beta_T - T$ ambiguity which is roughly orthogonal to that resulting from fits to the single particle spectra. This fact has recently been used by the NA49 Collaboration to constrain the freeze-out parameters to lie within the region $\langle\beta_T\rangle = 0.55 \pm 0.12$ and $T = 120 \pm 12$ MeV for central Pb + Pb collisions [6]. Alternatively, a recent analysis of π^+, K^+, and K^- distributions and π^+ and π^- two-particle correlations measured by the NA44 Collaboration for central Pb + Pb collisions using a nine-parameter hydrodynamical model fit [10] gave freeze-out parameters of $\langle\beta_T\rangle = 0.443 \pm 0.023$ and $T = 95.8 \pm 3.5$ MeV. These analyses suggest that a single set of freeze-out parameters can describe the hadron single particle distributions and two-particle correlations, with moderate temperature and large transverse flow velocity.

On the other hand, various thermal model analyses of particle production ratios, especially strangeness production (see, e.g., Ref. [11] for a recent summary), have indicated rather high chemical freeze-out temperatures. Use of integrated yields in these analyses allows one to obtain conclusions on the temperature which are insensitive to the amount of transverse flow. In a recent analysis of results at SPS energies, including Pb + Pb collisions, good agreement is obtained if partial strangeness saturation is assumed with a chemical freeze-out temperature of about 180 MeV [12].

A successful thermal interpretation of relativistic heavy ion collisions must provide an accurate description of the pion spectra since pions provide the "thermal bath" of the late stages of the collision. In this Letter we discuss the extraction of thermal freeze-out parameters from the neutral pion transverse mass distribution for central 158A GeV ^{208}Pb + ^{208}Pb collisions. These data provide important constraints due to their accuracy and coverage in transverse mass. The analysis of the π^0 spectrum, within a particular hydrodynamical model, reveals the importance of the shape of the velocity distribution at freeze-out. The default shape, derived from a Gaussian spatial distribution, favors a large thermal freeze-out temperature, similar to temperatures extracted for chemical freeze-out, but in contradiction to conclusions obtained based on analyses of limited coverage particle spectra and HBT results [6,10,13].

The CERN experiment WA98 [14–16] consists of large acceptance photon and hadron spectrometers together with several other large acceptance devices which allow one to measure various global variables on an event-by-event basis. The results presented here were obtained from an analysis of the data taken with Pb beams in 1995 and 1996. The 10% most central reactions ($\sigma_{\text{central}} \approx$ 630 mb) have been selected using the transverse energy E_T measured in the MIRAC calorimeter.

Neutral pions are reconstructed via their $\gamma\gamma$ decay branch using the WA98 lead-glass photon detector, LEDA, which consisted of 10 080 individual modules with photomultiplier readout. The detector was located at a distance of 21.5 m from the target and covered the pseudorapidity interval $2.35 < \eta < 2.95$. The general analysis procedure, described in [16], is similar to that used in the WA80 experiment [7]. The momentum distributions are fully corrected for geometrical acceptance and reconstruction efficiency. The systematic error on the absolute yield is $\approx$10% and increases sharply below $p_T = 0.4$ GeV/c. An additional systematic error originates from the uncertainty on the momentum scale of 1%. The influence of this rises slowly for large p_T and leads to an uncertainty on the yield of 15% at $p_T = 4$ GeV/c.

The measured neutral pion cross section from central Pb + Pb reactions as a function of $m_T - m_0$ is shown in Fig. 1. Included is a fit with a hydrodynamical model

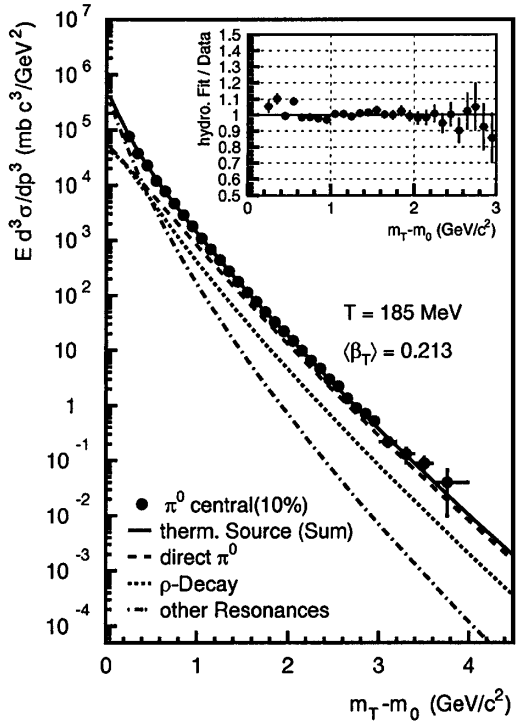

FIG. 1. Transverse mass spectra of neutral pions in central collisions (10% of minimum bias cross section) of 158*A* GeV Pb + Pb. The invariant cross section of neutral pions is compared to a fit using a hydrodynamical model [5] including transverse flow and resonance decays, with the direct production and the contribution of ρ decays and all other resonances shown separately. The ratio of the fit to the data is shown in the inset. m_0 is the π^0 mass.

[5] including transverse flow and resonance decays. This computer program calculates the direct production and the contributions from the most important resonances having two- or three-body decays including pions (ρ, K^0_S, $K^\star$, Δ, $\Sigma + \Lambda$, η, ω, η'). The code, originally intended for charged pions, has been adapted to predict neutral pion production. The model uses a Gaussian transverse spatial density profile truncated at 4σ. The transverse flow rapidity is assumed to be a linear function of the radius. For all results presented here, a baryonic chemical potential of $\mu_B = 200$ MeV has been used. The results are not very sensitive, however, to the choice of μ_B for the $m_T - m_0$ region considered here.

This model provides an excellent description of the neutral pion spectra with a temperature $T = 185$ MeV and an average flow velocity of $\langle\beta_T\rangle = 0.213$. These values are very similar to the parameters obtained with similar fits to neutral pion spectra in central reactions of ^{32}S + Au [7]. The 2σ lower limit on the temperature is $T^{\text{low}} = 171$ MeV, and the corresponding upper limit on the flow velocity is $\langle\beta_T^{\text{upp}}\rangle = 0.253$. (All limits given use the data for $m_T - m_0 > 2$ GeV/c^2 as upper limits only to allow for additional hard-scattering contributions.)

The observed curvature at low m_T is largely a result of resonance decay contributions. Performing a fit with only the direct contribution leads to $T = 142$ MeV and $\langle\beta_T\rangle = 0.301$, with corresponding 2σ limits of $T^{\text{low}} = 135$ MeV and $\langle\beta_T^{\text{upp}}\rangle = 0.318$, similar to other analyses which have neglected decay contributions [6,17]. The larger average velocity which results in this case is due to the fact that all of the observed curvature must now be accounted for by transverse flow.

The high statistical accuracy and large transverse mass coverage of the present π^0 measurement reveals the concave curvature of the π^0 spectrum over a large m_T range, which constrains the parameters significantly. This is further demonstrated by studying the local slope at each m_T. The local (inverse) slope is given by

$$T^{-1}_{\text{local}} = -\left(E\,\frac{d^3\sigma}{dp^3}\right)^{-1} \frac{d}{dm_T}\left(E\,\frac{d^3\sigma}{dp^3}\right). \qquad (1)$$

The local slope results are plotted in Fig. 2. Each individual value of T_{local} has been extracted from 3 adjacent data points of Fig. 1. The data are compared to the hydrodynamical model best fit results of Fig. 1, as well as fits in which the transverse flow velocities have been fixed to larger values comparable to those obtained by Refs. [10] and NA49 [6] (sets 2 and 3). The corresponding fit parameters are given in Table I. The comparison demonstrates that while the large transverse flow velocity fits can provide a reasonable description of the data up to transverse masses of about 1 GeV, they significantly overpredict the local slopes at large transverse mass. While application of the hydrodynamical model at large transverse mass is questionable, the model cannot overpredict the measured yield. The observed overprediction therefore rules out the assumption of large transverse flow velocities, or points to a deficiency in the model assumptions used in these fits.

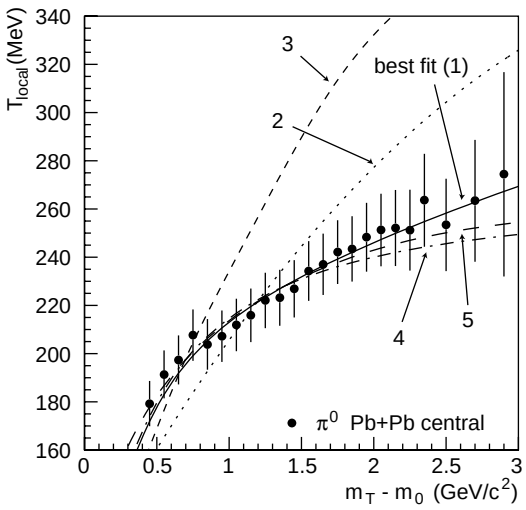

FIG. 2. The local inverse slope of the transverse mass spectrum of neutral pions in central collisions of 158*A* GeV Pb + Pb. The measured results (solid points) are compared to the hydrodynamical model best fit result (solid line; $T = 185$ MeV and $\langle\beta_T\rangle = 0.213$, also shown in Fig. 1) and to the other results given in Table I.

TABLE I. Parameters for different hydrodynamical model fits to the neutral pion spectrum shown in Figs. 2 and 3. The temperature T and average and rms transverse flow velocities $\langle\beta_T\rangle$ and $\beta_{\rm rms}$ are given together with the effective temperature $T_{\rm eff} = T/\sqrt{(1 - \langle\beta_T\rangle)/(1 + \langle\beta_T\rangle)}$.

Set	Spatial profile	T (MeV)	$\langle\beta_T\rangle$	$\beta_{\rm rms}$	$T_{\rm eff}$ (MeV)	χ^2/d.o.f.
1	Gauss	185 ± 4	0.213 ± 0.020	0.107	230	25.9/18
2	Gauss	75 ± 1	0.469	0.199	125	386/19
3	Gauss	49 ± 1	0.527	0.213	88	578/19
4	uniform	178 ± 13	0.274 ± 0.046	0.093	235	33.3/18
5	Woods-Saxon	$146\ ^{+21}_{-16}$	$0.365\ ^{+0.056}_{-0.069}$	0.137	214	26.7/18

The curvature in the π^0 spectrum at large transverse mass is a result of the distribution of transverse velocities. Although the spectrum is not directly sensitive to the spatial distribution of particle emission, within this model it is dependent indirectly on the spatial distribution due to the assumption that the transverse rapidity increases linearly with radius. The large curvature at large transverse mass is due to high velocity contributions which result from the tail of the assumed Gaussian density profile [18]. Figure 3 shows the transverse source velocity distributions $dN/d\beta_T$ for the different parameter sets. (More precisely these are source emission functions integrated over all variables except the transverse velocity and the rapidity; i.e., they are weighted with the produced particle multiplicity.) The curves labeled 1–3 correspond to the calculations in Fig. 2 using a Gaussian spatial profile. In addition, velocity profiles are shown for a uniform density profile (set 4) and for a Woods-Saxon distribution:

$$\rho(r) = \frac{1}{1 + \exp[(r - r_0)/\Delta]} \qquad (2)$$

with $\Delta/r_0 = 0.02$ (set 5). These are included in Figs. 2 and 3. It is seen that the uniform density assumption truncates the high velocity tail resulting in less curvature in the pion spectrum, while the Woods-Saxon has a more diffuse edge at high β_T.

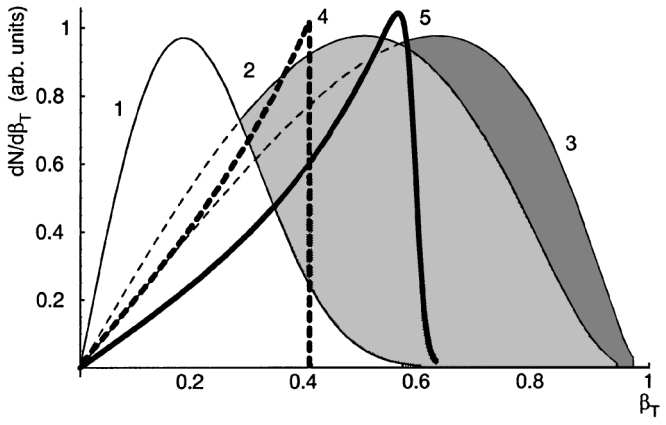

FIG. 3. Unnormalized multiplicity distributions as a function of the transverse source velocity for the parameter sets given in Table I.

While the Gaussian and uniform density assumptions have very different velocity profiles, it is interesting that both can provide acceptable fits to the pion spectrum with best fit results with similar $\langle\beta_T\rangle$ and T parameters, which give similar effective temperatures, and which have similar velocity widths, $\beta_{\rm rms}$, as shown in Table I. Compared to the Gaussian profile result, the best fit result using the uniform profile gives a lower temperature of 178 MeV and would lead to weaker limits of $\langle\beta_T^{\rm upp}\rangle = 0.42$ and $T^{\rm low} = 134$ MeV. Limits cannot be set using the Woods-Saxon profile due to increased fit ambiguity. If the data for $m_T - m_0 > 2$ GeV/c^2 are used only as upper limits, as explained above, a best fit result with $T = 129$ MeV and $\langle\beta_T\rangle = 0.42$ is obtained.

The data presented here can be well described with high thermal freeze-out temperatures, similar to temperatures which have been extracted for chemical freeze-out [12], and small transverse flow velocities. (Note again that chemical and thermal freeze-out are not necessarily expected to be the same.) On the other hand, if the larger velocities obtained in other analyses which have considered limited particle spectra together with HBT results [6,10,13] persist, then the present analysis suggests much lower thermal freeze-out temperatures. For example, none of the different velocity profile assumptions used in this analysis allowed us to reproduce the results of Ref. [6]—all profiles studied require a temperature of 90 MeV or less, if $\langle\beta_T\rangle = 0.55$ is assumed. The present data obviously provide important information on the shape of the freeze-out velocity distribution. A more extensive systematic study would require further guidance from full hydrodynamical calculations, which is beyond the scope of this paper. Recent hydrodynamical model calculations [19,20] have found reasonable agreement with transverse mass spectra within a broad range of assumptions. However, in these studies it was not attempted to limit the model parameters or assumptions by a rigorous comparison to the data.

In summary, we have argued that hydrodynamical models which attempt to extract the thermal freeze-out parameters of relativistic heavy ion collisions must provide an accurate description of the pion spectra, since pions most directly reflect the thermal evironment in the late stage of the collision. In particular, models, or parameter

sets, which overpredict the observed pion yields, even at large transverse mass, can immediately be ruled out. We have demonstrated that the high accuracy neutral pion spectra with large transverse mass coverage can constrain the thermal freeze-out parameters and model assumptions. Within the context of the hydrodynamical model of Ref. [5], the default velocity profile favors large thermal freeze-out temperatures similar to the chemical freeze-out temperature determined for the same system [12]. Only special choices of the velocity profile allow large average freeze-out velocities similar to those extracted from other recent analyses which consider also HBT results [6,10,13]. On the other hand, the corresponding freeze-out temperatures are then ≈ 90 MeV, significantly lower than other estimates. The present results indicate that the determination of the freeze-out parameters remains an open question. It will be important to determine whether full hydrodynamical models can reproduce the high precision pion data and thereby constrain the assumed freeze-out hypersurface.

We thank Urs Wiedemann for assistance with the model calculations and valuable discussions. (Received 26 June 1998)

The production of neutral pions in 158A GeV ^{208}Pb + ^{208}Pb collisions has been studied in the WA98 experiment at the CERN Super Proton Synchrotron (SPS). Transverse momentum spectra are studied for the range $0.3 \leq m_T - m_0 \leq 4.0$ GeV/c. The results for central collisions are compared to various models. The centrality dependence of the neutral pion spectral shape and yield is investigated. An invariance of the spectral shape and a simple scaling of the yield with the number of participating nucleons is observed for centralities with greater than about 30 participating nucleons. This is most naturally explained by assuming an equilibrated system. [S0031-9007(98)07532-2]

Ultrarelativistic heavy-ion collisions produce dense matter which is expected to be in the form of a deconfined phase of quarks and gluons, or quark gluon plasma (QGP), at sufficiently high energy densities. The transverse momentum spectra of produced pions can provide information on both the initial and the final state properties of the hot hadronic matter. The low p_T pion production would dominantly reflect the temperature of the hadronic system at the freeze-out stage occurring late in the reaction. It is strongly influenced by rescattering among the final state hadrons. The high p_T pion production is expected to be dominated by hard scattering of the partons. In pA collisions the high p_T region is known to be enhanced (Cronin effect [1]) due to initial state scattering of the incident partons leading to a broadening of their incoming p_T. In AA collisions, many of the scattered partons must traverse the excited matter to escape and therefore may undergo additional rescatterings and energy loss [2]. In the case of significant parton rescattering, the parton distributions may approach thermal distributions with a temperature reflecting the initial state of the excited matter. The intermediate p_T region of the pion spectrum might then reflect this initial temperature. Indeed, one of the earliest signatures of QGP formation, proposed by Van Hove [3], was the observation of a saturation of the average transverse momentum with increasing energy (or entropy) density for systems excited just above the critical energy density. With increasing energy density, the initial temperature would not rise above the critical temperature until all of the latent heat of the QQP phase transition had been extracted.

For these reasons it is of interest to study the centrality dependence of the pion production. It is generally believed that the initial energy density increases with increasing centrality, due to the many overlapping interactions. Also, the volume of the excited matter increases with centrality, as well as the amount of rescattering. Since rescattering is the feature which distinguishes AA collisions nontrivially from pp collisions, and since significant rescattering is a prerequisite for thermalization, it is imperative to demonstrate an understanding of the centrality dependence of the AA results in order to understand the effects of rescattering. While those effects may be minor on extensive observables, like the particle multiplicity or transverse energy, they should be most evident on the momentum distribution of the produced particles. Recently it has been argued that a parton cascade description could successfully describe many of the features of central Pb + Pb collisions at the CERN Super Proton Synchrotron (SPS) energies [4]. Surprisingly, low momentum transfer soft parton collisions were found to have little influence on the final observables. Similarly, recent perturbative QCD calculations were able to reproduce the preliminary WA98 neutral pion result for central collisions [5,6] without need for the effects of parton energy loss or rescattering [7]. In this Letter we present neutral pion spectra for 158A GeV ^{208}Pb + ^{208}Pb collisions and investigate in detail the centrality dependence of the spectral shape and yield.

The CERN experiment WA98 [5,8] consists of large acceptance photon and hadron spectrometers together with several other large acceptance devices which allow one to measure various global variables on an event-by-event basis. The results presented here were obtained from an analysis of the data taken with Pb beams in 1995 and 1996. The minimum bias (min-bias) reactions ($\sigma_{\text{min-bias}} \approx 6300$ mb) are divided into eight centrality classes using the transverse energy E_T measured in the MIRAC calorimeter. In total, $\approx 9.6 \times 10^6$ reactions have been analyzed.

Neutral pions are reconstructed via their $\gamma\gamma$ decay branch using the WA98 lead-glass photon detector, LEDA, which consisted of 10 080 individual modules with photomultiplier readout. The detector was located at a distance of 21.5 m from the target and covered the pseudorapidity interval $2.35 < \eta < 2.95$. The measurement of neutral pions, though difficult at low transverse momenta, is superior to those of charged pions at high momenta because of the improving energy resolution of the calorimetric measurement.

The general analysis procedure is similar to that used in the WA80 experiment and described in [9]. Hits in the lead-glass detector are combined in pairs to provide distributions of pair mass vs pair transverse momentum (or transverse mass) for all possible combinations. Subtraction of the combinatorial background is performed using mixed event distributions. The resulting momentum distributions are corrected for geometrical acceptance and reconstruction efficiency. The efficiency depends on the particle occupancy in the detector and therefore has been calculated independently for each centrality bin. The systematic error of the pion yields is mainly due to errors in the reconstruction efficiency for central collisions and to corrections for nontarget interactions for peripheral collisions. The systematic error on the absolute yield is $\approx 10\%$ and increases sharply below $p_T = 0.4$ GeV/c. An additional systematic error originates from the uncertainty of the momentum scale of 1%. The influence of this rises slowly for higher p_T and leads to an error of 15% at $p_T = 4$ GeV/c. A detailed discussion of the analysis procedure and the error contributions will be given in a forthcoming publication.

The measured neutral pion spectrum from central Pb + Pb reactions (10% of min-bias cross section) as a function of $m_T - m_0$ is shown in Fig. 1. The data are compared to predictions of the string model Monte Carlo generators FRITIOF 7.02 [10] and VENUS 4.12 [11]. As already observed in S + Au reactions [9], both generators fail to describe the data well at large m_T. The FRITIOF prediction is more than an order of magnitude lower at high m_T while VENUS significantly overpredicts the data. Alternatively, it has recently been shown that

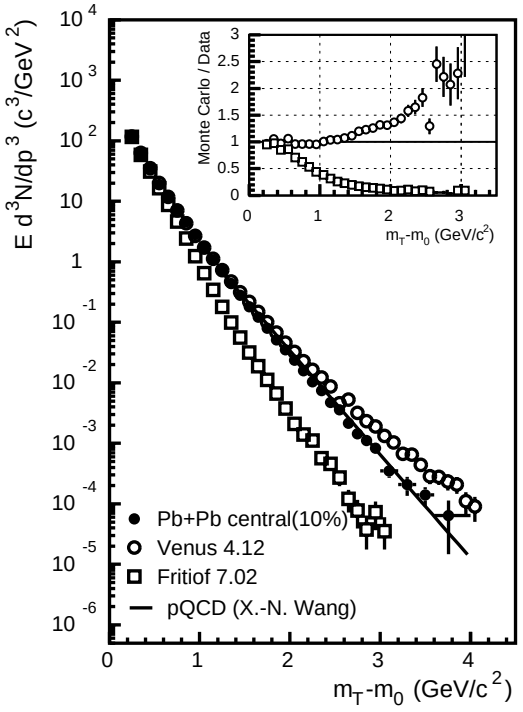

FIG. 1. Transverse mass spectra of neutral pions in central collisions of 158*A* GeV Pb + Pb. Invariant yields per event are compared to calculations using the FRITIOF 7.02 [10] and VENUS 4.12 [11] Monte Carlo programs. Predictions of a pQCD calculation [7] are included as a solid line. The inset shows the ratios of the results of the Monte Carlo codes to the experimental data.

perturbative QCD (pQCD) calculations, including initial state multiple scattering and intrinsic p_T [7], are able to describe the preliminary WA98 data at intermediate and high p_T. This prediction is included in Fig. 1 as a solid line. (The results shown have been corrected for a small numerical error by the author of [7] and have changed by $\approx 10\%-30\%$ compared to the publication.) The pQCD calculation shows a very good agreement in the high m_T region. This surprising agreement has been interpreted as an indication for unexpectedly small effects of parton energy loss [7]. On the other hand, the parton cascade Monte Carlo code, VNI, which provides a more detailed pQCD description, overpredicts the measured WA98 result by more than a factor of 10 at large p_T [4]. In an alternative picture, hydrodynamical descriptions (see, e.g., [12]) with properly adjusted parameters can describe the momentum spectra reasonably well.

In view of the above discussion and the difficulty to describe the details of the neutral pion spectrum, it is apparent that the theoretical description of ultrarelativistic nucleus-nucleus collisons remains uncertain. In order to demonstrate a consistent description of nuclear effects it is important to investigate the details of the pion production as a function of the system size. To study the centrality dependence of the spectral shape in a manner which is independent of model or fit function we have used the truncated mean transverse momentum $\langle p_T(p_T^{\min})\rangle$, where

$$\langle p_T(p_T^{\min})\rangle = \left(\int_{p_T^{\min}}^{\infty} p_T \frac{dN}{dp_T}\, dp_T \Big/ \int_{p_T^{\min}}^{\infty} \frac{dN}{dp_T}\, dp_T\right) - p_T^{\min}. \quad (1)$$

The lower cutoff $p_T^{\min} = 0.4$ GeV/c is introduced to avoid systematic errors from extrapolation to low p_T and has been chosen according to the lowest p_T of the present data where systematic uncertainties imposed by the necessary corrections are still small. In general, the value of $\langle p_T(p_T^{\min})\rangle$ differs from the true average p_T, except in the case of a purely exponential distribution $d\sigma/dp_T$. For a purely exponential invariant cross section, $d^2\sigma/dp_T^2$, $\langle p_T(p_T^{\min})\rangle$ decreases with increasing $p_T^{\min}$.

Figure 2 shows $\langle p_T(p_T^{\min})\rangle$ as a function of the average number of participants N_{part} for 158*A* GeV ^{208}Pb + Pb collisions. For comparison, $\langle p_T(p_T^{\min})\rangle$ values for 200*A* GeV S + Au [9] and from a parametrization of pp data [13] are also included. N_{part} is extracted by the assumption of a monotonic relation between impact parameter and transverse energy and using the resulting correspondence between measured cross section and impact parameter. The average number of participants is calculated from nuclear geometry using the extracted impact parameter. Together these data show the general trend of a rapid increase of $\langle p_T(p_T^{\min})\rangle$ compared to pp results for small system sizes. For N_{part} greater than about 30 the

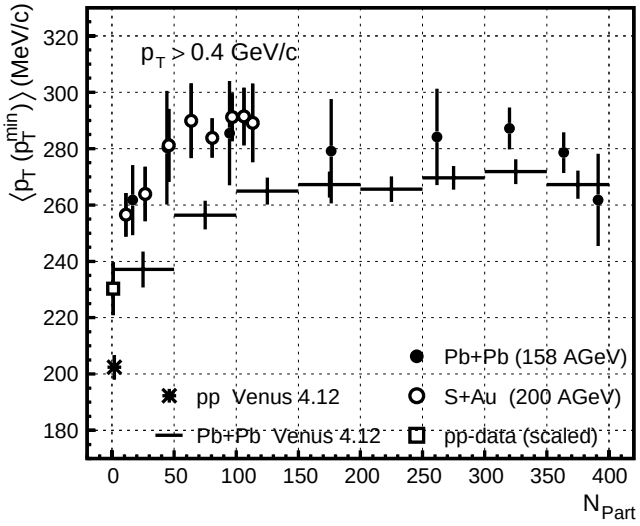

FIG. 2. Truncated mean transverse momentum $\langle p_T(p_T^{\min})\rangle$ of π^0 mesons as defined by Eq. (1) plotted as a function of the average number of participants N_{part}. The solid circles correspond to the 8 E_T based centrality selections for Pb + Pb. The open square shows $\langle p_T(p_T^{\min})\rangle$ extracted from a parametrization of pp data scaled to the same c.m. energy [13], the open circles the results for S + Au collisions at 200*A* GeV [9]. For comparison, results from VENUS 4.12 [11] are included as histograms for Pb + Pb collisions and as a star for pp. A cut parameter $p_T^{\min} = 0.4$ GeV/c was used.

mean transverse momentum appears to attain a limiting value of ≈ 280 MeV$/c^2$. [The variation of $\langle p_T(p_T^{\min})\rangle$ has been studied for values of $p_T^{\min} = 0.2$–1.0 GeV$/c$. The saturation is always observed; the statistical significance, however, decreases with increasing threshold.] VENUS 4.12 [11] calculations show a qualitatively similar behavior, but underpredict the present data, as well as the pp data. The simple implementation of rescattering which is used in this model seems to be strong enough to lead to a saturation for semiperipheral collisions as in the experimental data. One should, however, keep in mind that VENUS 4.12 does not correctly describe pion production at high p_T (see Fig. 1).

Earlier investigations of the dependence of $\langle p_T\rangle$ of pions on system size [9,14,15] at SPS energies have suggested such a saturation for large systems. The present study is the first investigation of the dependence with Pb ions at the SPS. Preliminary results from the AGS have indicated a weak increase in the average m_T of pions with the number of participants for Au + Au collisions [16].

It is important to note that the observed limiting behavior is very different from the observations in pp or $p\overline{p}$ collisions. For very high energies $\langle p_T\rangle$ rises with the pseudorapidity density of charged particles [17–20]. In that case, more violent parton scatterings presumably result in a harder spectrum of leading particles together with a greater multiplicity of fragmentation products. This would lead to the observed correlation between $\langle p_T\rangle$ and multiplicity. At lower $\sqrt{s}$, comparable to the data presented here, $\langle p_T\rangle$ decreases for increasing multiplicity [21], most likely due to energy conservation. In the case of nuclear reactions, this anticorrelation is lost due to the large number of binary collisions. Instead, the initial increase of $\langle p_T(p_T^{\min})\rangle$ with N_{part} is interpreted as a result of multiple scattering. Initial state multiple scattering, as suggested as an explanation for the Cronin effect [1], would imply a continuing increase of $\langle p_T(p_T^{\min})\rangle$ for more central collisions. Here, however, the surprising observation is that additional multiple scattering, implied by increasing N_{part}, does not alter the pion distributions. This is most easily understood as a consequence of final state rescattering and is, of course, the behavior expected for a thermalized system.

More detailed information about the centrality dependence of the pion spectral shape and yield is shown in Fig. 3 where the neutral pion yield per event has been parametrized as $Ed^3N/dp^3 \propto N_{\text{part}}^{\alpha(p_T)}\sigma_0(p_T)$. The results for $N_{\text{part}} > 30$ are well described by this scaling with an exponent $\alpha(p_T) \approx 1.3$, independent of p_T. Consistent with the previous discussion, the results indicate a constant spectral shape over the entire interval of measurement from $0.5 < p_T < 3$ GeV$/c$. The observed $N_{\text{part}}^{4/3}$ scaling for symmetric systems implies a scaling with the number of nucleon collisions, as confirmed by a similar analysis. However, this scaling does not extrapolate from the pp results. On the contrary, when comparing semiperipheral Pb + Pb collisions with pp the exponent

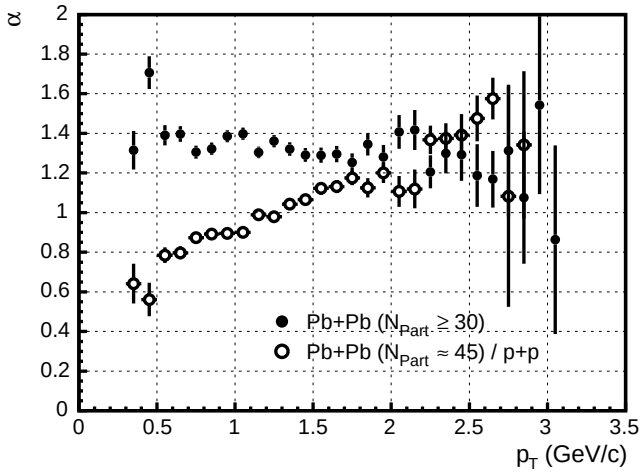

FIG. 3. The exponent $\alpha(p_T)$ of the dependence of the π^0 yield on the average number of participants N_{part} plotted as a function of the transverse momentum for 158A GeV Pb + Pb. The solid circles are calculated based on a fit to the centrality selections with $N_{\text{part}} \geq 30$. The open circles are calculated based on the ratio of the semiperipheral data ($N_{\text{part}} \approx 45$) to a parametrization of pp data.

α varies over the entire p_T interval, confirming the very different spectral shapes.

In summary, we have analyzed the centrality dependence of high precision transverse momentum spectra of neutral pions from 158A GeV Pb + Pb collisions. The neutral pion spectra are observed to show increasing deviation from pp results with increasing centrality, indicating the importance of multiple scattering effects. However, for centralities with more than about 30 participating nucleons, the shape of the transverse momentum spectrum becomes invariant over the interval $0.5 < p_T < 3$ GeV$/c$. In this interval the pion yield scales like $N_{\text{part}}^{1.3}$, or like the number of nucleon collisions, for this range of centralities. Since the amount of rescattering increases with centrality, the invariance of the spectral shape with respect to the number of rescatterings, most naturally suggests a dominantly thermal emission process. It will be important to determine whether cascade models which reproduce the observed invariant spectral shape will support the interpretation as an "effective" thermalization due to significant rescattering.

We wish to express our gratitude to the CERN accelerator division for excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians, and support staff who have participated in the construction of the experiment. This work was supported jointly by the German BMBF and DFG, the U.S. DOE, the Swedish NFR and FRN, the Dutch Stichting FOM, the Stiftung für Deutsch-Polnische Zusammenarbeit, the Grant Agency of the Czech Republic under Contract No. 202/95/0217, the Department of Atomic Energy, the Department of Science and

Technology, the Council of Scientific and Industrial Research and the University Grants Commission of the Government of India, the Indo-FRG Exchange Program, the PPE division of CERN, the Swiss National Fund, the International Science Foundation under Contract No. N8Y000, the INTAS under Contract No. INTAS-93-2773, ORISE, Research-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science and Culture, the University of Tsukuba Special Research Projects, and the JSPS Research Fellowships for Young Scientists. ORNL is managed by Lockheed Martin Energy Research Corporation under Contract No. DE-AC05-96OR22464 with the U.S. Department of Energy. The MIT group has been supported by the U.S. Department of Energy under the cooperative agreement DE-FC02-94ER40818.

(WA98 Collaboration)

In this paper, the absolute cross section determination associated with the different centrality selections was made with a limited data set which was not representative of the full analysis. This resulted in a systematic overestimate of the number of participants N_{part} (or the number of collisions). The relative magnitude of this correction is significant for the most peripheral centrality class and nearly negligible for the most central event class. The neutral pion transverse momentum spectra are unchanged. As a result of this correction, the data points of Fig. 2 should be shifted by varying degrees towards the origin on the number of participants scale. However, the conclusion of a saturation of the average transverse momentum with increasing centrality drawn from this figure remains unchanged.

Similarly, the major conclusion of Fig. 3 remains unchanged: In the region of centralities where the saturation of the average transverse momentum is observed, the scaling of the pion yield is independent of the transverse momentum; i.e.,

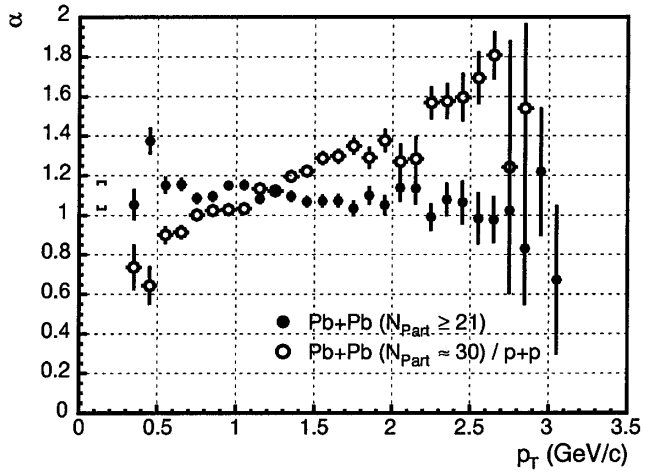

FIG. 1. The exponent $\alpha(p_T)$ of the dependence of the π^0 yield on the average number of participants N_{part} plotted as a function of the transverse momentum for 158*A* GeV Pb + Pb. The solid circles are calculated based on the centrality selections with $N_{\text{part}} \geq 21$. The open circles are calculated based on the ratio of the semiperipheral data ($N_{\text{part}} \approx 30$) to a parametrization of *pp* data. The brackets indicate the estimated systematic error on the exponent α.

the spectral shape does not change. However, with the corrected assignment of the number of participants the scaling exponent is reduced to $\alpha \approx 1.1$ from the value of $\alpha \approx 1.3$ given previously. The corrected version of Fig. 3 is displayed in Fig. 1. In addition to the correction of the cross section determination, the event generator VENUS 4.12 [1] has been used to relate the measured cross section to the number of participants N_{part}. The differences in N_{part} from this calculation compared to various Glauber calculations are used to estimate the systematic error on the exponent α shown in Fig. 1. The values for the exponents α of the scaling from pp data compared to semiperipheral Pb + Pb data are slightly higher than before, while the fit using semiperipheral up to very central Pb + Pb data yields a significantly smaller value. A further conclusion can be drawn from this corrected analysis: At high transverse momentum the increase in pion production going from pp to peripheral heavy ion reactions is much stronger than in going from semiperipheral to central heavy ion reactions.

Abstract

The restoration of chiral symmetry and its subsequent breaking through a phase transition has been predicted to create regions of Disoriented Chiral Condensates (DCC). This phenomenon has been predicted to cause anomalous fluctuations in the relative production of charged and neutral pions in high-energy hadronic and nuclear collisions. The WA98 experiment has been used to measure charged and photon multiplicities in the central region of 158 AGeV Pb + Pb collisions at the CERN SPS. In a sample of 212646 events, no clear DCC signal can be distinguished. Using a simple DCC model, we have set a 90% C.L. upper limit on the maximum DCC production allowed by the data. © 1998 Elsevier Science B.V.

1. Introduction

The approximate chiral symmetry of the QCD vacuum is believed to be spontaneously broken in nature by the formation of an isoscalar quark condensate. Disoriented Chiral Condensates (DCC) may form in large, hot regions of hadronic matter where this symmetry has been briefly restored [1]. A DCC has an equal probability to be in any state related to the normal vacuum by a chiral rotation. By projecting the space of these available states onto a basis of definite isospin, it has been found that the charge distribution of pions emitted from a single, large DCC domain has a characteristic form [2,3]:

$$P(f) = \frac{1}{2\sqrt{f}} \tag{1}$$

where f is the neutral fraction,

$$f = \frac{N_{\pi^0}}{N_{\pi^0} + N_{\pi^+} + N_{\pi^-}} \quad (2)$$

where N_{π^0}, N_{π^+} and N_{π^-} are respectively the numbers of neutral, positive and negative pions produced. This allows the possibility of hadronic interactions with anomalous fluctuations between charged pions and neutral pions, as seen through their two-photon decay channel.

The phenomenology of DCCs was first introduced in the context of hadronic collisions by Bjorken et al., whose "Baked Alaska" model [4] postulated that a hot shell, expanding at the speed of light, could shield the cool interior from the influence of the normal vacuum outside, allowing a large region of DCC to form. Rajagopal and Wilczek [5,6] studied the production of DCCs in nuclear collisions by studying the chiral phase transition in QCD, via its similarity to the O(4) Heisenberg magnet [7]. Through numerical simulations, they found that as the system rapidly expands and cools through the phase transition, the equations of motion induce a non-equilibrium relaxation of the chiral fields which amplifies the production of soft pion modes in a well-defined chiral direction. This effectively creates clusters of low-p_T pions, with the cluster charge distribution following Eq. (1). It should be noted that, in both studies, the strongest influence on the final state composition is the symmetry itself rather than the exact physics scenario studied. Further work confirmed these initial results, even after accounting for quantum fluctuations, and proposed other mechanisms which might allow for large, long-lived DCCs [1].

By allowing the possibility of events with almost no electromagnetic energy, DCCs are an attractive hypothesis to explain the "Centauro" events seen in cosmic rays [8]. These events have already motivated searches for unusual charge fluctuations at the $S\bar{p}pS$ (by UA1 [9] and UA5 [10]) and at the Tevatron (by Minimax [11] and CDF [12]). And yet, there have been no systematic studies utilizing the simultaneous measurement of charged and neutral multiplicities in heavy ion collisions at any energy. It has been argued [1] that heavy ion collisions at SPS energies, the highest currently available, might create the large volumes which favor the development of long-wavelength oscillations within the reaction zone. It is true that large baryon number in the central region complicates theoretical calculations and may obscure the initial signal via the rescattering of secondaries. It is also possible that most of the pions measured in pp collisions at comparable energies are produced resonantly [13], leaving few "direct" pions which may be influenced by a DCC. We must keep in mind, however, that these are extrapolations from lower energies and smaller systems. Their cumulative effect is uncertain, especially at higher energies where the formation of a quark-gluon plasma would render previous measurements inapplicable. In any case, in the absence of any substantial experimental evidence for or against DCCs in heavy ion collisions at SPS energies, and a great deal of theoretical evidence in their favor, it is imperative to simultaneously measure charged and neutral particles at the SPS and analyze their fluctuations to perhaps isolate a DCC signal. Observing such a signal might be an indication of the chiral phase transition in hot nuclear matter.

2. Experimental setup

The WA98 experiment [14] is a general-purpose, large-acceptance photon and hadron spectrometer with the ability to measure several different global observables event-by-event. For this search, we use a subset of the full apparatus, shown schematically in Fig. 1. We measure charged particles with a Silicon Pad Multiplicity Detector (SPMD) and photons with a Photon Multiplicity Detector (PMD). Using these, we are able to count charged particles and photons in the central pseudorapidity region on an event-by-event basis. For a determination of the centrality of each collision, we use the transverse energy (E_T) measured in the Midrapidity Calorimeter (MIRAC [15]). For removal of background events, we also use the Zero-Degree Calorimeter (ZDC) and the Plastic Ball detector [16].

2.1. Charged particle multiplicity

We count charged particles using a circular Silicon Pad Multiplicity Detector (SPMD) [17] located

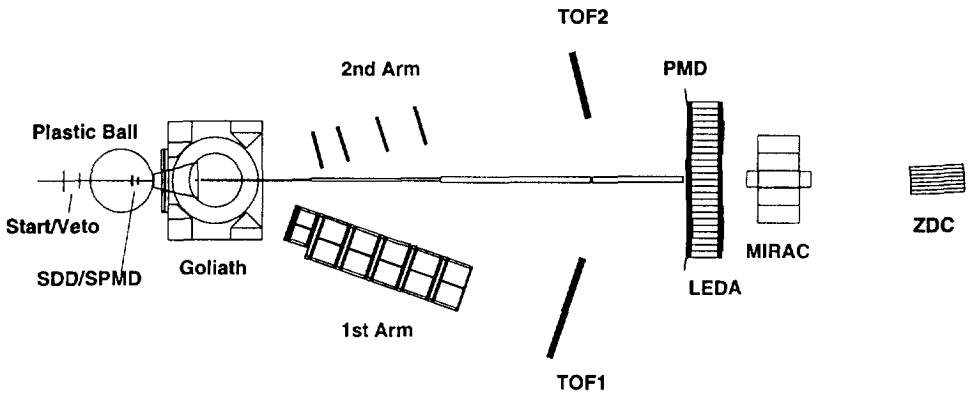

Fig. 1. The WA98 Experiment at the CERN SPS. This analysis uses the Silicon Pad Multiplicity Detector (SPMD) and the Photon Multiplicity Detector (PMD) to measure the charged and neutral multiplicity for each event, and the Mid-Rapidity Calorimeter (MIRAC) for the measurement of event centrality.

32.8 cm from the target covering $2.35 < \eta < 3.75$, the central rapidity region at SPS energies (where $\eta_{\rm CMS} = 2.9$), and full azimuth. The detector consists of four overlapping quadrants, each fabricated from a single 300 μm thick silicon wafer. The active area of each quadrant is divided into 1012 pads forming 46 azimuthal wedges and 22 radial bins with a pad size increasing with radius to provide uniform pseudorapidity coverage. The efficiency of detecting a charged particle in the active area has been determined in a test beam to be better than 99%. Conversely, the detector is transparent to high energy photons, since only about 0.2% are expected to interact in the silicon. During the data taking, 95% of the pads worked properly and are used in this analysis.

In a central Pb + Pb collision, the occupancy can be as high as 20%, implying that $\approx 20\%$ of the hit pads contain two or more particles, a "hit" being defined as a pad with a deposited energy exceeding 1/2 of the most probable energy loss. An unbiased way to estimate the total number of charged particles in a given event under such conditions is to use the sum of the energy deposited in hit pads divided by the mean energy loss per particle as determined in low-multiplicity events:

$$N_{\rm ch} = \sum_{i=\rm hits} \frac{dE/dx_i}{\langle dE/dx \rangle}.$$

Because of the fluctuations in the energy loss, described by a Landau distribution, the uncertainty on $N_{\rm ch}$ can be estimated to be $\Delta N_{\rm ch}/N_{\rm ch} = 60\%/\sqrt{N_{\rm ch}}$, the numerator being the width of the Landau distribution with the peak normalized to 1. For typical central events with a multiplicity of ≈ 600, this gives an uncertainty of about 2%. To check the overall scale, we compare the results with the multiplicity obtained by assuming that the particles are distributed uniformly so the multi-hit probability is given by Poisson statistics. A simple calculation gives $N'_{\rm ch} = -N_{\rm pads}\log(1 - N_{\rm hits}/N_{\rm pads})$, where $N_{\rm pads}$ is the total number of pads, and $N_{\rm hits}$ is the total number of hits. Using this as a check, we estimate the systematic error on $N_{\rm ch}$, due to uncertainties in the gains and backgrounds, to be about 4%.

2.2. Photon multiplicity

We count photons in the preshower Photon Multiplicity Detector (PMD) situated 21.5 m from the target, covering the region $2.8 < \eta < 4.4$. The photons impinging on the detector are converted in 3.34 X_0 thick lead and iron and the secondaries are detected in 3mm-thick square plastic scintillator pads of varying sizes (15mm, 20mm and 23mm). A matrix of 50 × 38 pads is placed in one light-tight box module and read out individually via wavelength shifting optical fibers coupled to an image intensifier and CCD camera system similar to that described in [18]. The modules with smaller pads were mounted in the forward angle region to minimize cluster overlap at large multiplicities and to provide reason-

ably uniform occupancy. Out of a total of 28 box modules implemented in the PMD, the data presented here correspond to 19 box modules having 35524 pads. The average occupancy for the part of the detector considered in the present case is around 15% for central events.

The principle of photon identification makes use of the fact that photons are more likely to shower in the lead converter and produce a large signal in the scintillator pads, while non-showering hadrons will produce a signal corresponding to a single minimum ionizing particle (MIP). Signals from several neighbouring pads are combined to form clusters and those with energy deposition larger than that corresponding to 3 MIPs are considered to be "γ-like" clusters. We denote the number of γ-like clusters in each event as "$N_{\gamma\text{-like}}$". This selection criteria gives an average photon counting efficiency of about 70% which is almost uniform over the range of centrality and pseudorapidity considered. It also creates an effective lower p_T cutoff of 30 MeV/c, at which point the efficiency falls below 35%. About 15% of the produced hadrons impinging on the PMD interact in the converter, generating secondaries which also deposit large energy on the detector. This contamination constitutes a background to photon counting. In order to minimize effects due to variations in the angular distributions of charged particles, we only use data with the Goliath magnet turned off.

The lead target, the exit window of the vacuum chamber (extending to the edge of the magnet), and the air gap between the magnet and the PMD constitute about $10\% X_o$ of material upstream of the PMD. Although some low-energy photons tend to convert in the material and escape detection, higher-energy photons tend to be detected via a high-energy conversion electron or positron.

The photon counting efficiency, hadron contamination and the associated errors are derived using test beam data and GEANT simulation using a method similar to the ones described in [18,19]. The level of hadron contamination in the PMD was verified by comparing the azimuthal distribution of hits for magnet-on and magnet-off data [20]. The azimuthal distribution of charged tracks becomes very non-uniform in the presence of the magnetic field, the amount of non-uniformity indicating the magnitude of the hadron contamination.

It should be emphasized that in this analysis, we do not correct the data using the abovementioned parameters. Instead we account for all of the detector effects by fully simulating the conversion of particles in the detector, as described below.

2.3. Data and event selection

In this analysis, we study reactions induced by a 158 AGeV Pb beam incident upon a 213 μm thick ^{208}Pb target. The fundamental "beam" trigger condition consists of a signal in a gas Čerenkov start counter [21] located 3.5 meters upstream of the target and no coincident signal in a veto counter with a 3mm circular hole located 2.7 meters upstream from the target. A beam trigger is considered to be a minimum-bias interaction if the transverse energy sum in the full MIRAC acceptance exceeds a lower threshold.

Pileup events are eliminated by a combination of the start counter ADC, which measures the number of beam particles passing through the counter, and a system of TDCs each started by a particular trigger counter and stopped by a second trigger. Using these, we remove events where a second interaction trigger occurred within a $\pm 10\mu$s window before and after the recorded event. After these cuts, we estimate that .02% of the remaining events are due to pileup. In addition pileup events are eliminated by requiring the sum of energy deposited in the MIRAC ($3.5 < \eta < 5.5$) and ZDC ($\eta > 6$) to be consistent with a single event. This leaves us with .01% of the event sample which may contain pileup events with less than 70 additional particles at mid-rapidity. After applying all cuts, 70% of the data sample remains.

3. General features of data and comparison with VENUS 4.12

To describe the bulk of the data, we use the VENUS 4.12 [22] event generator with its default settings. To compare VENUS with our data, we propagate the raw generator output through a full simulation of our experimental setup using the GEANT 3.21 [23] package from CERN. The simulation incorporates the detector physics effects and

folds them into the generated data, which is then analyzed using the same code used for the raw experimental data. In the rest of this paper, the term "VENUS" refers to the combination of VENUS 4.12 and the full GEANT 3.21 detector simulation, not to the raw generator output, unless otherwise specified.

The SPMD simulation includes the effect of Landau fluctuations in the energy loss of charged particles in the silicon and the pad geometry of the detector. In addition to the secondaries from the ion-ion collision itself, the SPMD is also sensitive to the beam halo as well as the δ-rays generated by the $^{82+}$Pb ion passing through the lead target. Since we have no means by which to distinguish the two components, we refer to all of the particles produced in beam events as "δ-rays". We can get a conservative estimate of the δ-ray multiplicity in physics events by studying events that satisfy the conditions for a beam trigger but not the interaction trigger. These "beam" events have a mean multiplicity in the SPMD of $11.4 \pm .5$ and a width of $5.9 \pm .3$. The angular distribution is consistent with a spatially uniform illumination of the detector surface. To include these ion-induced δ-rays in the simulation, we sample the measured charged multiplicity distribution for beam events and add it to the charged particle multiplicity for each simulated event. We estimate the uncertainty in the absolute scale of $N_{\rm ch}$ from the simulation to be less than 3% and the relative uncertainty between data and VENUS to be less than 2%.

The PMD simulation also incorporates the effects of additional fluctuations to the energy loss arising due to the statistical nature of the scintillation process; light transport through the wavelength shifting fibres and the image intensifier chains; and imperfections in the electro-optical imaging. The widths due to this extra fluctuation were obtained by a comparison of the GEANT and test beam results using single pions and electrons at various energies. As all of the readout chains were not used in the test beam experiment, a method of detailed intercomparison of the various features of data and simulation was used to obtain the gains of the individual readout units. We estimate the uncertainty on the absolute multiplicity scale of simulated γ-like clusters, due to uncertainties in various parameters of the simulation and data analysis, to be 15%, and that the relative uncertainty between data and VENUS is 5%.

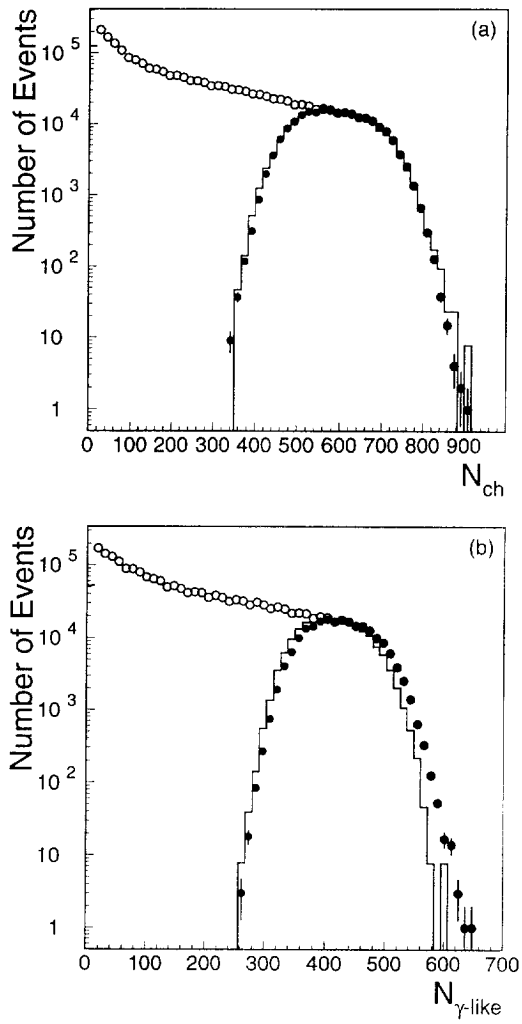

Fig. 2. The charged and neutral multiplicity distributions are shown in a) and b). The open circles represent the minimum-bias distribution. The "central" sample ($E_T > 300$ GeV) is represented by closed circles for the data and by histograms for VENUS.

In Figs. 2a and 2b we present the minimum-bias multiplicity distribution for charged particles and γ-like clusters. For the DCC search, we will concentrate on the most central events, defined by a measured transverse energy of at least 300 GeV in $3.5 < \eta < 5.5$. These correspond roughly to 10% of the measured Pb + Pb minimum bias cross section $\sigma_{\rm mb} = 6200 \pm 620$ mb. After all cuts are applied,

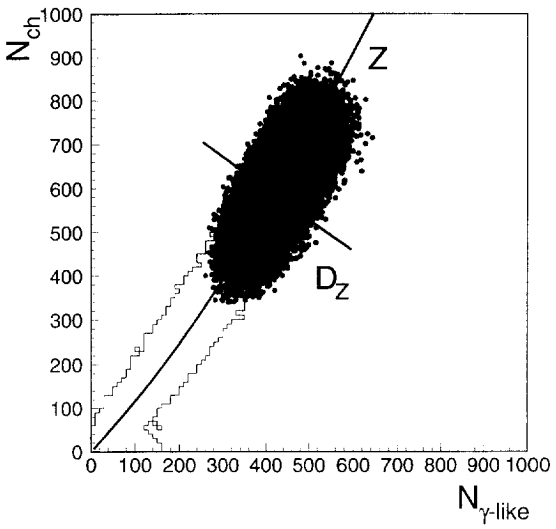

Fig. 3. The scatter plot showing the correlation between N_{ch} and $N_{\gamma\text{-like}}$. The solid outline shows the trend of the minimum bias data. The central sample (with $E_T > 300$ GeV) is shown as points for the data and as a hatched region for VENUS (with much lower statistics). Overlaid on the plot are the Z axis and the D_Z axis at a particular value of Z as explained in the text.

there are 212646 events in this sample, which we will refer to as the "central" sample in the rest of this paper. The central data sample is shown by closed circles in Figs. 2a and 2b and a comparison with VENUS events chosen by identical cuts is shown by the histogram. The correlation between the charged and neutral multiplicities is presented in Fig. 3 with the minimum bias distribution outlined, the central VENUS events hatched, and the central data events shown as scattered points, each point corresponding to a single event.

The most distinctive feature of the scatter plot is the strong correlation between the charged and neutral multiplicities. A reasonable explanation of this would be if most of the produced particles are pions with their charge states partitioned binomially, as measured in pp experiments at similar energies [24,25]. A binomial distribution leads to a correlation width $\sigma(N_{ch} - N_\gamma) \propto \sqrt{N_{ch} + N_\gamma}$, which would explain the very tight correlation, since the relative fluctuations are proportional to $1/\sqrt{N_{ch} + N_\gamma}$ and $N_\gamma \propto N_{\gamma\text{-like}}$. As this is seen in both data and VENUS, we can study the contributions to the different multiplicities to verify this hypothesis. In fact, about 80% of the charged particles produced in VENUS and detected in the SPMD are pions, the rest being protons and kaons. Most of the particles are produced at the interaction vertex, the rest being from η and strange decays, 12% coming from V_o's alone. About 85% of produced photons come from π^0 decays. Thus, by simply counting the charged particles and photons produced in a heavy ion collision, we have a reasonable estimate of the number of charged and neutral pions created.

We verify the binomial nature of the charge fluctuations in VENUS by studying its "binomiality":

$$B = \frac{N_{\pi_{ch}} - p_{ch} N_\pi}{\sqrt{p_{ch}(1 - p_{ch}) N_\pi}} \tag{3}$$

where $N_{\pi_{ch}}$ and N_π are number of charged pions and the total number of pions for each event, and $p_{ch} = N_{\pi_{ch}}/N_\pi$ is the probability that a pion is charged. For a pure binomial distribution, $p_{ch} = 2/3$ and B has a Gaussian distribution with a mean at zero and an RMS of one. For VENUS without GEANT, we find an RMS of approximately .95 for pions produced in the central rapidity region in events with an impact parameter less than 6 fm. This is consistent with the hypothesis that the correlation arises mainly from the binomial partition of N_π, the total pion multiplicity.

4. Event-by-event search for DCCs

DCCs should modify the binomial partitioning of N_π into charged and neutral pions. Events in which a DCC is produced (henceforth referred to as "DCC events") will show up as deviations from the binomial behavior and appear as outliers with respect to the bulk of the data. We have already discussed that the charged and neutral multiplicities are directly sensitive to the charged and neutral pion multiplicities in each event. Thus, DCC events should appear in the correlation of charged and neutral multiplicities, while the individual distributions will be mainly unaffected.

4.1. Data analysis

The strong correlation between charged and neutral multiplicities described above suggests a more

appropriate coordinate system with one axis being the measured correlation axis and the other perpendicular to it. If all detected particles were pions and the detectors were perfect and had identical pseudorapidity acceptance, then the correlation axis would be a straight line. Instead, we must account for the fact that at high multiplicities, the pseudorapidity distributions tend to narrow, changing the relative acceptance of charged and neutral particles due to the non-identical apertures of the SPMD and PMD. Moreover, the large occupancies in the PMD lead to a slight saturation effect. It is then useful to define a coordinate system consisting of a correlation axis (Z) described by a second-order polynomial, and the perpendicular distance (D_Z) from it, which is defined to be positive for points below this Z axis. These axes are shown superimposed on Fig. 3 and the projection along the Z-axis is shown in Fig. 4a. The full projection along the D_Z-axis is shown in Fig. 4b. To a very good approximation, the data are Gaussian distributed, which is consistent with binomial partition. The VENUS results, shown by the histogram, are also Gaussian, but with a slightly smaller width.

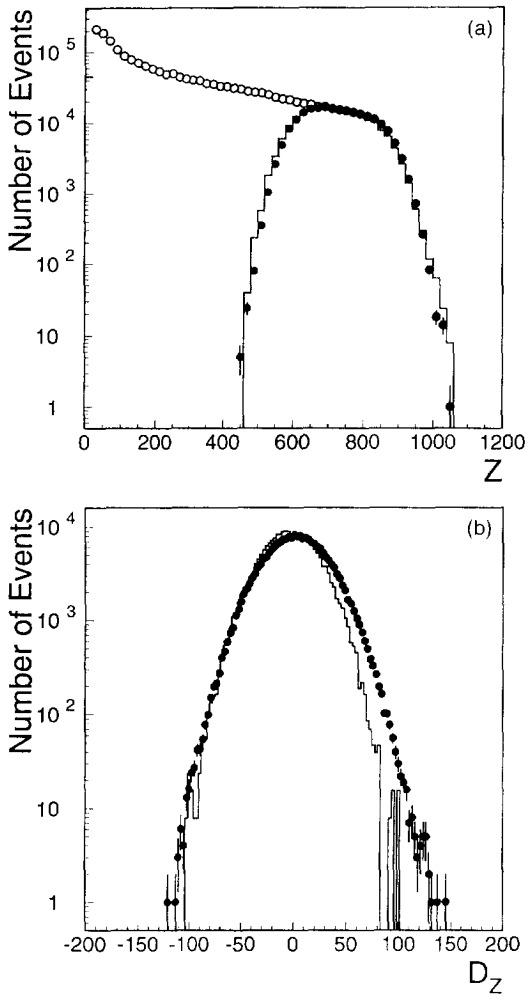

Fig. 4. a.) The distribution of Z, with the same conventions as in Fig. 2. b.) The distribution of D_Z in the "central" sample for the data (closed circles) and for VENUS (histogram). The difference in the mean between the two distributions arises due to the overall scale differences discussed in Section 3.

In both cases, σ_{D_Z}, the standard deviation of a gaussian fit in the D_Z direction, increases with increasing Z. We have chosen to work with the scaled variable $S_Z \equiv D_Z/\sigma_{D_Z}$ in order to compare relative fluctuations at different multiplicities. While binomial partition leads to fluctuations that grow as $\sqrt{N_\pi}$, the data as well as VENUS follow a slightly different power law, due to the presence of contaminating particles, like nucleons kaons, and etas. A reasonable parametrization of σ_{D_Z} for $Z > 200$ has been found to be $\sigma_{D_Z} = C + Z^\beta$ where $C = 7.5 \pm .1$ for the data, and $C = 4.8 \pm .1$ for the simulated events, the exponent being fixed to $\beta = .46$ in both cases. The discrepancy between VENUS and the data can be seen more clearly by measuring the width of the S_Z distribution with the σ_{D_Z} in the denominator taken from the simulation. The VENUS distribution is a gaussian of width $.998 \pm .002$ (fit error only) and the data is also gaussian, of width $1.13 \pm .07$ (error from relative scale uncertainties included). Henceforth, S_Z will refer to D_Z/σ_{D_Z}(VENUS) unless otherwise specified.

4.2. Model of DCC production

To estimate the effect of DCC production we have modified the VENUS events to include characteristic fluctuations in the relative production of charged and neutral pions. We assume that only a single domain of DCC is formed in each central collision. A certain fraction $\zeta = N_\pi^{\mathrm{DCC}}/N_\pi$ of the VENUS pions is associated with this domain (where N_π^{DCC} is the number of DCC pions) and a value of f

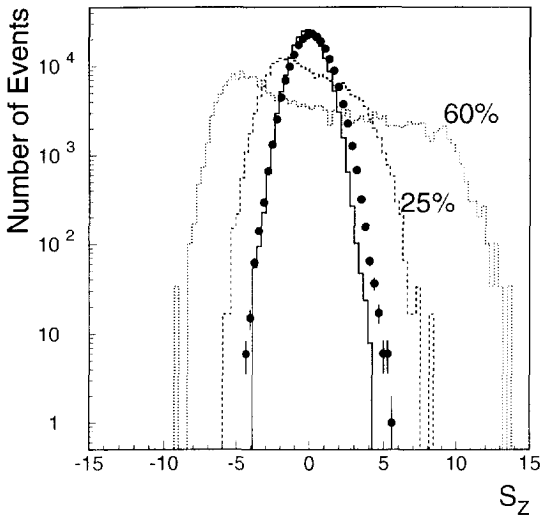

Fig. 5. S_Z distribution for the experimental data is shown, overlaid with VENUS simulations incorporating 0%, 25% and 60% DCC in every event. All of the distributions are normalized to the total number of real events.

is chosen randomly according to the distribution shown in Eq. (1). Then the charges of the pions are interchanged pairwise ($\pi^+\pi^-$ or $\pi^0\pi^0$) until the charge distribution matches the chosen value of f. We do not modify the momentum of the chosen pions, therefore the momentum spectrum of pions produced by a DCC is the same as for the non-DCC pions. This simulates a DCC accompanied by the normal hadronic background in a way that conserves energy, momentum, and charge. The S_Z distribution for the $\zeta = 0\%$, 25% and 60% DCC hypotheses are shown in Fig. 5 with the data overlaid as closed circles. It is clear that the distributions get wider as ζ is increased.

4.3. Upper limit calculation

As seen in the previous section, DCC events will show up as non-statistical tails on the D_Z axis. We see no such events in our data sample. Thus, we are faced with the possibilities that single-domain DCCs are very rare, very small, or both. To check which hypotheses are consistent with our data, we determine upper limits on the frequency of DCC production as a function of its size, as represented by ζ.

We have computed S_Z distributions for several values of ζ, ranging from 15% to 90%. To define an efficiency for detecting DCCs, we start from the observation that the distribution assuming the null hypothesis is Gaussian. With our statistics, we expect few events farther than 5 to 6 σ from the mean. An event containing a DCC, however, has an enhanced probability of being found in this region. The cut $|S_Z| > S_{\rm cut}$ then defines a two-dimensional region in the scatter plot in which all events are considered to be "DCC candidates". Once the cut is set, the DCC efficiency is defined, for $N_{\rm MC}$ VENUS events, as

$$\epsilon(S_{\rm cut},\zeta) = \frac{N(|S_Z| > S_{\rm cut},\zeta)}{N_{\rm MC}} \tag{4}$$

which is a function of both the DCC fraction and the cut position.

The expected non-DCC background is determined by a Gaussian fit to the VENUS distribution assuming $\zeta = 0$, in order to extrapolate beyond the Monte Carlo statistics. With the efficiency and background determined, we calculate the Poisson upper limit $N_{\rm U.L.}$ for a 90% confidence level, which is ≈ 2.3 if there are no measured events over the cut and no background events are expected. These three numbers are combined into an upper limit, for $N_{\rm Data}$ central events, via the formula:

$$\frac{N_{\rm DCC}}{N_{\rm Data}}(S_{\rm cut},\zeta) \le \frac{N_{\rm U.L.}}{\epsilon(S_{\rm cut},\zeta)}\frac{1}{N_{\rm Data}} \tag{5}$$

where $N_{\rm DCC}$ is the number of DCC events.

We have calculated limits for two scenarios. The first is based upon the conservative assumption that VENUS should describe the data perfectly in the absence of a DCC signal. Under these assumptions, $S_Z = D_Z/\sigma_{D_Z}$(VENUS) as obtained from VENUS (the default procedure) and $S_{\rm cut} = 6.$, which is well away from the data point with the largest S_Z. The 90% C.L. limit is presented in Fig. 6 as a solid line. The other scenario assumes that the difference between the data and VENUS is due to detector effects and that the widths should be the same. In this case, $S_Z = D_Z/\sigma_{D_Z}$(data), with σ_{D_Z} taken from the data, and we choose a tighter cut $S_{\rm cut} = 5$. This limit is presented in the same figure as a dashed line. The two limits are quite different at $\zeta = 15\%$ but get closer at $\zeta > 30\%$. In both cases, the uncertainty in the absolute comparisons between the data and

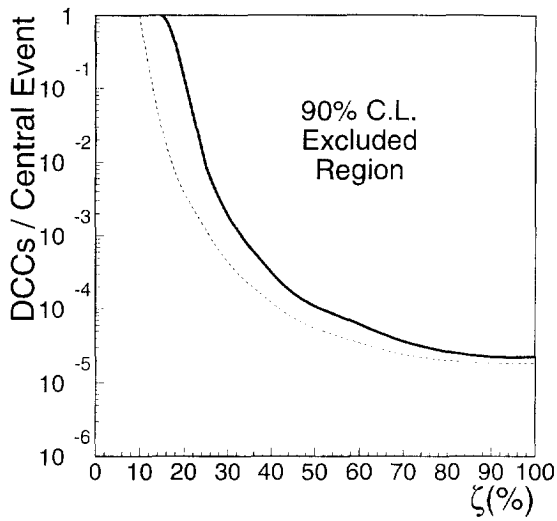

Fig. 6. 90% C.L upper limit on DCC production per central event as a function of the fraction of DCC pions under two assumptions. The thick line gives the upper limit obtained by assuming the σ_{D_Z} in S_Z is completely given by the VENUS calculation requiring to make a cut at 6σ. The dashed line shows a less conservative limit obtained by using the σ_{D_Z} measured in the data itself. This allows us to make a tighter cut at 5σ, increasing the DCC detection efficiency.

VENUS have not been included in the upper limit estimate.

5. Discussion

Earlier studies estimated the DCC radius to be around $R \approx 3$–4 fm. Coupled with a vacuum energy density u given by the chiral effective potential to be 60–120 MeV/fm^3, and an assumed Gaussian p_T distribution of width $\approx 1/R$, an average DCC was thought to generate $\frac{4}{3}\pi R^3(u/m_\pi) \approx 50$–230 pions [26]. The SPMD sees all of the charged particles produced in the central rapidity region, 80% of which are pions, letting us estimate the total number of centrally produced pions in an average event to be about 720. Thus, we would expect a DCC to correspond to $\zeta \approx$ 5–30%. Our analysis clearly rules out anything larger than about 25% within the scope of the assumed model, but cannot say much about anything smaller. However, if the pions tend to cluster in phase space, there are methods that should be able to find DCC events, and these are currently under study [27,28].

A small and frequent DCC might also appear as a slightly enhanced width, similar to what we observe in our data when compared to VENUS. However, this enhancement could also result from uncertainties in the detector modelling or the underlying physics model itself. For instance, theoretical uncertainties might arise because no model has ever been used to study charge correlations in heavy ion collisions. Rescattering phenomena, resonances, or Bose-Einstein effects may have predictable effects on the expected binomial distribution. These issues will be addressed in future studies.

6. Conclusions

We have used the WA98 apparatus to perform the first search for the production of Disoriented Chiral Condensates in 158 AGeV Pb + Pb collisions. No events with large charged-neutral fluctuations have been observed. By comparing the correlations of the charged and neutral multiplicity, measured on an event-by-event basis, to a simple model incorporating a DCC signal into VENUS 4.12 events, we have set a 90% CL upper limit on the frequency of DCC production as a function of its size.

Acknowledgements

We wish to express our gratitude to the CERN accelerator division for excellent performance of the SPS accelerator complex. We acknowledge with appreciation the effort of all engineers, technicians and support staff who have participated in the construction of the this experiment. This work was supported jointly by the German BMBF and DFG, the US DOE, ORISE, the Swedish NFR, the Dutch Stichting FOM, the Stiftung fuer Deutsch-Polnische Zusammenarbeit, the Grant Agency of the Czech Republic under contract No. 202/95/0217, the Department of Atomic Energy, the Department of Science and Technology, the Council of Scientific and Industrial Research and the University Grants Commission of the Government of India, the Indo-FRG Exchange Programme, the PPE division of CERN, the Swiss National Fund, the International Science Foundation under Contract N8Y000, the INTAS under Contract

INTAS-93-2773, Research-in-Aid for Scientific Research (Specially Promoted Research & International Scientific Research) of the Ministry of Education, Science and Culture, the University of Tsukuba Special Research Projects, and the JSPS Research Fellowships for Young Scientists. ORNL is managed by Lockheed Martin Energy Research Corporation under contract DE-AC05-96OR22464 with the US Department of Energy. The MIT group has been supported by the US Dept. of Energy under the cooperative agreement DE-FC02-94ER40818. In addition we would like to thank R. Birgeneau, H.Y. Chang, A.E. Chen, W.S. Edgerly, W.T. Lin, O. Runolfsson and B. Wadsworth.
